In each case, the accessibility of the new resource (measured by both net energy and economic methods) was better than that of the previous one. This meant costs were lower, so substitution could proceed rapidly after the technology developed. This outcome is believed by some to be the result of factors internal to economic systems. To the extent that technological developments were required, this is partially true. The underlying physical accessibility mechanism is a separate issue, however, subject to the laws of physics and should not be excluded from the argument.

There is increasing evidence that energy is becoming more difficult to obtain and process into readily usable forms. Geological resources are not homogeneous, and humankind has exploited the easily accessible, high-quality resources first. Lower quality, less accessible resources are left for future generations in the expectation that the price mechanism will offset any shortages.

As an economy changes its sources over time from high-quality (high-availability) energy sources to low-quality (low-availability) sources, the second law of thermodynamics indicates that the efficiency with which work may be done by these resources will decline. In addition, the change from resources that are easy to mine to those that are deeper and/or more difficult to mine means that a greater amount of economic (e.g., engineering) effort will have to be expended in order to tap these resources and to supply useful net energy to the economy. Thus, the resources become less accessible. In both cases (Figs. 5–7), a greater flow of either G or F (or both) is needed to maintain a constant flow E. Over time, the energy transformation industry will have to grow and absorb a steadily increasing quantity of economic output just to maintain the system.

If there is a steady increase in the resources that need to be expended from the economy (flow F) in order to obtain a given quantity of energy E, then in the long term one can envisage a situation in which no net energy is supplied. In other words, the energy content (embodied in buildings, machinery, maintenance, and operation) of the economic effort needed to extract energy and deliver it could increase to such a level that as much embodied energy flows back into the energy supply industry as is supplied to the economy. If $F = E$, a point of futility has been reached, where much socioeconomic effort is going into a process equivalent (in energy terms) to going around in circles.

When resources are relatively inaccessible, the primary resource flow will be greater than that for

the earlier, high-accessibility case. Thus, the rate of depletion of primary resources will also increase for a given (constant) flow of net energy to the economy. Pollution and other externalities will also be greater due to the increased rejection of unavailable energy.

Of course, technical change can often act to lower energy and other costs, thereby offsetting to a greater or lesser extent the depletion effect. Improved technologies may also have an energy cost, however, especially if they involve heavy capital investment with the associated indirect energy costs of manufacture. Nevertheless, many such technologies show substantial benefits. Although very valuable in the short term, in the longer term the constraints set by the laws of physics must prevail.

Thermodynamics is concerned with the properties of systems, not of things on their own. In energy analysis, the expenditure of energy and time to do work is a linking mechanism between the natural environment system and the human socioeconomic system. This link may enable a unified, more complete analysis of the combined environment–economy system to be carried out.

5.1 Net Energy of Resources of Declining Accessibility

As an example of the type of a situation that could happen, consider a simple coal mine. Assume that the coal seam is vertical, starting at the surface. (This example is exaggerated to make a point, but it provides a good indication of the type of situation that will happen in the long term because coal that is closest to the surface will always be extracted first, leaving deeper seams until later.) Initially, only simple materials and resources are needed to mine the coal and deliver it to trucks or railway cars. As the coal face goes lower, the total work that has to be done to get the coal to the surface increases because of the greater height which it has to be lifted. The greater the height, the heavier and more complex the lifting mechanism has to be and the faster it has to run just to maintain a constant rate of delivery of coal at the surface. At this stage, a substantial proportion of the energy in the coal delivered to the surface will be needed just to manufacture, maintain, and run the machinery needed to get it out. This is quite separate from the effort expended in other activities, such as pumping water to keep the mine dry and the precautions necessary to ensure safety at the coal face, where the working conditions are becoming ever more inhospitable.

As the depth increases, the amount of net energy delivered to the surface declines because increasingly more of the mine's output is needed just to drive the mining machinery. To ensure even a constant supply of net energy E delivered to the economy at the surface, the rate of extraction of coal will have to increase. It is not difficult to appreciate that the mining rate G will accelerate in such circumstances. The faster the miners try to get the coal out and the greater the demands placed on the mine by the economy, the faster the process approaches the stage at which the whole operation is energetically pointless. Clearly, the end result is stalemate in that the mining operation does not actually do anything for the economy other than supply employment. Beyond the point at which the net energy yield is zero, the operation is in fact taking more than it supplies. This will happen irrespective of the amount of coal left in the mine. After a certain stage, therefore, further mining is pointless and the resource is economically and energetically useless.

It is possible to predict from dynamic energy analysis the maximum depth at which the work required to lift the coal exactly equals that available from the energy in the coal lifted. The lower the quality of the energy resource, the sooner this will happen. Peat or lignite will be accessible to shallower depths than bituminous coal or anthracite. The direct and indirect energy requirements of the other parts of the mining activity will ensure that in practice, the depth that is mineable will be very much shallower than that which is calculated from the energy requirements of lifting alone.

From the economic viewpoint, many people support the notion that improvements in technology will ensure that the economy will always get what it wants. Such a view is not supported by the physics. It is quite possible that lifting machinery and water pumps will be improved, but there is an absolute minimum energy requirement for lifting a tonne of coal to the surface and pumping a liter of water that is absolutely unalterable by technology, being a consequence of the second law of thermodynamics. The most that can be hoped for from technology is that it will enable mining to go a little deeper; the constraint remains. It should be mentioned, however, that few if any mines have reached the depth at which the net energy yield is zero; the point of this discussion is that the raw energy requirement of delivered consumer energy will increase, and at an accelerating rate, in the future, not that we will run out of the resource.

5.2 Dynamic Energy Systems Analysis

The example of the coal mine illustrates stages in the evolution of energy supply to an economy. To generalize the analysis, we must acknowledge that in reality the energy system and the economy are changing all the time. As described previously, the inevitability of declining resource quality means that accessibility will steadily decrease. For awhile, improvements in technology can be expected to compensate for this problem or even improve the overall situation. However, the second law of thermodynamics ensures that there are absolute limits to the improvements that are possible in the efficiency of conversion of primary energy into consumer energy and then into end-use energy. It is therefore necessary to examine the way in which the energy supply system and the economy interact over a long period of time in order to understand the nature of net energy effects.

Empirical data confirm that as an energy system expands into resources of decreasing accessibility, the primary energy intensity of economic activity does indeed increase, with the result that in some circumstances the total primary energy input to the economy can be expected to increase very rapidly for only modest increases in production of goods and services. In addition to the increased energy intensity of economic activity that results from such system growth are increases in the cost of substitute forms of energy. In an economy in which energy costs are increasing rapidly in real terms (as is likely in the later stages of life of many major natural gas fields, which is already occurring), it can be expected that the cost of plant to manufacture substitutes (e.g., synthetic natural gas from coal) will also increase.

From our understanding of the behavior of complex systems, we also must acknowledge that the future is indeterminate. Thus, we cannot make a realistic forecast of when a gas field will run out, let alone an estimate of the costs of substitute gas. The only reliable conclusion we can make is that current predictions appear to seriously underestimate the current value of gas and other high-quality scarce fuels and encourage wasteful use.

5.3 The Importance of Growth Rate

A great deal of energy-intensive capital investment goes into the development and expansion of energy sources, and under high-growth rates it is quite conceivable for energy-supply programs to be net consumers of energy. A very important factor here is the rate of expansion; the lower the rate, the better the net energy performance.

It appears that the rate of growth of consumer energy demand E may be a critical factor in evaluating the net energy obtainable from a system because of the strong positive-feedback energy flows F required for rapid system growth. Although net energy is not the only resource that an energy technology must supply, one can conclude that it is the most important.

It is a basic tenet of neoclassical economics that substitution is always possible, which effectively makes scarcity only relative. From biophysical systems reasoning, however, substitution of a resource by another of lower accessibility is not a situation in which the two resources can be considered separately: They exist in a systemic relationship, in which one affects the other. The increased energy requirements of access to new primary energy resources suggest that the cost of delivered energy could increase at an accelerating rate in the future and that substitution is by no means automatic. The extent to which this argument applies to the transition from fossil fuels to renewable energy sources is still an open question.

5.4 Renewable Energy

Solar inputs are essential to the functioning of any economy, not only directly but also indirectly through their part in "driving" the natural cycles that provide the ecosystem services that are essential for all forms of life, including economic. Solar sources also provide small but rapidly increasing supplies of electricity (photovoltaic and wind) and refined biomass fuels (ethanol and biodiesel) to many economies. Although environmentally more benign than the use of fossil fuels, these still have to obey the thermodynamic imperatives summarized in Figs. 5–7 via energy transformation sectors. As with fossil resources, the accessibility of solar energy is not uniform, either with latitude or with the seasons. However, the fact that annual solar inputs to Earth are many orders of magnitude greater than fossil fuel inputs means that the potential for contributions to economic activity can be expected to increase enormously in the future.

A caveat is important at this point. Investment in solar energy capture for electricity, for example, requires preinvestment from fossil-fueled economic processes. In other words, solar capture technologies (wind machines, photovoltaic cells, etc.) must be manufactured from metals, glass, plastics, ceramics,

and other products of an economy in which these materials are produced predominantly by fossil-fueled industries. The transition from present-day economies to future economies that are entirely solar powered will not be easy and can be expected to take a long time. It is not clear whether present-day patterns of consumption of goods and services can be maintained in an economy that is entirely solar based.

6. ENERGY AND ITS IMPORTANCE TO POLICIES FOR SUSTAINABILITY

In the early 21st century, the issue of sustainability of economic activity has moved to center stage of policy development in many countries. For many, the policy issues involve integration of the environmental, the social, and the economic into a policy-formation nexus. Figure 9 inverts the mainstream economic model of Fig. 4, showing from the biophysical perspective Mitchell's concentric model, in which the economy's sustainability is subordinate to that of the society, whose sustainability is in turn subordinate to that of its surrounding and sustaining environment. Fig. 9 also indicates the place of branches of thermodynamics and economics in addressing the sustainability of these parts.

The fundamental question of purpose arises. In one respect, there is no doubt that by replacing fossil fuel inputs with solar inputs to the economy there would be very substantial environmental advantages. There would also likely be substantial economic advantages (in terms of increased employment and improved health due to reduced localized pollution).

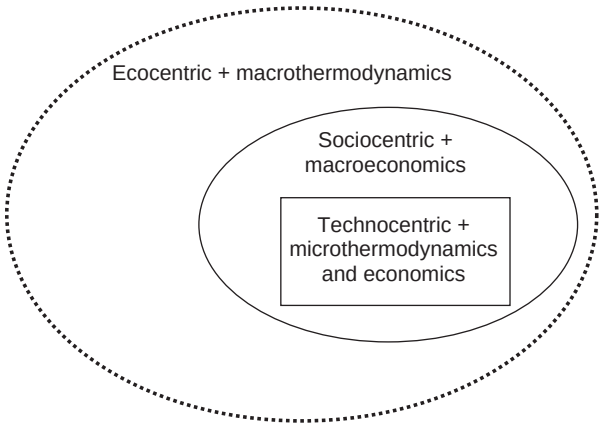

FIGURE 9 Mitchell's concentric model. From Mitchell, C. A. (2000). *Trans. Instit. Chem. Eng.* **78**, B237–242, with permission.

However, there remains the question: What is it all for? If one only envisages the replacement of fossil fuels by clean solar fuels, does that mean continuing increases in the use of private cars? Does that mean 3-ton "green" SUVs spending hours in traffic jams? To take the question further, could it mean solar photovoltaic-powered or wind-powered aluminum smelters to produce green aluminum for throwaway beer or soft drink cans?

These examples raise important questions about the relationship between energy and economics. As noted previously and demonstrated in Fig. 6, the ultimate purpose of use of energy resources is to satisfy the needs of people. In other words, the key requirement is to match means with ends.

Substituting solar for fossil fuels simply addresses the requirement of minimizing adverse impacts on the natural system while doing nothing directly to better address people's basic needs. The overall issue is much more complex than the simple substitution of one primary source of energy by another, no matter how apparently benign. The ethical positions of society are inherently relevant to our discussion and need to be applied to decisions about future economic processes.

7. AIMS OF THE BIOPHYSICAL SYSTEMS WORLDVIEW

From the previous discussion, it is clear that the biophysical systems perception has little to contribute to the determination of how people are likely to react in social situations because it is based on and applicable to issues involving the physical world, not the social. With few exceptions, most physical scientists would agree that the perception is applicable to the physical constraints and long-term limits to social activities and not to the day-to-day activities of people within those limits.

The universality of the process of consumption of available energy and its rejection as unavailable energy by physical systems makes energy one logical means of studying the structure and dynamic behavior of real physical systems. It also provides one means of assisting development of a more unified understanding of the behavior of complex physical systems.

The most important attribute of the biophysical systems approach, however, is that it is an entirely different way of thinking—a different worldview. In any real system, the ruling state is metastable, reflecting physical disequilibrium. This understanding is essential to a proper understanding of economic

activity within its physical environment. This concept gives an entirely different viewpoint on development in an economy, and of its impacts on options for future development, than is gained from the standard economic perspective. Together, they help us gain a perspective that is clearer and more powerful than those obtained from either used alone.

If the insights obtained from this perspective alone were to be incorporated into resource economics and the treatment of subjects such as depletion, then the economics of sustainable alternatives such as energy demand management (energy conservation) would be seen to be much more favorable. The approach makes it clear that there are strong indications of the existence of limits to growth of economies, in any sense involving the production and consumption of material goods and services. Although the immediate aims of the biophysical systems perception are modest, the effects of acceptance of the findings would be far-reaching, not least in the field of the use of energy resources in society.

Glossary

ancient atomism Natural bodies composed of indivisible units of matter possessing size, shape, weight, and an intrinsic source of motion.
classical economics Early modern theories based on the primacy of production processes.
early idea of energy The principle of activity, force in action, the "go of things."
fire A very active and subtle substance or element used to explain motion and activity in nature and in organisms, including sensitivity in antiquity and in early modern chemistry and physiology.
neoclassical theory The modern exchange approach to economics based on scarcity and marginal utility.
phlogiston A volatile component of combustible substances in 18th century chemistry captured from sunlight by plants and released in vital processes, combustion, and reduction.
work A late-18th-century measure of the effect produced by machines and labor employing natural powers.

Economic theory and its history conveniently divide in two parts: an "early modern" production theory focused on how a society uses resources provided by nature to produce physical goods and services and a "modern" exchange theory centered on the study of the efficient allocation of scarce resources to satisfy the unlimited demands of consumers. The first, pre-classical and classical economics (1650–1850), evolved in a close and ongoing relationship with early modern scientific theories of nature's physical fecundity and organization including mechanics, matter theory, chemistry, physiology, and psychology. Mainstream neoclassical economics (1870 to the present) took its direction from the conceptual and mathematical framework of 19th-century analytical mechanics. Production is treated as an analogue of a spatial (and nondissipative) energy/output gradient, which effectively eliminated any substantive treatment of material and energy resources and physical "converters" from production theory. Neoclassical economics neglects material and energy resources and technologies and is inconsistent with their inclusion. The theory is inherently static and cannot explain physical processes, the dynamics of change in economics, or even how an economic system is coordinated.

1. INTRODUCTION

The production approach to economics that emerges in the mid-17th century took its inspiration form a broad range of sciences: Galilean mechanics, ancient ideas of active matter, Harvey's new circulation physiology, the proto-ecological natural histories developed by the scientific academies, and psychological and political theories of sentiment and organization with roots in antiquity. For nearly two centuries, economic ideas of physical production and economic behavior drew on the natural sciences,

including physiology and medicine. This early connection between economics and natural philosophy has been little studied by economists but provides an essential key for understanding the evolution and structure of the classical approach.

In the second half of the 19th century, the focus of theoretical inquiry shifted from a production economics to a theory of market exchange. Neoclassical economics was constructed on two related ideas: the universal scarcity of resources and diminishing marginal productivity applied to resources and consumption goods alike. This basic idea, formulated in terms of simple partial derivatives, is that additions of any single input (or good), everything else held constant, yield a stream of positive albeit diminishing additions to output (or psychic benefit). But according to the conservation matter and energy, physical output cannot be increased if material and energy inputs are held constant. The central idea of neoclassical theory, the doctrine of marginal productivity, violates the laws of thermodynamics. Basing economic theory and its regulatory mechanisms on the conceptual structures and mathematics of analytical mechanics and field theory eliminated material and energetic processes (and much else including technology, organization, and psychology) from economic theory. Economics became an autonomous science isolated any real connection to nature or to society.

Our concern is to show how the material and energy ideas of early modern science were used to shape early economic theory and how these ideas were gradually lost. These early connections between science and economics have been hidden for the reason that they were considered heretical and were not generally openly avowed by the scientists and the economic thinkers who took them up to avoid censorship or religious condemnation. Contemporary readers could be assumed to know the coded language of their presentation. Modern investigators face the double difficulty of not knowing the language of the early sciences or the coded messages of radical materialism. They are also trained in economic theories that have severed any connection to nature and therefore lack any conception of the necessary interdependence that exists between material and energy processes in nature and in human economies. The discovery of these connections requires a sustained investigation of the shifting and forgotten labyrinths of early science. Thanks to the breadth of work in the history of science, an archaeology of the material and energetic foundations of early economics is now under way.

The next section surveys the main energy ideas employed in the sciences and economic thought during the first two centuries of early economic theory. Subsequent sections focus on the main economic writers and their very individual connections to the scientific ideas of their time starting with Thomas Hobbes and William Petty in the 17th century. The main developments move back and forth between Britain and France. Classical theory ends in Britain with J. S. Mill in the mid-19th century who moves away from grappling with the fundamental question of the meaning of energy for economic production. A final section briefly sketches the analytical focus that has governed neoclassical theory.

2. EARLY ENERGY IDEAS

The idea of energy we use is Wicken's suggestion that energy "is the go of things." We are interested in concepts that provided explanations of physical and vital motions in early modern natural philosophy and the influence of these ideas on the formation of early economic theory. Since energy comes in a material form and is not used for itself but to make or do something, we are also concerned with material transformations and physical technologies that convert energy and materials. These components of production are inextricably linked in the economic process.

Material and energy conversions are subject to physical principles: (1) matter and energy are neither created nor destroyed in ordinary processes; (2) energy is degraded in quality as it is used and becomes unavailable for use (useless energy); and (3) material processes also follow physical and chemical rules. Theories of economic production must be consistent with scientific principles including the basic complementarity that exists between materials, energy, and physical converters. If economic principles are not consistent with the sciences of nature, then economic theory must be reformulated. Economics is not an autonomous science.

The first energetic concept we isolate is the material fire, which provided the active principle of matter theory in the natural philosophies of antiquity and early modern era. Fire was a very subtle and active matter used to explain the visible fire of combustion (by a disassociation of the matter of combustible bodies by the penetration of fire atoms), the invisible flame of the vital heat in animal bodies, and sensitivity in plants and animals.

The mechanist philosophies that emerged in the wake of the victory of the new science of mechanics of Kepler and Galileo are generally assumed to have regarded matter as entirely passive. But nature required sources of motion and ideas of active matter remained central in many 17th-century philosophies. The revival of Stoic, Epicurean, and Democritean theories of matter, the close connection between a mechanical explanation of nature and ideas of active matter in antiquity, the Renaissance Aristotelianism taught in the Italian medical schools, and the growing influence of an alchemy joined to atomism all promoted ideas of active matter. Fire, the active principle of matter theory, was a basic doctrine in these theories.

Attempts to construct a unified mechanical philosophy of nature reopened the conflict between doctrines of active matter and religion. Nature, in church doctrine, was passive and God the sole source of motion in the universe. After Galileo, matter theory proved more problematic for natural philosophers than Copernicanism. Descartes canceled plans to publish *Le Monde* with its naturalistic account of the universe and moved to ground his natural philosophy on a metaphysical argument that all motion was due to God. Despite a prohibition against teaching atomism, Gassendi, a Catholic priest and astronomer protected by powerful friends, proposed a version of atomism consistent with the creation. God, according to Gassendi, could have made the world in any number of ways but chose to make it from atoms endowed with an enduring source of motion. His union of atomism with 17th-century atomistic chemistry and with Hippocratic biology provided an attractive package for the development of chemical and physiological ideas and was quickly adopted by physicians in France and by Harvey's disciples in England. His followers had to express their ideas clandestinely. Hobbes developed a entirely naturalistic account of motion but had to parry accusations of antagonists that he held a theory of self-moving matter. Newton fought materialism all his life and denied material powers to "brute matter." But by treating gravity and other active principles as powers of bodies and speculating on material ethers and vegetative powers, he fostered the materialism of the Enlightenment.

Thanks perhaps to the flux in religious regimes, England was fertile soil for energetic and atomistic ideas of matter as is evident in the work of Thomas Harriot and Walter Warner in the late 1500s and after, Bacon's atomistic speculations in the 1620s, and the Cavendish circle at Welbeck in the 1630s (which included Hobbes) who knew Warner's work. Harvey's *De generatione*, which circulated for two decades before publication in 1651, was another source of energetic ideas. His physician disciples in Oxford and London were quick to take up the "Democritean and Epicurean system" associated with Hobbes and Gassendi. The latter had a considerable influence thanks to the flexibility of his system and close connection to chemistry.

The introduction of Gassendi's atomism in England has been credited to Walter Charleton's translations of Gassendi's early works on Epicurus in the 1650s. But the young physician and future economist William Petty provides an earlier source. Petty met and became friends with Gassendi during the mid-1640s in Paris when he served as Hobbes's scribe and tutor in anatomy. The two also took a course in chemistry. We can assume he introduced the ideas of Hobbes and Gassendi to his colleagues, including Robert Boyle, in Hartlib's circle in London, where he learned the chemistry of Cornelius Drebbel; in Oxford in 1649 where he led research meetings in his lodgings, and to his cousin, Nathanial Highmore, who became a Gassendian.

Gassendi's synthesis of atomistic chemistry and Hippocratic physiology provided the basic framework that Harvey's physician disciples employed for four decades to develop the new circulation physiology. They conducted a remarkable series of experiments investigating combustion and the nutrition and respiration of plants and animals using nitre, sulfur, and other chemically active substances that brought them close to modern ideas about combustion and respiration. They also used ideas of fire as the active element of the nutritive, animate, and intellectual souls of living things, concepts Descartes had supposedly banned from biology.

The union of Harvey's circulation physiology and atomistic chemistry was quickly embraced by the scientists of the newly organized Academy of Sciences in Paris who initiated anatomical and chemical studies of plant and animals that were sustained, thanks to Royal patronage, over many decades. Early papers extended the circulation model to the preparation and movement of sap in plants. Long the neglected orphans of science, plants were now recognized as occupying the critical position in the physical and chemical circuits linking living organisms to the soil, air, and sunlight. They were the assemblers of the materials and energetic substances feeding and maintaining the other organisms. Cycles of production and consumption bound

all the parts of nature together in conditions of "mutual need." Harvey's circulation physiology extended to larger systems of circulating nutrients and materials provided a new vision of the unity and interdependence of nature and an obvious model for the human economy.

A second and closely related locus of energy ideas in 18th-century scientific and economic thought was the phlogiston chemistry formulated by the German chemist and physician, Georg Stahl, at the beginning of the century. Phlogiston, or "matter of fire," was an imponderable (unweighable) substance that joined other substances in chemical reactions (synthesis) and was released in chemical decompositions (analysis). Combustible substances such as plants, alcohol, and coal were assumed to have high concentrations of phlogiston. One of Stahl's key contributions was to emphasize the importance of the principle of conservation of matter in the methods of analysis and synthesis of compounds that became a basic tool of chemical research thereafter. Together with the "elective affinity" that different elements of matter revealed for undergoing reactions with other elements, phlogiston chemistry provided the main framework for chemical theorizing until it was supplanted by Lavoisier's oxygen theory. As an early version of potential energy, it continued to provide an energetic explanation of nature's operations into the next century.

Phlogiston chemistry was taught in the medical schools in Montpelier and Edinburgh and employed in conjunction with physiological ideas of sensitive matter. G.-F. Rouelle taught a version of phlogiston chemistry at the Royal Garden under Buffon. His students, some of whom wrote the chemistry articles in Diderot's *Encyclopédie,* rejected mechanistic chemistry in favor of ideas of energetic and sensitive matter. This vision of sensitive molecules informed the theories of psychological sensibility (sentiment) advanced by the scientists of the radical Enlightenment. These ideas informed François Quesnay's *Essay on the Animal Oeconomy* (1847) and were implicit in his doctrine of economic productivity. Adam Smith in turn praised the "philosophical chemistry" of his friends for the theoretical connections it made between the processes of the art of the furnace and the "vital flame" in animals. His associates justified their physiological and medical theories of sensitive substances by referencing the psychological theories of Hume and Smith. Phlogiston chemistry and its ideas of energetic substance were also central to the 18th-century scientists who influenced Thomas Malthus and David Ricardo.

The third basic energy idea to shape economic thinking in the classical period was the new understanding and definition of work done in harnessing and using natural powers. The British engineer, William Smeaton, made the critical contribution in a study of the efficiency of different types of water wheels in converting a given head of waterpower into work. His study, published in 1759, established the superior efficiency of overshot wheels and enabled an increase in effective water power capacity in Britain by a third in a period when water power was critical to economic growth. He defined work as the capacity to lift a given weight a given distance in a given amount of time and made comparisons of the "work done" by horses, humans, and wind, water, and steam engines. Adam Smith adopted his definition of work but unfortunately confined its consideration to human labor, which he made the center of this theory.

The new mechanical theory of work was taken up by the French engineers Charles Coloumb and Lazare Carnot. Coulomb's thrust was to assimilate machines to the work done by humans and to make machines "an economic object, a producer of work." Carnot's great study, published in 1783, was concerned with a theoretical analysis of machines as devices for transmitting motion form one body to another. Carnot was concerned with general principles irrespective of the source of power. He emphasized the notion of power over that of force and machines as agents for the transmission of power. His work received little notice until he was promoted to the top leadership in the new Republic and celebrated for his reorganization of the military as "the organizer of the victory." His contributions to the theory of machines were taken up by J.-B. Say who recognized Smith's neglect of the central role of machines employing natural powers in industrial productivity. Say's construction of a general theory of production based on materials, forces of nature, and machines to multiply labor will receive important elaborations by the mathematician and engineer Charles Babbage, the economist Nassau Senior, and the physicist William Whewell. Their contributions do not, however, receive any sustained attention by subsequent economists. As happens to many good ideas, they were passed over in silence by the leading theorists of the time who followed J. S. Mill's shift of focus from a physical theory of production to economizing, which brought the classical epoch to an end.

3. EARLY PHYSIOLOGICAL ECONOMICS: HOBBES, PETTY, BOISGUILBERT

Despite his considerable contributions to the psychological and political framework of early economics, Thomas Hobbes is considered to have made little or no contribution to the core ideas of economic theory. He is also widely seen as a mechanistic philosopher who reduced everything to Galileo's new mechanics. Most historians of philosophy and economics have not understood the central importance physiological ideas have in his system, his hierarchical conception of the sciences, and the use he makes of Harveyian physiology to extend the materials provisioning approach Aristotle initiated in his *Politics* but failed to complete. Hobbes in fact makes the first sketch the core ideas that will characterize preclassical and classical theory thereafter.

Like Gassendi, Hobbes constructs a conception of nature and society that proceeds from a basic energetic physics of matter in motion and avoids reductionism by treating each level of activity according to what he took to be the organizing principles and evidence for the topic at hand. In addition to the atomism of Democritus and Galileo, he knew and used Aristotle's biological and psychological ideas; Harvey's theories of generation, organic sensibility, and circulation; and the economic ideas of Aristotle's *Politics* and the pseudo-Aristotelian *Oeconomia*. This physics and physiology informs the production approach to economics he sets out under the heading of "The nutrition and procreation of commonwealths" in *Leviathan* in 1651. An economy, like living bodies, obtains the materials and "nutriments" it needs to produce a commodious existence from the land and sea by human industry. These material resources are passed through various stages of concoction (heating) and preparation and circulated via the conduits of trade to all parts of the body politic. His chapter also covers the institutions of property, contracts, and so on that were part of the evolutionary sociopolitical framework initiated by Democritus and his successors.

The energetic thrust of Hobbes's ideas is subtle but clear enough. He knew the atomism and active matter theories of Harriot, Warner, Bacon, and Gassendi but adopts the more dynamical approach of Galileo. He had met Galileo in 1635 and reports carrying away a vision of a world filled with motion. Every seemingly solid body was alive with the internal motions (agitations) of its smallest parts. He defines each specie of body by the imperceptible motions of its smallest particles. These motions constituted the specific capacities of each body for the initiating motions (endeavors) triggered by interactions with other bodies (the explosion of gunpowder by a spark, etc.). Hobbes's idea of endeavor as an imperceptible but actual motion is recognized as an influence on the very different ideas of force developed by Leibniz and Newton.

The basic source of motion in nature was the undulating wave-like motions of sunlight. Hobbes did not attempt any explanation of the connection between sunlight, plants, and the food consumed by animals. In his *De homine* (of man) of 1658, he attributes the motions of the heart and muscles to motions of "the invisible atoms … of a salt or niter" taken into blood via respiration. This idea, long popular among Harvey's and Hobbes's alchemically minded friends, was restated in 1654 by Ralph Bathurst, a supporter of Hobbes and associate of Petty at Oxford.

Hobbes's sketch was fleshed out by the brilliant William Petty (who may have contributed to their formulation in Paris). Petty had studied navigation, geography, physics, mathematics, and medicine in France and Holland, and he was familiar with the work of Hobbes and Gassendi and the scientific ideas of the Puritan reformers in the Hartlib's circle in London. He returned to take his medical degree at Oxford in 1650 where he organized research projects and quickly attained high positions in the university. The siren of political preferment and reform called him to Ireland. Briefly chief physician for the army, he reorganized and completed the Down Survey of Irish lands in breathtaking speed and became one of Ireland's largest landholders. Spending most of his time defending and managing his estates and seeking support for his political and economic projects, his scientific interests shifted towards the socioeconomic topics he called "political arithmetic." His Baconian-inspired works include a succession of acute but scattered theoretical insights central to classical economics, which were never drawn together in a single work.

His first contribution was the elaboration, in a *Treatise on Taxes* in 1662, of the idea of a surplus that the ancient atomists made the basis of social and economic evolution. Petty takes up the surplus in order to explain the source of taxable revenue. The surplus is the difference between the total food produced on the land and the portion that must be reserved to replace the inputs (food, fodder, seed, and equipment) used in production. It is effectively the energy available to support and feed the rest of

society, including the artisan and commercial sectors. His proposal was to tax the revenue going to the wealthiest land owners and direct it to projects increasing access to markets, land productivity, and the skills and habits of unemployed workers.

He sketches the implications of the surplus for a theory of competitive profits across sectors, which he terms "neat rents" (not the differential rents earned on more productive or favorably located soils). A "neat" or net rent is the ratio of net earnings from an activity to the cost of carrying it out. He applies this idea to agriculture and extends it to mining and casting coin. Higher returns in one sector, he suggests, lead to a flow of labor and capital goods to that sector, equalizing the rate of return between activities. In addition to this idea of an equal rate of profit (our term), he also developed a concept of differential rent for favorably located lands.

Energy ideas inform a production approach to prices in his *Political Arithmetic*. These are cost-based prices set by the food, materials, and tools needed plus profit. He reduces these in turn to labor, land, and food, given that humans and beasts must "eat, so as to live, labor and generate." The ultimate determinate of prices is thus the "energy" required, directly and indirectly in production. He distinguishes between short-run prices (reflecting day to day movements of market forces) and the "intrinsic" prices determined by production costs. This distinction becomes a basic feature in classical economics via Richard Cantillon and Adam Smith.

The next significant development of a physiological economics was made by Pierre Boisguilbert, the Lieutenant-General of Normandy (active 1695–1714). Boisguilbert was obviously aware of Hobbes's *Leviathan* and Petty's theory of the surplus, which he made the basis of the emergence of the professions in modern society. A deep study of agriculture and its commerce inform his writings. He was also a close student of the new sciences of nature of the Academy of Sciences in Paris and the work of his younger cousin, Bernard Fontenelle, who was establishing himself as a leading interpreter of the new science. Neither he nor his more radical cousin were Cartesians. Boisguilbert's commitments were to the Stoicism of his uncle (Pierre Corneille) and the Epicureanism of Gassendi and François Bernier. The latter was well known for his travels in the East and critique of Oriental Despotism—the aggrandizement of resources by the few and the absence of property rights and basic civil protections, which the Epicureans regarded as critical incentives for social intercourse, production, and prosperity. Bernier implies a critique of France's aristocratic economy, which Boisguilbert makes explicit.

The work of the Royal Academy of Science provided a new conception of nature linked together in a circuit of chemical exchanges. Plants were the prime producers of the energetic substances maintaining all organisms in "a state of reciprocal and mutual need." Boisguilbert develops similar ideas in economics. Agriculture produces the "basic" goods (grain, wine, and plant and animal tissues) that, like the chemical elements, produce the rest. The fecundity of nature supplies the means that give birth to the 200 or so professions of the state.

The academy's model of the circulation of sap in plants provided Boisguilbert (as Harvey's theory did for Hobbes) a model for economic production and circulation. The plant model makes a clear separation of production sites. Primary materials assembled and processed at one site are perfected at others and move in distinct "circuits." Boisguilbert likewise sees goods produced on the land and in artisan shops moving along distinct circuits between farms and towns. He extends a distinction between the sites of agricultural and manufacturing production to recognize and explain the very different price and quantity behavior between the two sectors.

He recognizes that the strict requirements that nutritional needs impose for maintaining the production and flow of food to consumers requires in turn the reciprocal needs of artisans for markets for their goods and services. Any break in this mutual circulation threatens a widening disequilibrium endangering the health of the whole society. Given the ferocious pursuit of self-interest by traders, equilibrium is maintained on the edge of a sword where a strong movement of supplies or fall in demand can become self-feeding. Such instability is magnified by the sectoral differences in conditions of production and market behavior. The price instability of agricultural markets has disastrous effects for maintaining productive investments and fertility of the soil. In urban industries, workers resist cuts in pay and employers respond to falling demand by laying off workers. The result exacerbates the crisis. His acute analysis captures an asymmetry in market behavior that continues to perplex modern equilibrium theorists.

Prices obviously play an important role in maintaining economic equilibrium but the analysis goes beyond the sphere of exchange to assume that nature's conserving operations extend to the economy. Nature has the capacity to sense injury to the economy and the power to regulate and to heal

itself. His ideas reflect the Stoic vision of natural order and harmony that Gassendi and Bernier extend from animate nature to the universe and the Hippocratic medicine advocated by Gassendian physicians. Good policy can maintain health but when illnesses arrive they must follow a natural course. Nature not the physician heals, thus, "let nature alone." These properties of self-regulation are the laws, God's invisible hand, that maintain order in the world.

Boisguilbert's psychological and social ideas also reflect Gassendi's reinterpretation of Epicurean psychological and ethics. Living organisms are designed with natural capacities for sensing what is good for them and what to avoid. Pleasure and pain are part of God's design to direct the activity of nature's creatures to life, health, and reproduction. This naturalist psychology extends to the direction and regulation of human society where the desire for the goods of the world, property, and security induce individuals to establish collective agreements to respect and protect the property and rights of others. The ruler is bound in turn to protect property and individual rights and to advance the common good, which includes protecting the weak from the depredations of the strong and wicked. Boisguilbert's use of this clandestine current of ideas links him to a lineage of economic thinkers going back to Hobbes and forward to Smith.

4. FRANÇOIS QUESNAY: THE ENERGETIC PREMISES OF PHYSIOCRACY

Before Quesnay became an economist, he was a surgeon and physician whose *Physical Essay on the Animal Economy* of 1747 was dedicated to establishing the physical and chemical foundation of the nutrition, generation, and sensitivity of living organisms. For Quesnay, this was the ancient physics revived by Gassendi, the energetic chemistry taught by Rouelle, and an Epicurean psychology extended by the physiological and psychological theories of sentiment of the Montpelier physicians—the chemical and psychological doctrines of Diderot's *Encyclopedia*. Quesnay presents this radical energetic materialism in the form of a critique of ancient ideas, a skeptical strategy designed to avoid censorship (which has also misled historians of economics).

Thanks to his skills as a surgeon and systematic thinker, Quesnay rose from lowly origins to become physician to Madam de Pompadour at the Court of Versailles. The grant of a rural estate by the king turned his attention to the problems of French agriculture. His articles in Diderot's *Encylopedia* on farming in the 1650s and his famous *Economic Table* at the end of the decade include his infamous economic doctrine of the exclusive productivity of agriculture and corresponding sterility of commerce and manufacturing. Developed within the context of an agrarian economy, his argument was that only agriculture is regenerative in the sense of replacing what is consumed. Artisan industry (assuming all inputs come from the land) only transforms and consumes things that have been produced by the farmers. These ideas can be seen to depend on the energetic theory of his physiology that plants are the only producers in nature and the rest of nature (and humans) only exist by consuming what plants have made.

According to the 1747 *Essay*, the cycle of nature's production begins "in the womb of the earth" where elements from the atmosphere and soil are chemically combined in simple compounds and taken up by the plants where they are joined to the "very subtle and active matter" of fire provided by the sun. These organic compounds provide the active energetic substance of fire circulated throughout nature by the animals that eat the plants, the animals that eat animals, and so on. The materials are returned to the earth (recycled), but the subtle energetic matter is lost in the decaying compounds and has to be replaced by a new cycle of primary production.

Two basic criticisms have been leveled at Quesnay. The first is that he mistakenly assumed that only agriculture was capable of producing a surplus (and profit) and that he neglected the obvious importance of manufacturing and growing industrial productivity to human welfare. The criticism is valid. The second criticism is that he failed to apply the conservation of matter to agriculture in the same way he does in artisan manufacturing. Quesnay, however, would agree that production in both sectors obeys the conservation of matter. No output, let alone a surplus of grain, can be produced without the appropriate flow of material inputs from the soil and air. His point is rather that only plants can produce the vital energetic matter. His argument neglects the energy resources and inorganic materials used in industry that do not come from agricultural land. But within the assumption of a renewable resource economy limited to the use of plant biomass for materials and energy, his theory of the exclusive productivity of agriculture holds.

5. ADAM SMITH: THE WORK AND POWERS OF NATURE AND LABOR

Adam Smith is popularly regarded as the founder of classical economics, a judgment that owes more to the accessibility of his vision of a self-regulating market economy operating within an institutional framework offering something for everyone than to any fundamental contribution to theory. His laissez-faire vision excites some, his production orientation others. The heart of his production theory is the proposition that increases in the division of labor are the prime driver of productivity growth and the wealth of nations. He employs the new engineering treatment of work and natural powers to set out his theory. What is astounding, however, is the absence of any mention of the work done by natural powers other than labor (and land). This lacunae will have far reaching consequences for the treatment of energy and technology by later writers.

Smith wrote impressive histories of astronomy and ancient physics and reviews of Buffon, Linnaeus, Diderot, Rousseau, and others designed to introduce the ideas of the Enlightenment to his countrymen. He knew Gassendi's work and was good friends with Quesnay. His intimate circle included the philosopher David Hume; the chemist-physicians William Cullen, Joseph Black, and James Hutton (famous as a geologist); and the physicist John Playfair. Smith's early writings and *Theory of Moral Sentiments*, published in 1756, suggest theories of nature's design and operations, organic sensibility, and social evolution at the center of Enlightenment thought.

Smith's references to the system of the world as a great self-regulating machine have been taken to indicate an adherence to Newtonian orthodoxy. This inference is problematic. Smith, as did Hume, placed himself under Newton's mantle, but his ideas of nature's design and principles of operation are at variance with the theistic, antimaterialistic, and neoPlatonic metaphysics of immaterial principles connected with Newtonian "orthodoxy." In his "History of Astronomy," Smith interpreted gravity and inertia as balancing "material principles" that ensure a self-regulating universe. In his "Essay on Ancient Physics," he favorably compares the Stoic system of the world which used the idea of fire as the vital principle forming the world and living things to unify the design and the operation of the world, to the theism of Plato (and Newton), which artificially separated the principles of intelligence that formed and animated the world from those carrying out the ongoing operations of nature.

He also praises the "philosophical chemistry" of his associates for the "connecting principles" it provided for explaining the operation of fire in furnaces and the "invisible fire" or "vital principle" of plants and animals. He noted with regret how little this science was known outside the chemists who practice the "art of the furnace." Indeed, his idea of fire and what he calls the Stoical system was straight out of Bernier, which makes Gassendi a central source for the vision of nature's capacities of operation and self-regulation he both lauds and applies in his own work. Like Hutton and Playfair, who saw an eternal and self-regulating universe operating by natural laws, Smith appears closer to the deism of the Enlightenment than to Newton's theism.

The chemical ideas of fire and phlogiston continue to inform Smith's idea of the productivity of land in the *Wealth of Nations*. In this regard, he remains close to Quesnay. Agriculture is the source of the energetic matter feeding the human and animal populations. But he employs the new terminology of work and natural powers to displace Quesnay's view that "land is the unique source of wealth" and shift the emphasis of production theory to labor and the factors contributing to labor productivity as the source of wealth. The productivity differences characterizing nations and regions are not related to differences in nature but to the effects of the division of labor, which augments the efficiency of workers. Labor (work) is the primary source of growing wealth, which he contrasts to the "niggardliness of nature."

Smeaton's reports on the conversion of mechanical power by hydraulic and animate engines and definition of work as a universal measure of mechanical effect and value are the obvious source for Smith's ideas. He likely knew these ideas directly (the volumes are in his library) and discussed them with his friend James Watt in the 1760s when they were colleagues at the University of Glasgow. We know that Watt discussed his innovation of a separate condenser for the steam engine with Smith. Smeaton provides the engineer's concern with efficiency in the use of a given quantity of work capacity, the idea of work as a universal measure of effect and value in all times and places, and the notion of work as equivalent to effort or pain exerted over a defined period. All these ideas are prominent in Smith.

While this framework is pregnant with possibilities for a new foundation for production, Smith makes no mention of the work of machines in harnessing nature's resources and powers in his

economics. The new ideas of work are confined to labor and the related ideas of natural powers are confined to land and human labor (and working animals). The efficiency concerns of Smeaton's analysis picked up, but there is no discussion of the work done in the economy by natural powers of wind, falling water, or the immense sources of heat from coal, which had replaced wood in the industrial processes powering Britain's industrial growth.

Smith notes in passing the great investments made in "furnaces, forges, and slit mills." He would have known the great Carron ironworks near Glasgow—the first integrated iron works in Britain to employ coke in all its operations, whose blowing engines for the blast furnaces and water wheels and steam pumping engines supplying the mills with a continuous source of motive power were designed by Smeaton. He should also have known that nails and pins were made by power-driven machinery in rolling, slitting, and wire-drawing mills. Yet he illustrates the principle of the division of labor using the example of an artisan pin factory unassisted by machinery.

Modern economists tend to see Smith's division of labor and increases in the efficiency of labor in combination with increasing market size as an ever enlarging spiral of growth. It could not have been in Smith's theory since the original source of natural "powers" converted by labor in his theory continued to be, as it was in Quesnay, the energy fixed by plants. In Book II of the *Wealth of Nations*, he declares agriculture to be more productive than manufacturing because it employs two powers (nature and labor) in contrast to manufacturing which only employs one (labor). But the energy supplied by plants must be divided between workers in agriculture, manufacturing, transport, and a multitude of other uses and remains the fundamental limit on the economy. Hence his emphasis on the division of labor and productive employment as opposed to unproductive servants. His lack of clarity about the role of energy in agriculture and his neglect of industrial sources of power are major reasons for the neglect of energy in economics.

6. J.-B. SAY: GENERAL THEORY OF THE WORK OF NATURE, LABOR, AND MACHINES

The first general application of the new ideas of work in production theory was made by the French economist Jean-Baptiste Say in 1803. Despite strong literary interests, his father sent him to a commercial school in England and then apprenticed him to a powerful French banker. Say left business to work for a newspaper run by Mirabeau (Quesnay's close associate), which led to his appointment as an editor for an important revolutionary journal that included a coverage of science. Aided by his brother, an engineer, he attempted to acquaint himself with "all of science." He knew Lavoisier's chemistry and the contributions of Lazare Carnot and Charles Coloumb to the new science of work. Reading Smith he was immediately critical of Smith's emphasis on labor and neglect of nature and machines. The greatest development of productive forces, he argued, came not from the division of labor but from machinery using the forces of nature. Smith did not understand the true theory of machines in producing wealth.

Say was even more critical of the physiocrats who failed to see that all production, whether it was the production of wheat in a field or the making of a watch in a workshop, did not create new matter but only rearranged or assembled existing matter. All production was subject to the conservation of matter and required the forces of nature. Quesnay, we have seen, would not have disagreed but was making an argument that only agriculture renewed the energetic properties of materials required for life. Say's contribution was to see that human production was exploiting other sources of power by inventing new machines and that production theory must be concerned with the fundamental contributions of materials and forces of nature in human production. His ideas were clearly shaped by Lavoisier's emphasis on the importance of the conservation of matter in chemical analysis and the energetic ideas employed by French engineers and scientists. He knew the energy mechanics of Lazare Carnot (a revolutionary hero) whose work was reviewed in Say's journal, Charles Coulomb's comparisons of the work of machines, animals, and labor, and most likely Lavoisier's ideas of energy conversions by animals and machines.

Say defined the work of humans and the work of nature as "the continuous action which is exerted for executing an operation of industry." He argues that all material production whether in the field or the factory requires the same basic categories of elements (i.e., materials, forces of nature, and actions of labor, and machines). He compares land to a machine but knows that labor and machines are powerless to produce on their own without materials and a source

of power. He understands the importance of production in economics and insists that economic theory must begin with production before taking up the topics of value, distribution, and consumption.

Say provided the first general physical theory of production based on the new theory of work and mechanical energy. Unfortunately, his achievement was obscured by a diffuse presentation (especially in the first edition of the *Treatise*) and his failure to develop the implications of his new approach for a production-based theory of prices. He incorrectly argues that production creates nothing new, only utilities. While production does not create new matter, a watch is more than the gross weight of its parts. It is a new physical entity, and its conditions of production as well as its utility are important for how it is priced or valued. Say's attempt to assimilate his theory to the French scarcity and utility approach to value ignored the interdependence between production and value and contributed to the misunderstanding of his important contribution to classical production theory by the English classicals who failed to take up his production approach and its specific concerns with materials, energy, and machines.

7. MALTHUS AND RICARDO: LIMITS ON POWERS OF LAND

Like Smith, Robert Malthus has been seen as a disciple of Newton in his scientific, economic, and theological ideas. Malthus took his degree in mathematics at Cambridge, which was basically the rational mechanics of Newton and he made good use of his training in formulating regulatory mechanisms for population and price theory. But the natural philosophy and theology he outlined in the first *Essay on Population* in 1798 is neither orthodox nor Newtonian. His ideas of an ongoing creation, the evolution of mind from "a speck of matter," and the forging of mental and moral qualities by the struggle to overcome evil have their sources in the associationist psychology and theology of David Hartley; the scientific and theological ideas of Joseph Priestley, Hartley's leading disciple; and the evolutionary physiology of the physician and biologist, Erasmus Darwin, grandfather of Charles Darwin.

Out of this heady brew, Malthus constructs a decidedly heterodox philosophy and theology which sees nature, mind, and human progress as products of a long struggle against adversity. He makes an important break with ideas of natural harmony by drawing out the implications of Priestley's theological vision of God's imperfect but evolving creation and recognition of limited resources (even God faced limits in what he could do). Given the inherent drive to reproduce and the scarcity of resources, the capacities of the population of each species to outrun its food supply must eventually produce a struggle for existence in nature. Malthus recasts Priestley's progressive theology of struggle and growth into a theodicy of scarcity refracted through the mathematics of exponential growth and the focusing lens of regulatory mechanics. His ideas also reflect the absolute limits of an energetic perspective. Priestley was a phlogiston chemist and co-discoverer of photosynthesis. In a period when the nutrient limits of soils were not understood, the primary limit on agricultural production appeared to be the ability of plants to fix energetic matter as opposed to a shortage of particular (and augmentable) nutrients.

Malthus's preoccupation with the availability of food was reinforced by a theological vision of nature's design. Struggle against limits was necessary for progress. A preoccupation with food and limits, reflecting energy theory and theology, helps explain why Malthus's contributions to areas of production theory outside agriculture were so limited. Despite his acute observations on the central differences between returns and costs in industry (where techniques are replicated and constantly improved) compared to agriculture and an understanding of the energetic basis of production, he does not develop a general theory of the material and energetic transformations specific to industrial production. He certainly knows Say's production theory. It would appear that the idea of constraints and limits, which were rooted in theology and energy theory, carry implications for limits on human progress that explain his reluctance to engage Say's more general theoretical framework with its quite different vision of human progress.

The scientific underpinning of David Ricardo's powerful theorizing has received little attention from historians. What is known of his scientific interests and cast of his thinking suggests that natural philosophy played an important methodological and conceptual role in his economics. He had early interests in chemistry and geology. A convert to Unitarianism, we can expect he was familiar with the philosophical and chemical ideas of Priestley, the intellectual leader of the movement. The fact that Ricardo was a trustee of the London Geological Society, whose directors sought to advance James Hutton's uniformitarian geology, suggests he knew Hutton's powerful energetic arguments about the

geological and biological processes forming the earth and his method of dynamic (energy) equilibrium (and his tendency to ignore historical processes). Hutton was one of the leading energy thinkers of his generation and the likely source for Ricardo's similarly powerful focus on dynamic processes.

Energy ideas play a central role in Ricardo's early corn theory of profit, which is set out as a ratio of the surplus of corn to its costs of production (measured in corn). If land (and energy) increase relative to labor, profits rise. Corn continues to play a central role in the dynamics of his labor theory of production and value after Malthus convinced him that capital could not be limited to corn. The relative availability and cost of corn (the energy source running the organic machines of the agricultural and artisan economy) continued to provide the foundation of his theory of relative costs, profits, and rents, and thus the long-run dynamics of the economy.

Although Ricardo noted the merit of Say's division of economic theory into production, distribution, and value, he did not make the explicit treatment of the production principles that Say's plan suggested. Instead, he begins his *Principles* with a chapter on how the values of commodities are determined. His analysis is clearly informed by a vision of production but the physical perspective of contemporary scientific ideas that informs it must be reconstructed from the wording Ricardo employs, a footnote or two, and the tenor of his arguments. We can catch a glimpse of his acute understanding of the contribution of the natural powers employed in industry when he refutes Smith's notion that nature does nothing in manufactures. The passage reflects Say's language but is pure Hutton in its energetic focus:

> *Are the powers of wind and water which move machinery, and assist navigation, nothing? The pressure of the atmosphere and elasticity of steam which move the most stupendous engines—are they not the gifts of nature? to say nothing of the effects of the matter of heat in softening and melting metals, of the decomposition of the atmosphere in the process of dyeing and fermentation. There is not a manufacture … in which nature does not give her assistance to man, and give it too, generously and gratuitously.*

8. LATE CLASSICAL THEORY: BABBAGE, SENIOR, AND J. S. MILL

Until the mid-1830s, the energy ideas entertained by classical economists, apart from Say and Ricardo, were effectively confined to plants and biological engines. Thanks to Babbage's pioneering study of the new industrial "Economy of Machinery and Manufactures" in 1832 and Andrew Ure's study of the factory system in 1835, the importance of coal and steam engines for industrial production and transportation and for Britain's industrial ascendancy were now in the public eye. In reviews of Babbage and Ure, the economist John McCulloch noted the link between Britain's industrial prosperity and the exploitation of coal technologies. He argued that the increase in the quantity of iron made with coal lowered the costs of machinery (and steam engines) leading to more output at lower unit costs and more demand for coal, iron, and machines. He did not, however, attempt to incorporate these ideas into a theory of production.

Babbage's great study of principles of a machine economy distinguished two types of machines, those which produced power and those designed to transmit force and execute work. The first class included water and wind mills. But it was the adoption and continued innovation in steam engines employing coal for fuel that captured Babbage's imagination (the heat-based industries need equal attention as well). Economies of scale and high fixed costs pushed mill owners to continuous operation and opened opportunities for new professions (accountants, etc.) and industries, such as gas lighting. New power sources and technologies created new products and materials and new uses for materials that formerly had little value. The principles of the machine (and coal and iron) economy extended beyond the factory to the larger political economy and society generating new knowledge and new models for administration.

The only economist to apply Babbage's theory of machines to a theory of production inputs and returns was Nassau Senior, whose contributions in this regard, however limited, were completely ignored by his contemporaries. Babbage's suggestion that "practical knowledge" would continue to grow without limit appeared in the third of Senior's "elementary propositions of economic science," which stated that "the powers of labor and the other instruments that produce wealth can be increased indefinitely." Senior's fourth proposition posited the existence of diminishing returns to additional labor employed on the land and increasing returns in manufacturing. While he understands the conservation of matter in manufacturing industry when he states that "no additional labour or machinery can work up a pound of raw cotton into more than a pound of manufac-

tured cotton," his attribution of diminishing returns in agricultural production to the employment of additional labor "on the *same* material" does not make it clear that additional output here requires additional materials from the soil and atmosphere and additional solar energy to produce another bushel of corn or pound of cotton seed.

Senior used Babbage to advance Adam Smith's distinction between fixed and circulating capital (structures and agents versus material flows). He distinguished tools and instruments from materials embodied in production and subdivided machines into those producing and transferring power. He separated natural powers from ordinary materials on the grounds the former are not embodied in output but did not know where to put food, coal, and other natural powers. Instead of distinguishing a subcategory of natural powers or energetic flows along side materials, he lumped food and coal with "fixed capital." Clearly, more insight about the nature of power and the agents and machines applying and using power was needed. His laudable efforts to grapple with a physical classification of production inputs and their implications for production returns were not, unfortunately, taken up by subsequent economic writers. Indeed, J. S. Mill attempts to undermine both Senior's classification efforts and treatment of production returns.

Another extremely important treatment of the ideas of the sources and application of power in human economy was that of the scientist and mathematician William Whewell in 1841, who extended Babbage's classification of machinery to include moving power, trains of mechanism connecting power to work and work done. Whewell also recognized that the engine economy and its sources of power were dissipative and would eventually be exhausted (including the engine of the sun). He concluded, Norton Wise points out, that no balance existed in nature (or economy). In Whewell, the steam economy replaced the equilibrium of the balance with disequilibrium and decay, foreshadowing the second law of thermodynamics. Whewell embraced decay as part of a Christian escatology but would have not been happy that evolutionary processes are the other side of a dissipative and temporal universe.

Despite his friendship with Babbage and adoption of J.-B. Say's ordering of economic theory (Book I of his *Principles* is devoted to production), the socially progressive J. S. Mill made no attempt to apply physical or engineering insights to production theory. He follows Say (and Senior) in classifying production inputs under the headings of labor, natural agents, and capital, but his concern throughout is to emphasize economic aspects of production. He shows no interest in the physical foundations of economic theory. Book I has three chapters on capital and at least two on labor but none on the characteristics of land or natural agents. He isolated "labor and natural objects" as the two "requisites of production." But in contrast to his elaborate classification of indirect labor, and the separation he makes between materials and powers in nature, he refuses to make any distinction between materials, food, and fuels as circulating capital.

Ignoring Babbage, Senior, and Whewell, Mill argued that "political economists generally include all things used as *immediate* means of production either in the class of implements or materials to avoid a multiplication of classes [and] distinctions of no scientific importance." He made the distinction between materials and machines turn on whether an "instrument of production can only be used once" and declared that a "fleece is destroyed as a fleece" in making a garment just as a fuel is consumed to make heat (which indicates he did not understand the distinction between energy and materials). He responded to the "able reviewer" of the first edition of his work (Senior) who objected to subsuming coals for engines and food for workers under the class of materials by admitting that while his terminology was not in accord with the physical or scientific meaning of material, the distinction between materials and fuels is "almost irrelevant to political economy."

Mill correctly recognized that tools and machinery lack productive powers of their own. But after declaring that the only productive powers are labor and natural agents he denied this status to "food and other materials" (and thus fuels). The fact that steam engines burning fuels are productive and a worker lacking food is not exposes the weakness of his position. By undermining Babbage and Senior's extension of Smith's distinction between physical structures that process and store materials and flows of materials and energetic powers, Mill brought the development of engineering ideas about the machines and powers in production theory to a halt.

Mill recognized the existence of increasing returns in manufacturing and argued that the causes increasing "the productiveness of [manufacturing] industry preponderate greatly over the one cause [the increasing expense of materials] which tends to diminish that productivity." Yet he treated increasing returns as a subsidiary proposition to "the general

law of agricultural industry," that is, diminishing returns, which he calls "the most important proposition in political economy." Increasing returns is not given an independent development. The statement of neither proposition includes a consideration of the essential inputs required to increase output according to the conservation laws which tie output to material and energy input. Mill was aware of the complementarity between capital and natural powers and materials and output but his lack of concern with accurate scientific terminology and any systematic consideration of the physical principles of production fail to preserve or advance the physical production framework advanced by Say, Ricardo, and Senior let alone Babbage or Whewell. Given the that Mill's work was a common point of departure for neoclassical theorists, his failure was a critical factor in the neoclassical failure to seriously grapple with energy and scientific approach to production theory.

9. HOW ENERGY CAME UP MISSING IN NEOCLASSICAL ECONOMICS

The main early neoclassical economists, including William Stanley Jevons, Leon Walras, Alfred Marshall, and Wilfredo Pareto, took their inspiration from the rational and analytical mechanics of the 18th century and 19th century. Thanks to the construction of mechanics in terms of the equilibrium between forces, mechanics provided economics with a powerful mathematical language of analysis that included a model of self-regulating activity produced by the inexorable operation of opposing forces. Neoclassical economics abandoned the production approach of the classicals to reconstruct economics as a mathematical science of behavior and markets expressing the interplay of demand and supply based on theories of marginal utility, marginal productivity, and universal scarcity, the latter being the consequence of the substitution assumption or "law of variable proportions," which assumes that any nonscarce good of interest to economics will become scarce by being substituted for other goods.

We have already noted how the standard formulation of diminishing marginal productivity violates the basic laws of thermodynamics. The adoption of the idea of marginalism necessarily pushed materials and energy and any scientific formulation of production from the scene. William S. Jevons eliminated fixed capital from his theory and provided no treatment of the role of energy in his treatment of production despite having written and entire book on the critical importance of coal to British industrialization just a few years before. Leon Walras had initially specified raw materials as an intermediate input but then proceeded to vertically aggregate production so that output was a direct function of the "original factors of production," land, labor, and capital. Capital was assumed to be like land so that adding more labor to a given amount of capital could be assumed to add more output albeit subject to diminishing returns.

But the theoretical problems of marginal productivity are not confined to a special assumption (individual inputs are productive everything else constant) that can be relaxed by adding more inputs. The assumption reflects a structural feature of the theory, which effectively prevents any realistic physical reformulation of the theory. Thanks to the adoption of the mathematics of field-theory as the structural framework informing utility and production theory, every input in the production function (which is based on the potential function of analytical mechanics) is effectively assumed to have productive capacities because of the existence of an energy gradient in the space over which the production function is defined. Each production input is effectively considered to be an axis in n-dimensional space. Thus, an increase in any input (an increase along one axis) automatically involves a movement to a higher energy gradient. Output, defined as the potential function of the field, increases. These movements, moreover, are always reversible since the field theoretical framework is nondissipative and conservative.

In the 18th and early 19th centuries, nature (economics included) had been assumed to be self-regulating as a metaphysical principle grounded in nature's design. In the late 19th century, despite the development of a new energy physics based on the laws of thermodynamics and an understanding of the inexorable processes of entropic dissipation, economics had found a new and powerful mathematical and conceptual framework in field theory for expressing and developing its vision of order, stability, harmony, and rational allocation. For economics, the virtue of a theory of electromagnetic or gravitational fields is that there is no dissipation. Unlike other energy conversions, which are dissipative, the energy principles of field theory are conservative (no dissipation takes place). This provides a framework taken from physics that

isolates economics from the troubling questions about natural resources or sustainability. These issues have little meaning once the assumptions of the theory have been accepted.

Glossary

ascendency A summary measure of the magnitude of the fluxes within a network and of the degree to which the paths of flow within the network are organized or preferentially directed.

available energy The potential to do work.

ecological integrity The state of structural completeness of components and maximum function of processes in an ecosystem operating under a given set of external forcing energies. In this state, the empower of the ecosystem network is near the maximum possible.

ecosystem An organized system of biotic and abiotic components including land, water, mineral cycles, living organisms, and their behavioral control mechanisms.

ecosystem health The functional integrity of an ecosystem as characterized by a state of vigorous self-renewal in the ecosystem as a whole and in its components (soil, water, animals, plants, etc.). One measure is the empower gained by the ecosystem from a given set of external energy sources.

emergy The available energy of one kind previously used up both directly and indirectly in making a product or service. Emergy has units of emjoules to connote energy used in the past.

empower Emergy per unit time or emergy flux.

energy flow network The interconnected energy flows in an ecosystem.

energy (emergy) signature The suite of external forcing energies from which an ecosystem can capture available energy. When the external energies are converted to emergy, the entire suite is called the emergy signature of the ecosystem.

enthalpy (heat content) The internal energy plus the product of the pressure times the volume. Relative changes in enthalpy are easily measured by calorimetric methods, which have been widely used to determine the heat content of biomass.

exergy The potential that energy has to do work relative to a reference state. As used by some ecologists, exergy includes the higher potential that energy associated with lower-probability structures has for the capture of additional available energy.

homeorhetic The tendency for a system to maintain constancy in its dynamic properties (e.g., energy flow).

maximum power (empower) principle The principle originally formulated by Alfred J. Lotka as "natural selection tends to make the [available] energy flux through the system a maximum, so far as compatible with the constraints to which the system is subject." H. T. Odum realized that available energies of different kinds have different abilities to do work when used within an ecosystem network. Conversion to emergy flux (empower) expresses the energy fluxes of many kinds in units with the same quality (e.g., solar joules), allowing the maximum to be accurately determined.

pulsing paradigm The theory that alternating production/storage with consumption/release on all hierarchical scales maximizes power.

self-organization The use of net energy to build increasingly complex patterns of feedback and design to capture more available energy for the ecosystem; the properties of this process as they govern the creation of order in far-from-equilibrium systems.

solar transformity The solar emergy required to make a unit of energy of a product or service. Its standard units are solar emjoules per joule.

specific emergy The emergy per unit mass of a flow, product, or service, its standard units being solar emjoules per gram.

Just as for human beings health is a concept that applies to the condition of the whole organism, the health of an ecosystem refers to the condition of the ecosystem as a whole. For this reason the study and characterization of ecosystems is fundamental to establishing accurate measures of ecosystem health. By definition, the idea of health is closely related to the optimal functioning of an organism or other entity. This idea can be applied to ecosystems, economies, and other organized systems in general and not simply to living organisms. Health is more than the simple absence of disease; rather it is a state that reflects the overall well-being of the system, whether it is a human organism, an ecosystem, or the economy of a nation.

1. ECOSYSTEM HEALTH AND ECOLOGICAL INTEGRITY

Integrity is a complex idea closely related to health that has two meanings relevant to ecosystems. The first important meaning of integrity is that it requires an entity to be unimpaired when compared to an original condition. This implies that a reference condition must be defined and that the presence or absence of integrity can be measured relative to this standard state. Health is also often measured with respect to a reference condition. A second relevant meaning of integrity is that it defines a state of organic unity, or wholeness within a system. Health and integrity are complementary ideas that together are capable of describing the well-being of any system. Because these ideas are so closely related (both share the meaning of soundness), they have not always been clearly distinguished in scientific and other writings.

2. HISTORICAL BACKGROUND ON ECOSYSTEM HEALTH

Early depictions of ecosystems as organized networks by A. J. Lotka, A. Leopold, G. E. Hutchinson, and R. L. Lindemann and their insights into the role of energy flow, storage, and conversion efficiency in the healthy organization and functioning of ecosystems provided the basis for later assessment of ecosystem health in terms of the status and dynamics of various energy measures. However, the direct application of health, and its sister concept integrity, to ecosystems can be traced to the writings of Aldo Leopold during the late 1930s and 1940s. Leopold developed the concepts of a land ethic and land health that presaged the scientific interest in ecological integrity and ecosystem health, respectively. Leopold equates health of the land to its functional integrity, which he defines as a state of vigorous self-renewal in the land as a whole and in its components (soil, water, animals, plants, etc.). Leopold's concept of land is similar to our present idea of an ecosystem. Leopold's poetic description of land as a hierarchy of energy circuits implicitly called for the development of a quantitative tool like the energy circuit language, which H. T. Odum developed 30 years later.

The scientific interest in ecosystem health had its origin in the field of stress ecology that developed during the late 1970s and 1980s. Some research in stress ecology built on the earlier work of H. T. Odum, who showed that stress in ecosystems had the common property of acting as an energy drain, preventing available energy from flowing into useful structures and functions. Hans Selye discussed evidence for a nonspecific, generalized stress syndrome in humans. This work served as a basis for moving from the idea of stress in an organism to that of stress in an ecosystem, which led David Rapport and others logically to a consideration of ecosystem health. In the late 1980s, more research on ecosystem health, based on an analogy with medicine, began to appear. The First International Symposium on Aquatic Ecosystem Health was held in July 1990 and set the stage for a new publication, *Journal of Aquatic Ecosystem Health*. David Rapport characterized ecosystem health as a transdisciplinary science, which includes the study of ecosystem structure and function, along with socioeconomic factors and human health as they relate to the overall well-being of an environmental system.

3. ENERGY SYSTEMS ANALYSIS, HEALTH AND EMERGY

Robert Costanza proposed that the health of an ecosystem could be characterized by the vigor, network organization, and resiliency of the system.

These three general properties of ecosystems are essentially the total energy flow through the network, the arrangement of those energy flows into an organized network, and the excess energy flow or scope for growth that an ecosystem can use to recover from disturbance. These three characteristics relate to ecosystems and their functioning over time, and therefore systems analysis and simulation are fundamental tools needed to characterize ecosystem health. In this article the concepts of ecosystem health and ecological integrity are defined, measured, and interpreted from the perspective of energy systems theory and other systems approaches, such as information theory (ascendency), that are capable of analyzing networks of energy flow. Since the focus is on energy indicators of ecosystem health, the authors judge this perspective to be the most informative. Other perspectives on ecosystem health exist and are valid for certain purposes, but they are not considered here.

Energy systems theory provides tools and methods for describing and analyzing the hierarchical organization of ecosystem networks. Analyzing the energy hierarchy led to the insight that all energies are not equal in their ability to do work in a network. Emergy measures the relative ability to do work of the energy flowing through different components in an ecosystem network. Emergy values are always based on an underlying energy flow or storage times an appropriate emergy per unit coefficient. Emergy places energies of different kinds on the same scale so that they are directly comparable. The base unit for expressing emergy in ecosystems is the solar emjoule, sej. An emjoule is a joule of a particular kind of available energy that has been used in the past to make a product or service. Where the coefficient converts energy to solar emergy it is called the solar transformity and has units of sej/J. Also, mass in grams can be multiplied by the specific emergy of the item in sej/g to obtain emergy. Power must be converted to empower to gain a true picture of the relative importance of changes in different energy flows. The maximum power principle must be evaluated in terms of empower to obtain an accurate criterion for judging the relative health of ecosystems.

4. ENERGY AND ECOSYSTEMS

Available energy drives every known process at every level of organization in the universal hierarchy of natural phenomena. The existence of available energy potentials of sufficient magnitude is the fundamental basis for all self-organizing structures that exist far from thermodynamic equilibrium (e.g., ecosystems, organisms, and societies). The use of available energy potentials enables ecosystems and their components (e.g., individuals, populations, and communities) to perform their natural functions. Ecosystems self-organize into hierarchical networks of components connected by energy flow. These flows interact to link ecosystem components into energy flow networks through pathways of power and control (Fig. 1). Some controlling feedbacks interact with external energy sources to capture more available energy for use in building the network. Hierarchical levels of organization are also linked by energy flow (Fig. 1). Energy is a common denominator among ecosystems that makes it possible to identify and characterize similar processes and functions in ecosystems of many kinds. Because of the fundamental role of power (energy flow) in ecosystem self-organization, it is logical to expect that measures of power will be useful in characterizing the functional integrity (health) of ecosystems and that changes in energy flow will measure possible disturbances in healthy ecosystem processes.

4.1 Energy Intake and Ecosystem Health

Ecosystems consist of biotic and abiotic elements organized as structures, gradients, and flows that are maintained far from thermodynamic equilibrium through the capture and transformation of available energy. The persistence of such organization is continuously threatened and disrupted by the dissipative tendencies of the established structures and gradients within the system and its surroundings. The second law of thermodynamics governs these tendencies toward disorder, and ecosystems as well as organisms must continuously draw in available energy to repair and counteract them. For ecosystems, many external forces such as solar radiation, heat, wind, nutrients, and invasive organisms can be either sources of available energy or disordering forces depending on their form, magnitude, or intensity. The similarity between the condition of ecosystems and organisms with regard to the maintenance of necessary structure has motivated the development of the various energy indicators of ecosystem health—for example, the ratio of the energy used in respiration to the structure that it supports is called the Schrödinger ratio, a measure of the energy cost to maintain a unit of structure.

Both the persistence and growth of ecosystems depend on the continuous influx of available energy

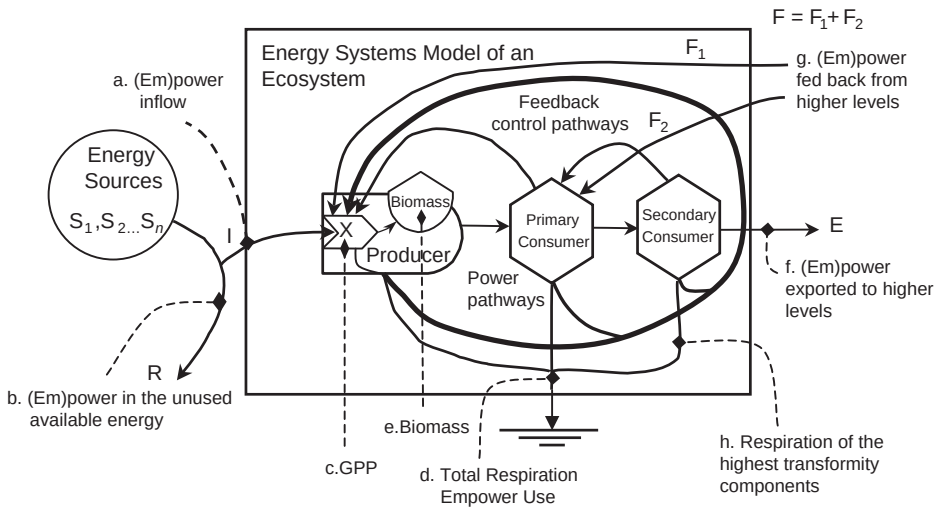

FIGURE 1 Energy systems model showing some of the general characteristics of ecosystems and the points where power and empower might be measured (labeled daimonds) to indicate ecosystem health. Symbols are briefly defined as follows: circles are energy sources, tanks are stored quantities, bullet symbols are producers, hexagons are consumers, and the block arrow is a work gate or interaction. Energy flows on the lines in the direction indicated by the arrowheads; light gray lines show flows of used energy to the heat sink (ground symbol), and the thicker, darker gray lines show the recycle of materials. and the transformation of this energy within the system to provide for its own self-renewal (i.e., structural maintenance and reinforcement of energy inflows) under the conditions imposed on it by its surroundings. When the structures, flows, and gradients within an ecosystem are organized to provide a capacity for maintenance and self-renewal that results in a sustained flourishing of the ecosystem, the system is healthy. For an organism or cell to remain healthy, both a sufficient metabolic rate *in toto* and an appropriate balance among the rates of specific metabolic processes are required to maintain the structural integrity and the functions on which its life depends. This same condition applies to ecosystems. Energy systems theorists have hypothesized that the maximum power principle governs the acquisition of energy by ecosystems. According to this principle, ecosystems prevail when the total rate of energy acquisition and conversion is sufficient to be competitive compared with the power acquisition rates of alternative ecosystem designs. If this principle is correct, ecosystem health depends on meeting this criterion for survival in evolutionary competition, and healthy systems will have total power flows that approach the maximum possible for a given set of inputs. To capture more of the available energy in external sources, ecosystems must develop an appropriate balance among the specific applications of this energy to maintain the internal structures and functions on which the viability of the ecosystem depends. Developing and maintaining the capacity to respond to pulsing on several hierarchical scales (the pulsing paradigm) is a condition for maximizing empower when energy is stored. Using the energy systems perspective and substituting emergy for energy and empower for power, the preceding concepts of ecological integrity and ecosystem health are defined and related in the following statement: ecological integrity is an emergent property of ecosystems that is greatest when all the structural components of a system that should be there based on the emergy sources received by the ecosystem are there (i.e., structural integrity is complete) and all the processes operating within this system of components are functioning at the optimum efficiency for maximum empower (i.e., the ecosystem is healthy). Therefore, ecosystem health (maximum network empower) is one component of the overall ecological integrity of an ecosystem, and structural integrity (completeness) is the other.

4.2 Properties of Healthy Ecosystems

Healthy ecosystems can be described by a relatively few properties that accompany maximal energy but more specifically emergy intake. Since ecosystems undergo a regular cycle of change, the expected values for these properties will be different depending on the stage of ecosystem development. One sign of stress for the ecosystem is a change in the expected course of succession and regression that characterize this cycle. The maximum power principle indicates

that healthy ecosystems will maintain optimally efficient energy transfers and nutrient cycling to maximize energy intake from available energy sources. This optimum ecological organization includes characteristic sets of species. These species sets vary with the stage of ecosystem development and with the particular ecosystem type, but in general a diverse species assemblage dominated by long-lived larger organisms characterizes the mature (climax) stage of ecosystem development. Healthy ecosystems also have the energy and information reserves to resist or adapt to change, and therefore they show resiliency in the face of perturbations or debilitating factors. The state of health involves optimization in terms of the allocation of resources because adaptation to any disordering factor entails tradeoffs with other factors including the maximum growth potential of the system.

4.3 Energy Indicators of Ecosystem Health

The characterization of the state of health of an ecosystem as defined earlier requires measures that express the condition of the ecosystem as a whole or some aspect of the system that can be quantitatively related to overall condition. Self-organization of ecosystems for maximum power has resulted in general design properties that are common to all ecosystems. The energy systems language model in Fig. 1 illustrates the following common design properties: (1) a set of external energy sources, (2) a web of interacting components, (3) convergence of successive energy transformations in a chain of increasing energy quality (emergy per unit energy), (4) storage of mass and information, (5) recycle of materials, (6) feedback control systems, (7) interactions of energy flows of different quality to maximize power by rewarding components that contribute, and (8) connection to other hierarchical levels of organization through imports and exports of energy. Important points where energy indicators of ecosystem health can be measured are marked on the diagram. The flows and storages of available energy that provide information about the health of ecosystems are (a) the energy inflow, (b) the albedo or unused energy, (c) gross primary production (GPP), (d) respiration of the whole system, populations, or groups of populations, (e) total biomass, the biomass of system components, and changes in biomass, (f) energy export from the system, (g) energy import into the system, and (h) the energy used by the highest transformity elements of the ecosystem. In the system diagram in Fig. 1, the total inflow of empower in the available energy captured (F + I) will be close to a maximum in healthy systems operating under a given set of external energies. When the external energy sources are constant or remain within an expected range, ecosystem health might be measured by comparison to reference levels of (F + I) or reference values of any other flow that has a known relationship to (F + I). When the spectrum of external emergies (the emergy signature) is changing, health can only be judged by comparison of the network empower of alternative system designs.

5. DIRECT MEASURES OF ECOSYSTEM HEALTH

Figure 1 shows many points at which the energy flow in an ecosystem network can be measured. Other measurement points are also possible. Each point of measurement tells us something different about ecosystem function and all will have their usefulness. The indices that will be the most useful in characterizing ecosystem health remain to be proven by empirical testing.

5.1 Biomass: Energy Storage as an Indicator

The most direct and earliest measures of energy status and dynamics include the enthalpy stored by the biotic community and the rates of enthalpy capture by and transfer within this community. Measures of community and population biomass provide an estimate of energy storage and its organization when standard factors are used to convert biomass dry-wt. values to enthalpies. Based on representative carbohydrate, lipid, and protein fractions in the major biological taxa, typical conversion factors range from 19 kJ/g for terrestrial plants to 26 kJ/g for vertebrates on an ash-free dry-wt. basis. Because total community biomass increases during ecosystem succession and generally decreases in response to stress, this measure can serve as an indicator of ecosystem health, particularly if a reference for comparison can be established. Relatively little effort has been made to identify such reference values due to practical difficulties arising from the great variability among ecosystems in community biomass and in the factors affecting it. If these factors could be adequately accounted for, total community biomass might provide a reasonable

initial indication of an ecosystem's health in terms of its energy flow.

Biomass alone could be a very misleading indicator, if diversity and balance among ecosystem elements are important components of ecosystem health. The productivity that produces a high biomass could result from the predominance of a minimal number of energy flows and conversions that are highly efficient under a narrow range of conditions. When such efficiency is attained at the expense of the redundancy and diversity of flows and conversions that are critical to the long-term persistence of the ecosystem, high biomass does not accurately indicate a robustly healthy ecosystem. Diversity measures can also be derived from the stored biomass in an ecosystem's respective populations to provide an index of organization that has been proposed as a predictor of ecosystem stability and resilience. However, no consistent relation between these health-related properties and such diversity has been established.

5.2 Productivity: Energy Flow Rate as an Indicator

Gross primary productivity is the rate of conversion of the energy captured by the biotic community or its respective autotrophic populations to chemical energy in biomass. It is an indicator that is closely related to energy flow within the system and thus should be more sensitive than biomass is to changes in health. However, if gross primary productivity is measured only at the community level, the homeorhetic nature of biological production and respiration severely diminishes the sensitivity of this indicator. A decrease in the productivity in one population is often compensated for by an increase in the productivity of another. Productivity is also quite variable and measurements must be taken over a long enough period of time to obtain a representative average. The diversity (Shannon-Weiner index) of productivity (energy flows among an ecosystem's populations) has also been considered as a measure of ecosystem health based on a hypothesized dependence of stability (a characteristic of healthy systems) on diversity. The extent of this dependence has yet to be established. Some increase in homeorhetic potential with increasing diversity is expected at low diversities. In general, diversity appears to correlate with ecosystem but not population stability. Even though methods exist to estimate gross primary production from measurements of total system metabolism, the difficulty of measuring gross productivity directly (because respiration simultaneously consumes the organic matter produced) has been an impediment to the successful development of productivity-related indicators of ecosystem health.

5.3 Respiration: Energy Dissipation as an Indicator

The community respiration rate has also been proposed as an indicator of ecosystem health because of its close association with processes of maintenance and repair. As one of the first effects of stress, the demand for these processes is expected to increase, and thus an increase in respiration could be an initial indication of the exposure of an ecosystem to an environmental change that adversely affects its health. In the longer term, community respiration typically declines as the productivity of an ecosystem is diminished by an adverse condition that reduces energy intake. Because processes of biotic self-organization and renewal, including growth and reproduction as well as maintenance and repair, are driven by the energy used in respiration, ecosystem health as described here is clearly related to respiration.

A healthy ecosystem might be characterized as one that maintains its respiration rate through periods of relative stability and in response to slow changes in its energy sources. Since stress acts as an energy drain, an increase in respiration rate over that expected for a particular ecosystem might indicate a decline in health. Optimal (or healthy) values for an ecosystem's respiration rate and for the time-dependent variability in this rate will differ with prevailing environmental conditions, and standards appropriate to any given set of conditions are not yet available. If such standards could be developed, deviations from the standard could provide a useful indication of a lack of healthy adaptation to extant stress. Where opposing effects of multiple stressors affect metabolic rates, simulation models would be needed to predict impairment. The difficulty and infrequency with which community respiration is measured and the complications involved in developing and validating diagnostic standards present obstacles to the use of community respiration rate as an indicator of ecosystem health.

5.4 Energy Absorbed: Energy Intake as an Indicator

The solar energy absorbed by terrestrial ecosystems and its complement the albedo are arguably the most direct measures of ecosystem health for these systems. This measure varies greatly among system

types, but it also varies within a system according to the overall condition of the system. Remotely sensed measures of ecosystem condition include the Normalized Difference Vegetation Index (NDVI), or greenness index, which shows clearly the effects of wet and dry years on the condition of forests and other terrestrial vegetation. Methods to determine the long-term changes in energy capture by an ecosystem show promise in documenting the regional effects of global climate change on ecosystem health. Because of the efficiency and power of remote sensing in characterizing large areas with high-resolution data, these methods may hold the most promise for developing future energy indicators of ecosystem functioning.

5.5 Energy Ratios as Indicators

Ratios among the preceding measures (i.e., *P*/*R*, *P*/*B*, and *R*/*B*, where *P* is gross community productivity, *R* is community respiration, and *B* is community biomass) have also been proposed as indicators of ecosystem health or disease (i.e., lack of healthy adaptation to an extant stress). Production and respiration are the two essential processes within ecosystems, and the ratio of these two energy flows provides considerable information on the state of the ecosystem (Fig. 2). In ecosystems that are not subject to large net imports or exports of organic matter, the *P*/*R* ratio will eventually become balanced (at close to 1). Imbalances in the forcing energy signature as well as stressful factors that alter community production or respiration or that increase respiration in response to biotic damage can shift this ratio away from 1, indicating impaired ecosystem health for these systems. The *P*/*R* ratio is less dependent on a comparison to previous measures of community metabolism or established standards for ecosystem types than is an indicator based on *P*, *R*, or *B* considered independently. Its interpretation is dependent on knowledge of external factors such as imports and exports of organic matter and of any

large disturbances to which the ecosystem may have been subjected.

The ratios *P*/*B* and *R*/*B* have been advanced in association with the hypothesis that the self-organization of healthy ecosystems results in a maximization of biomass subject to available energy constraints. Thus, decreases in these ratios under a stable energy regime would indicate a stress that had undermined in some manner the healthy self-organization of the ecosystem. From an energy systems perspective trends in biomass are viewed as secondary to the priority of maximizing empower in the network. Thus, ecosystems build structure and organization as the means of increasing the use of the available energies.

The *R*/*B* ratio (sometimes also called the metabolic quotient, especially when measured in units of carbon stored and respired, or the Schrödinger ratio) has been the more thoroughly investigated of the two, especially with respect to soil ecosystems. The Schrödinger ratio is considered by some to be a thermodynamic order function in an ecosystem. E. Schrödinger, a physicist, showed that biological systems with molecular order affected by thermal vibrations must continuously pump out disorder if they are to maintain their internal order. Thus, the larger the biomass, the greater the maintenance cost. Although the energy required for maintenance of biological structure relative to the energy stored in that structure might be expected to increase with the application of stress, the observed direction of change in this ratio in the presence of common stress factors has varied with the ecosystem and the stress.

6. INDIRECT MEASURES OF ECOSYSTEM HEALTH

There are many possible methods for analyzing the properties of networks to indirectly measure ecosystem functional integrity or health. The three methods discussed in this section have been used in the literature to characterize ecosystem health. In addition, the reader should examine the references given in the bibliography.

6.1 Emergy Measures and Models

Emergy addresses the differences in the effects of different forms of available energy when used in a network. When the direct energy measures presented earlier are converted to emergy before calculating indices, a more accurate picture of the balance within the ecosystem should be gained. For example, the respiration of an ecosystem might decrease but the empower of respiration could increase if more of the energy in metabolism was due to higher transformity components. We expect that indices constructed using empower will be able to explain observations where power alone has failed. The fundamental theoretical connection between emergy measures and the response of systems to selective pressures might make these measures particularly suitable for indication of the long-term health status of ecosystems. Three emergy indicators of ecosystem health are (1) the empower used to maintain a given quantity of stored emergy in structure (similar to the respiration per unit biomass for an organism), (2) the dynamic transformity for the whole ecosystem or the ratio of the emergy required to produce a unit of energy flowing along all the pathways of an ecosystem to that unit of energy, which is an intensity factor for emergy in the ecosystem just as the temperature of an organism is an intensity factor for heat in the body, and (3) the ratio of the emergy stored to the emergy consumed in an ecosystem or the emergy *P*/*R* ratio, which may have characteristic values for systems with different characteristic emergy signatures. Figure 3 shows an example of two of these indicators calculated for control ecosystems and ecosystems impacted by hot water at Crystal River, Florida. Although emergy indicators are theoretically promising, they have not been tested and evaluated in large-scale studies of ecosystem health.

Simulation modeling is a viable means to develop indicators of ecological integrity and to identify criteria for ecosystem health. Ecological integrity and ecosystem health can be characterized through an analysis of validated simulation models of energy flow, when it has been demonstrated that the network of interactions in the model captures those factors that are primarily responsible for the behavior of the real system. In model simulations, ecosystem health is determined by calculating the empower at various points in the network of energy flows being simulated. The empower at any point in the network is calculated by multiplying the energy flow along the pathway by a dynamic transformity for that pathway. The value of the transformity depends on the external sources delivering emergy to the system as well as on the pathways of energy transformation within the system. Relative ecosystem health has been hypothesized to increase with empower on the pathways. In some studies of simulated ecosystems, this value has been found to

approach a maximum for a given set of external energy sources that remain constant. There are special rules for determining the emergy of storages. The empower of the network includes information on the energy flow on each pathway as well as information on the position and connectivity of the pathways, which is supplied by the dynamic transformity. Empower can be determined at any point in the system where there is an energy flow.

The capacity to measure anthropogenic stress factors as emergy flows and to integrate these flows within a single dynamic systems model of the human-ecosystem interaction provides a basis for both ex ante and ex post assessments of the effects of human decisions and activities on ecosystem health. This capacity also permits derivation of relative measures of ecosystem health that reflect dynamically changing human preferences for ecosystem services and functions. Within such an integrated dynamic systems analysis, not only can the subjective differences in human preferences be incorporated, but also the contributions of these preferences to the long-term likelihood of persistence and prevalence of both ecosystem and human economic subsystems can be estimated in terms of emergy acquisition and use. Furthermore, such dynamic analysis permits assessment of adaptation to fluctuating emergy inputs and the consequences of external or internal patterns of pulsing (i.e., emergy storage and release) that would not be possible through a static analysis.

6.2 Exergy

Exergy (in the sense in which this term has typically been used by systems ecologists) is a measure of the thermodynamic potential of an ecosystem with respect to a system at the same temperature and pressure and with the same elemental composition but in a state of thermodynamic equilibrium. This potential includes both the maximum work that could be acquired (through an entropy-free transfer of energy) from the ecosystem as it attained this equilibrium state and an estimate of the enhanced capacity for capturing or degrading a flow of available energy provided by low-probability structures maintained within the ecosystem. The first component of this potential (the maximum attainable work) has been estimated as the chemical potential of the organic matter in an ecosystem relative to that in the equilibrated system (i.e., using $-\Delta G_{org}$, the Gibbs free energy released by a unit of this organic matter—or of a representative combination of carbohydrates, fats, and proteins—upon complete oxidation).

There is no consensus on how (or in reference to what flow or process) the second component or capacity might be calculated, but the inclusion of this component reflects the aforementioned understanding that different forms of (available) energy can have very different capacities to affect ecosystem organization and function. One approach, which was proposed by S. E. Jorgensen, hypothesizes that the capacity of living organisms to increase the available energy capture by an ecosystem is positively correlated with the number of genes that they possess. The corresponding exergy contribution of an ecosystem compartment is then approximated based on the probability of producing the amino acid sequences coded by the DNA of the organisms in that compartment. The relevant compartments are selected by the ecosystem analyst based on their importance in maintaining or altering the thermodynamic gradients associated with the ecosystem. These probabilities are computed under two simplifying conditions: (1) the 20 amino acids used by organisms are all equally likely to appear at any point in the sequence and (2) each gene codes for a sequence of 700 amino acids. Given a typical number of genes possessed by the organisms within a compartment equal to n, the approximation for this probability is thus $20^{-700 \cdot n}$, and the corresponding exergy contribution is defined as $-R \cdot T \cdot c_i \ln 20^{-700 \cdot n}$, where R is the universal gas constant, T is the absolute temperature, and c_i is the concentration (e.g., in g/L of an aquatic system), of carbon, for instance, in compartment i. The total exergy of an ecosystem with M organic compartments, as estimated using Jorgensen's formulation, can thus be expressed as

$$Ex = -\Delta G_{org} \cdot c_{org} + R \cdot T \cdot \sum_{i=1}^{M} c_i \cdot \ln 20^{700 \cdot n_i},$$

where c_{org} is the total concentration (of the chemical element or species of interest) in all organic compartments of the ecosystem (and ΔG_{org} is in J/unit of this element or species in the organic matter).

Due to the first term in this formula, exergy is highly sensitive to changes in available energy capture. Changes in structure related to shifts in species composition affect the second term, although a substantial shift in composition will not affect exergy if the number of genes and concentrations in the new taxa are similar to those in the former taxa. Furthermore, the sensitivity of an exergy index to important changes in ecosystem structure depends on the success of the analyst in selecting those compartments that are most closely related to these changes. The preceding formula is offered only as an approximation that provides one index for the assessment of the relative health of similarly analyzed ecosystems or of the relative effects of changes in an ecosystem or its environment on the health of that ecosystem.

Ecosystem resilience is not captured in any direct manner by the formula, but modeling studies have indicated a relation between exergy and the resistance of ecosystem state variables to perturbations. On average, resistance increases with increasing exergy, but exergy does not provide specific information on the resistance and resilience of critical ecosystem functions with respect to potential changes in particular forcing functions. The structural exergy, or that component of total exergy contributed by the internal structure of the ecosystem, rather than by its size, is more specifically sensitive to changes in diversity that are likely to affect ecosystem health. This index can be calculated as $Ex/(R \cdot T \cdot c_{tot})$, where c_{tot} is the total concentration of the element or species of interest in all compartments of the ecosystem. Increases in diversity will tend to increase the structural component of exergy if these diversity increases reflect a fuller utilization of resources within the ecosystem through the realization of additional potential niches.

6.3 Ascendency

Ascendency (an index proposed by R. E. Ulanowicz) is a summary measure of system activity derived from the network of flows associated with that activity, in which each flow is associated with a source compartment and a destination compartment within the system or its surroundings. As such it integrates a measure of the total flux through the system with an estimate of the extent to which the diversity of the fluxes among the respective compartments is organized by preferential paths of flow. (While the relevant compartments within the system must be determined by the ecosystem analyst, all flows from the system are assigned to one of two external compartments [i.e., either export or dissipation], and all flows into the system are assigned to a single import compartment.) When the flows are measured in units of available energy, the total flux through the system (T) is the sum of all available energy fluxes among all the compartments. As such T reflects the vigor of an ecosystem's processing of available energy and thus its capacity for growth and self-renewal under the prevailing conditions at the time of its measurement.

The (Shannon-Weiner) diversity of these fluxes, when multiplied by T, is suggested as an indicator of the total capacity (C) for organizational development. In other words, the number of compartments, evenness of flux among compartments (at any given scale of compartment aggregation), and T all correlate positively with the capacity for organization of flows within a system. In this context, organization refers to the statistical dependence of the destinations and sources of the flows in a network. Thus, in a system with no network organization, the likelihood of a flow of available energy being directed to any given compartment would be independent of which compartment supplied the flow. Because optimal ecosystem health requires that the flow of available energy be selectively directed to its most efficient and productive processes of maintenance, repair, and increase, optimal health will coincide with an optimal organizational development in the sense indicated here, particularly if the selection of compartments by the analyst reflects the intrinsic division of viability-sustaining functions among the ecosystem's critical processes.

The extent to which flow destination is independent of (or unconditioned by) flow source can be expressed as a function of the conditional influx probabilities of the compartments. The conditional probability of flow to compartment j given that the source of this flow is compartment i is estimated as the flux from i to j divided by the total flux from i ($f_{ij}/f_{i\cdot}$). The conditional probability of flow from compartment i given that the destination of this flow is compartment j is similarly estimated as the flux from i to j divided by the total flux to j ($f_{ij}/f_{\cdot j}$). These terms are then used in the formula

$$O = -\sum_{i,j} f_{ij} \cdot \log_2\left(\frac{f_{ij}}{f_{i\cdot}} \cdot \frac{f_{ij}}{f_{\cdot j}}\right) \quad \text{for } i,\ j = 1 \text{ to } N,$$

where O (the system overhead) is the product of T and a measure of the independence of destinations and sources that has a maximum value equal to the $\log_2$ Shannon diversity of fluxes within an unorganized network, and N is the total number of compartments. Thus, O attains its (theoretical) maximum value of C in a network in which destinations are completely independent of sources. It attains its minimum value of 0 in a network (with all flows supported by a single import compartment) in which flow destination is completely determined by flow source (i.e., in which knowing the source of a flow removes all uncertainty as to its destination). Accordingly, ascendency ($C - O$) is an indicator of the organization of flows within the network scaled by the total flux through the network. Increases in vigor, in evenness among the total fluxes to (or from) a network's compartments, and in the selective direction of available energy in the network all contribute to a higher ascendency. Increases in the number and evenness of the influxes to each compartment, on the other hand, decrease ascendency while increasing O.

Maximum ascendency requires complete determination of flow destination by flow source, which occurs when flow from each compartment is directed exclusively to a single destination compartment. All ecosystem compartments and processes (maintained as they are away from thermodynamic equilibrium) must contribute some flow to the dissipation compartment, however, in addition to whatever flow they contribute to any other compartments that they support. Thus, this theoretical maximum is not attained. Furthermore, although the direction of all flow from each compartment to a single process might be compatible with maximum long-term efficiency and productivity—and thus with peak ecosystem health—in the absence of any environmental variability, optimal health must be achieved under conditions of varying environmental provision, stress, subsidy, and

disturbance. Thus, the ascendency attained at optimal health reflects the maintenance of the diversity of flows required to persist and thrive under this environmental variability.

Due to uncertainty with respect to the optimal balance between immediate gains in vigor through selective reinforcement of the most productive flows and the maintenance of other flows that might be critical to vigor or viability under possible or likely future conditions, no precise value for optimal ascendency is suggested. It might be possible instead to establish ranges in ascendency typically maintained by persistently thriving ecosystems within given environments and energy regimes. Alternatively, it might be necessary for ascendency to be used in conjunction with *O* (or with *O* and *T*) in the assessment of ecosystem health. In a plot of ascendency versus *O* for a given class of ecosystems, for instance, a region typical of persistently thriving ecosystems might be identifiable. Although ascendency is sensitive to all of the components of ecosystem health discussed previously, further empirical investigation is required to determine whether sufficient information is retained by this summary measure (if used alone) to provide an accurate or useful indication of ecosystem health. Of the three related measures, ascendency is most specifically associated with organization selectively reinforced for maximum efficiency and productivity, *T* is most specifically indicative of ecosystem vigor, and *O* of adaptive resiliency. A general use of any of these three measures to indicate health status will require comparison among ecosystems across similar scales and standards of aggregation. A more precise characterization of the optimal balances in the allocation of available energy between the most productive flows and potentially critical alternatives under a relevant range of energy and disturbance (or stress) regimes will also be needed.

Glossary

biogeochemical Pertaining to the abundance and movements of chemical elements or compounds in and between various components of an ecosystem or between ecosystems.

density dependence The situation in which the number of animals or plants at a future time is dependant on the number at an earlier time.

ecosystem A unit of nature, generally from 1 hectare to some thousands of square kilometers, with boundaries defined by the investigator, that includes plants, animals, microbes, and the abiotic environment.

endogenous A factor from inside the system that influences the system.

exogenous A factor from outside the system that influences the system.

trophic Pertaining to food.

We may consider ecosystems as machines that have been selected to use solar and occasionally other energies to reorganize the raw materials of the earth into systems that support life. Ecosystems, and their component organisms, use this energy to rearrange the chemical molecules of the earth's surface and of the atmosphere into living tissue according to those patterns that have high survival potential. They are, in this context, antientropic—that is ecosystems (and life in general) work against the tendency for the molecules of the world to degrade into relatively random arrangements. As such they are self-designed, in that their organization has emerged through natural selection for structures that capture, hold on to, and invest energy into further structure in a way that appears to be self-designed) the structure is generated to continue life and enhance over time its ability to capture and use energy). More generally, life is most explicitly nonrandom arrangements of molecules, and all organisms use energy to create and maintain these specific molecular arrangements. But individual organisms cannot survive in isolation because they need the supporting context of other species, the soil or other substrate, the atmosphere or water around them, proper hydrological cycling, and so on. Thus, to our knowledge, ecosystems are the minimum units of sustainable life outside of the laboratory. The proper functioning of the earth's ecosystems is also essential for human beings—for atmospheric and climatic stability; for the production of food, fiber, and clean water; and for physical and psychological well-being.

1. INTRODUCTION

1.1 Early Studies at the Ecosystem Level

Although the English term "ecosystem" was coined in 1935 by Tansley, ecosystems have been the subject of human inquiry for millennia. The first written records that survive include the work of Aristotle, an insightful and knowledgeable natural historian, and especially his student Theophrastus, who was interested in how different species of trees grew in different locations. Of course, practical people living on (or off) the land (fishermen, ranchers, hunters, trappers, many farmers) also knew and know a great deal of a practical nature about how ecosystems operate.

Well before Tansley, the formal scientific study of ecosystems was well developed by Russian and Ukraine scientists in the early part of this century. The serious student of ecosystems should return to the seminal, often brilliant earlier writings of Stanchinskii, Vernadaskii, Morozov, and their colleagues. Vernadsky in particular was interested in how ecosystems, and even the living world as a whole (the Biosphere), functioned. Unfortunately the work, and sometimes even the lives, of these early ecologists was terminated by Stalin and his henchman Lysenko because their view of nature's limits to human endeavors was in opposition to official communist social engineering.

The practical implications of understanding energy flow in ecosystems became obvious to a number of early investigators who often attempted to determine how much food could be harvested from a unit area of land or sea. Stanchinskii, mentioned earlier, attempted to examine the quantitative importance of the flows at each trophic (food) level in an Ukranian grassland. Wells *et al*. examined qualitatively the flow of energy from the sun through the food chain to the herring fisheries of the North Sea as early as 1939. The first study in North America is usually attributed to Raymond Lindeman, who quantified explicitly the flow of energy from the sun through primary producers to higher trophic levels in a bog lake in Minnesota. Lindeman generated most of his numbers from preexisting information but was extremely creative in organizing the organisms of an ecosystem as trophic (or food) levels, rather than simply by species. Although Lindeman made some errors (for example, by subtracting predation after estimating production from turnover rate), his work remains extremely important for our conceptualization of how energy flows through nature.

An especially important group of studies on the eneregetics of ecosystems were done by Eugene and especially Howard Odum. The brothers worked together measuring photosynthesis in a coral reef at Eniwetok. The most important of these studies was done by Howard on the ecosystem at Silver Springs, Florida. The particular advantage of this site was that the water flowing out of the main spring boil was always at a constant oxygen concentration, so that the deviation of the oxygen content of water downstream (higher during the day, lower at night) could be used to estimate photosynthesis and respiration of the entire ecosystem. Odum also measured explicitly the energy fixed or used by each trophic level by, for example, putting fish into cages and measuring their growth. Odum found that by far the largest proportion of the energy captured at a given trophic level was utilized by that trophic level for its own maintenance respiration, which was consequently unavailable to higher trophic levels. Lindeman had introduced the concept of trophic efficiency, defined as the ratio of production at one trophic level to production at the next. Trophic efficiency is commonly from 10 to 20% but occasionally may be very different. The concept is important and familiar in agriculture where beef or fish production per hectare is much less than the production of plants of that same area, due principally to the large maintenance respiration of both the plants and animals. Both Howard and Eugene Odum continued basic research on the relation of energy to ecosystem structure and function into the new millennia in astonishingly long and illustrative career in research and graduate training.

Research has emphasized that most trophic relations occur not as simple straight-line chains but as more complicated food webs, in which a given species and even different life stages of that species eat from different trophic levels. For example, a herring whose diet contained 50% algae and 50% herbivorous crustaceans would be assigned to trophic level 2.5. Many, perhaps most, organisms are omnivores rather than strictly herbivores or carnivores, and probably the majority eat dead rather than live food. The single most important attributes of food quality, other than its energy content, is its protein content, which is approximately proportional to the ratio of nitrogen to carbon in the food (Table I).

1.2 Ecosystems versus Species-Oriented Ecology

During this time something of a gulf developed between ecosystem-level ecologists and many other ecologists. This was due in part to the perception by

some that ecosystem ecologists were paying insufficient attention to the basic laws and mechanisms of nature, including natural selection, that had been especially well developed by biologists at the individual and population level. Some ecosystem-oriented papers appeared to these ecologists to be almost mystical in their message that the system knows best. On the other hand, ecosystem-level ecologists could point to the failure of population dynamics to do a good job in prediction and management of fisheries, in large part because the population-level ecologists tended to ignore spatial and interannual variations in the ecosystem productivity that often determined year class strength. As part of this debate throughout the literature of ecology, there has been considerable discussion and even tension about the relative importance of exogenous (meaning external to the system, such as climate variability, another phrase meaning the same thing is forcing function) controls versus endogenous (meaning internal to the system, such as density dependent survival) controls for determining the structure and function of ecosystems. To some degree the argument is specious, for obviously both are important, although the endogenous aspects have been overly emphasized. Clearly, as described here, climate (an exogenous factor) is critical in determining the basic possibilities for life, and evolution (basically an endogenous factor) is important in determining the response of living creatures in a region to the climate.

Part of the problem leading to this dichotomy was the seemingly completely disparate perceptions of the different groups on what was the important currency of ecology. Energy was perceived as the currency of the ecosystem-level ecologists, and fitness (reproductive potential over time that includes the abilities to both survive and reproduce) was seen as the currency of the population-level ecologists, and each group tended to dismiss, argue against, or ignore the perspectives of the other. These were spurious arguments, and although many previous papers hinted at the importance of energy for fitness, this has been especially well done in papers such as that by Thomas *et al*. titled "Energetic and Fitness Costs of Mismatching Resource Supply and Demand in Seasonally Breeding Birds." This is one of the best papers in ecology, and there is more good science packed into the two-and-one-half pages of this paper than in many books. Simple observations and measurements, and double labeled isotopes, were used to examine energy costs and energy gains of various populations of European tits (chickadees). Those birds that timed their migrations and reproductions appropriately to the availability of their preferred high-energy food (caterpillars, in turn dependent on the phenology of their oak-leaf food source) were much more fit in the evolutionary sense. That is, birds with optimal timing were much more successful at raising more and larger (and hence more likely to survive) offspring and were themselves more likely to survive and reproduce again the next year. Birds that timed their reproduction inappropriately relative to the caterpillar dynamics worked themselves into a frazzle trying to feed their less successful offspring. Finally Thomas *et al*. found that climate change was interfering with past successful timings because the birds were tending to arrive too late, since the phenology of the trees was responding more quickly to temperature increases than was the impetus for the birds to migrate. Presumably birds that had genetically determined behavioral patterns that were getting them on the breeding grounds too early in the past would be selected for if and as the climate continued to become warmer. This study also indicates the importance of the quality of energy. In this case, it was not simply total trophic energy available to the birds that was critical but also their quality as represented in their concentration as large food packages, showing again the importance of energy quality as well as quantity.

The paper by Thomas *et al*. shows elegantly and more explicitly than earlier studies what many suspected for a long time: probably the principal contributor to fitness is the net energy balance of an organism. The idea that energy costs and gains are related directly to fitness is not a new one, found, for example, as Cushing's match/mismatch hypothesis in fisheries, which in turn is a restatement of Hjort's 1914 paper about year class abundance in Scandinavian cod. Energetics, combined with climatic and other external forcing, can explain population dynamics much more powerfully than the density dependant population equations that still seem to dominate much of population ecology. Clearly density dependence exists. But how often is it the principal determinant of population year class strength? Perhaps the best way to consider the importance of density dependence is what Donald Strong calls density-vague relations—that is the empirical information shows that density dependence works sometimes but does not operate importantly every year. The way that we have set up many of our experiments in ecology virtually guarantees that we will find some density dependence even when it is not dominant.

1.3 General Principles of Energy for Ecosystems

Some general principles about energetics that have emerged from all of these studies are that (1) the world of nature is (of course) as beholden to the laws of thermodynamics as any other system; (2) ecosystems can be considered the products of self design—that is, given the environmental circumstances where they are found they "create" through natural selection (operating at various levels, from genes to organisms to species to coevolved groups of organisms) the systems that we see today; (3) virtually every ecological or even biological action or interaction has an important or even dominant energy component; (4) ecological efficiency, or transfer from one place to another, is low, from one or two to a few tens of a percent, principally because of the need for each level of a food chain to support its own maintenance metabolism; (5) each organism is an energy integrator that integrates through growth and reproductive output (i.e., fitness) all energy costs and gains; and (6) each specific organism is adapted to its own biophysical environment in a way that maximizes this difference between energy costs and gains. As a consequence, the collective energy captured and used by that ecosytem is thought to be maximized; (7) species are ways of packaging morphologies, physiologies, and behaviors that allow sufficient, or even maximum, reproductive output as a consequence of having more or less optimal patterns for that given environment. The ecosystems that have survived over time are thought by many to be maximizing the power (by operating at intermediate, not maximum, efficiency) obtainable under the existing physical circumstances.

More recent research on ecosystems and energetics (i.e., since about 1980) has focused on increasingly detailed examinations of the role and activity of particular species, a greater understanding of the factors that control ecosystems, the importance of disturbance, and recovery from disturbance and the role of microbial components in decomposition and regulation. An important component of this has been the 20 or so LTER (long-term ecological research) centers where basic studies are carried out for long time periods to see how, for example, ecosystem components respond to climate variability, long-term exclusion of herbivores, and so on. This approach has allowed the comparison of the basic patterns of ecosystem.

2. ENERGY AND THE STRUCTURE OF ECOSYSTEMS

Neither ecosystems nor their component species can exist without a constant supply of energy to maintain the biotic structures and their functions. The source of this energy is in almost all cases the sun. Clearly the sun runs the energy, carbon, and nitrogen fixation of green plants. Less obviously the sun does many other things for ecosystems: most important it evaporates and lifts water from the ocean and delivers it to continental ecosystems, replenishes carbon dioxide and other gases through winds, pumps water and associated minerals from the roots to the leaves via transpiration, provides nutrients through weathering, and so on.

Ecosystem studies tend to be different from much of the rest of ecology, and indeed science in general, in their emphasis on interdisciplinary and interactive studies. In most other subareas of science, including ecology, the emphasis is on understanding a specific phenomenon and on carefully controlled studies under exacting laboratory conditions. In contrast, when studying ecosystems it is generally necessary to consider aspects of physics, chemistry, geology, meteorology, hydrology, and biology, and in many cases some of the social sciences as well. Since it is impossible to replicate and control all of these factors carefully, as would be the case in the laboratory, ecosystem studies are more likely to be based on observation or correlation than experimental approaches. In these senses and in others, ecosystem science tends to be holistic—that is, it emphasizes the entirety of both a system and a problem rather than just some aspect, and it frequently uses the conceptual tools of systems analysis. For example, if we are to understand the relation between a particular ecosystem and the atmosphere, we obviously must consider the physics of the response of organisms to temperature, the chemistry of the relation of carbon exchange between plants and the atmosphere, the possible effects of changing climate on hydrology and hence the availability of the water needed for the plant to grow, the movement of gases through the atmosphere, and the social factors that are causing the carbon in the atmosphere to increase. In addition, we often need special integrative tools that are outside the traditional scientific disciplines that allow us to examine all or many of these factors in interaction. These tools include quantitative flow diagramming, computer simulation, and theories that are transcomponent.

Such a holistic, or, more accurately, systems perspective is increasingly important as human

impacts are changing many aspects of the earth rapidly. Such a perspective does not obviate other approaches to science; in fact, it tries to incorporate and integrate as possible all relevant levels and techniques of analysis. The problems that the increasing human population and its growing affluence are putting on the world require a whole different approach to science—one that is difficult if not impossible to do in the laboratory. Nevertheless it must adhere to the same basic standards as the rest of science in that the results of the science must make predictions that are consistent with the real world. This can lead to certain problems when scientists concerned with the destruction of ecosystems and their species are faced with attempting to apply their results to saving nature. The science of ecology is full of generalizations about the supposed virtues of undisturbed nature that have led to theories such as diversity and stability, diversity and productivity, and the intermediate disturbance hypothesis whose validity seems to wax and wane with each new study. Separating the robust ecological theory that will help with the genuine environmental crises we face from the good sounding but poorly extrapolateable theories has often been a difficult feat.

3. ORIGIN AND APPROACH OF ECOSYSTEM STUDIES

The word ecosystem is a combination of the words "ecology" and "system." The word ecology is derived from the Greek word *Oikos,* which means pertaining to the household, especially to the management of the household. The academic discipline of ecology refers to the study, interpretation, and management of our larger household, including that of the planet that supports our species and that provides the basis for our economy. System refers to all of the (or all of the important) components of whatever is being considered and the pathways and rules of interaction among the components. Thus, ecological system, or ecosystem, refers to the structure and function of the components that make up household earth and the interactions among those components.

Ecosystems generally are considered from the perspective of their structure, that is their composition and changes in structure (in terms of geological land forms, number, diversity, and abundances of species, biomass, height of vegetation, abundance of critical nutrients, etc.), their function, that is the pathways and rates of energy and nutrient flows, and the regulatory or control processes that govern those changes and flows. We might also want to ask many other kinds of questions about, for example, the diversity of the species that live there or how that diversity effects the function of the ecosystem. Ecosystem structure and function are related over evolutionary time. For example, tall trees functionally need to supply water and nutrients to growing leaf tips, which in the case of the rain forest might be 60 m above the ground. Consequently they have evolved elaborate structures, including a system of pipes, to pump the water to those growing tips. This in turn is possible only where the soil is generally wet and the air is dry, at least periodically.

An extremely useful basic assessment of the most important attributes of ecosystems is found in the classic paper "Relationships between Structure and Function in the Ecosystem" by E. P. Odum. Odum compared the basic attributes of an evergreen forest (such as might be found in the Southeastern United States) and a deep ocean ecosystem (such as might be found a few hundred kilometers to the west of that peninsula). Odum found that these ecosystems are very different in their physical structure—that is the physical characteristics of the ecosystem itself. The organisms themselves constitute the major physical structure in the rain forest. It is possible for the plants to be large here because the soil allows for an anchoring place for the tree, the climate is near optimal for plant growth, and there are no large grazing animals that can eat the tree. Therefore the trees can become very large and become themselves the principal determinant of the physical structure of the ecosystem.

In the ocean, by comparison, the lack of a firm substrate and the constantly changing position of a parcel of water makes it impossible for the organisms to change the nature of the physical medium (the water) significantly, and it is the water itself that forms the basic structure of the ecosystem. Since the organisms are constantly sinking or being swept away by turbulence, they must be small and be able to reproduce rapidly. The total biomass, or living weight, of the aquatic organisms is very small compared to that of the forest. Also, interestingly, the grazers (or animals that eat the plant) have nearly the same biomass as the algae in the water but are much less, as a proportion, in the forest.

One of the most interesting observations when comparing these two ecosystems is that although the biomass of the plants is thousands of times greater in the forest, the rates at which the plants capture the sun's energy (their primary productivity) is much more similar, especially in coastal areas (Table II). In

fact, given the greatly varying quantity of plant biomass around the world, most ecosystems have broadly similar rates of production, at least if there is enough water. Thus, we can say that the structure appears much more variable than the function, at least with respect to these particular attributes.

From an energy perspective, we know that the structure of an ecosystem is costly to build and costly to maintain. "Good" structure—that is structure that has been selected for—will be well worth it energetically for it will draw maximum power (i.e., useful energy sequestered per time) given the environmental possibilities, and it will become more abundant than those components that draw less power. Hence, structure and function, and the controls that link them, are intimately and functionally linked through natural selection.

One of the fundamental ideas used to analyze ecosystems is the idea of food chains, which is based on the transfer of energy originally derived from the sun through the biological system. The word "trophic" comes from the Greek word meaning food, and the study of feeding relations among organisms is called trophic analysis. More specifically, the study of trophic dynamics emphasizes the rates and quantities of transfer over time. Trophic processes are the essence of ecosystem processes, for they are the ways that solar energy is passed from the abiotic world to plants and to animals and decomposers, and they allow nonphotosynthetic organisms, including ourselves, to exist. These pathways of food are also a principal way that materials such as nutrients are passed from one location to another within an ecosystem. Trophic studies are an important component of ecology because trophic processes determine energy availability and hence what is and what is not possible for a given organism, and for all organisms collectively, within an ecosystem. In addition, many management concepts and objectives important to people, such as those relating to harvesting fish, timber, or crops, are oriented toward understanding and directing the trophic relations of nature. Energy is stored for a short time in the ecosystem in the biomass of the various organisms, soil, and so on, and some of this energy is transferred from one trophic level to the next (Fig. 1). For example, some of the free energy captured by the plants is eaten by heterotrophs, although a larger part is used by the plant itself. Thus, most of the energy once captured is lost from each trophic level as waste heat as organisms use that energy to fight entropy. Eventually, all the energy originally captured by autotrophs is degraded and returned to the surrounding environment as waste heat. Ecosystems do not recycle energy; instead, they capture a small percentage of the solar energy that falls on them, concentrate it, use it to do work, and then return it to the environment in the form of low-grade heat that is no longer available to do work. The principal work that has been done is the maintenance of life, and this has required energy to sequester and rearrange chemicals, overcome gravity, move either themselves (animals) or their chemical constitutes (plants and animals), generate microclimates, maintain general homeostasis, and then replicate the whole structure and functions through reproduction.

There is constant selective pressure operating on organisms to maximize the useful energy that they capture and to use it in ways that contribute to their survival and to propel their genes into the future. Many think that this process leads to the collective maximization of power at the level of the ecosystem—that is, those organisms and arrangements of nature will be selected for that most fully exploit available energy and use it most effectively compared to alternative organisms or patterns. Obviously this is a difficult idea to test at the level of entire ecosystems and on a scale of human generations, but it does offer intriguing hints that natural selection operates in ways that generate and maintain (or self-organize) entire systems. For example, although it is unlikely that many of the same species were present in the wet montane tropics 300 million years ago as are there now, it is likely that a recognizable

tropical wet forest was there that had similar functions and rates of processes as modern tropical wet forests.

3.1 Trophic Processes in More Detail

The pathway of energy conversion and transfer (the eating of one organism by another) goes from the initial capture of solar energy by autotrophs, to the herbivores that eat plants, to the first-level carnivores (that eat herbivores), on to the top carnivores. The principal pathways within a food chain can be represented as energy transfer through a series of steps. The power flow of an organism per unit area, or of a trophic level, is called productivity and normally is expressed in units of kilocalorie per square meter per time.

3.1.1 Autotrophs

In the first step autotrophs, or green plants, use chlorophyll to capture energy from solar-derived photons and store this energy by restructuring the carbon atoms of carbon dioxide derived from the surrounding atmosphere or water into complex organic compounds. Primary production is the fixation of solar energy by green plants. Gross productivity is total energy captured, whereas net production is that minus the energy required for respiration. Net energy is then allocated into tissue increments, leaf turnover, reproductive products, and, in time and through these processes, the replacement of the first plant with a second. In the second step herbivores or primary consumers obtain energy by eating autotrophs. Secondary production is the accumulation of animal or decomposer living tissue. Heterotrophs obtain metabolically useful energy from the consumption of the organic molecules in the food they obtain from other organisms.

3.1.2 Grazers

Since a substantial amount (perhaps 80 to 90%) of the energy captured by an ecosystem is used by the first trophic level for its own necessary maintenance metabolism, food chains are inherently and necessarily "inefficient." Thus, there is and must be much more production of biomass of deer than wolves or cougar in a forest, for the deer must use a large

portion of the energy in the leaves it eats for its own metabolism rather than for growth; much less is left for their own growth and the potential exploitation by the predators.

3.1.3 Decomposers

The world is covered with living creatures, and these creatures are continuously dying. Yet the world is not littered with carcasses, so obviously they disappear in some way. We call this process decomposition, and it is mediated principally by single-celled organisms, especially bacteria and fungi. In addition, the decomposition process gets a start initially by larger animals, from buzzards to maggots to protozoans, and in earlier days, even our own ancestors. Although humans are often disgusted by decomposition (and, in fact, have probably been selected for this quality), without decomposition the biological world would come to a stop, as all of the earth's available materials would be tied up in various carcasses!

Some food chains are complicated indeed. Think of a salmon feeding on the plankton of the mid-Pacific ocean and then swimming far up an Alaskan river, fueled by energy reserves built on this plankton, to spawn and die—or to be eaten by a bear. The offspring of the salmon that did spawn spend their first year of life in the freshwater environment, eating zooplankton that ate phytoplankton whose growth was fertilized by phosphorus leaching from the bones of the dead parents. Another way that food chains are complicated is that much of the energy flows not through live but through dead organisms. For example, in the rain forest most of the plant material is not eaten directly by live leaf munchers but instead by various insects and other small organisms that consume the dead leaf material called detritus.

3.2 Trophic Dynamics and Biomass Pyramids

Thus, of all the energy captured by green plants, progressively less and less flows to the next consumer, or, as it is often called, trophic level. When the rate of flow of energy is graphed, it nearly always will look like a pyramid, with the large base representing the energy captured by the autotrophs and each successive layer representing higher trophic levels, each further removed from the base (Fig. 2). This is called the pyramid of energy. Biomass plotted by trophic level may look like this but often looks more like a square than a pyramid. How can this be? The reason is that larger organisms often found in higher trophic levels generally respire (use up) energy more slowly; in a sense they get less energy, but they hold on to what they do get for a longer time. So in the ocean there is roughly the same biomass of algae, zooplankton, small fish, and large fish. The reason is that the small algae "turn over" much faster, meaning that they have a much higher rate of metabolism and loss to other organisms that eat them.

4. BIOGEOCHEMICAL CYCLES

A second critical area for the study and understanding of ecosystems is the structure and function of nutrient cycles. Nutrients can mean all of the chemical elements that an organism or an ecosystem needs to grow and function, but most commonly the term is restricted to a consideration of nitrogen, phosphorus, potassium, and less commonly calcium, sulfur, iron, and micronutrients such as copper, cobalt, and molybdenum. Sometimes, but not generally, CO_2 is considered a nutrient, for it too can limit growth of plants. Finally, it also (rarely) can mean complex organic materials necessary for growth, such as vitamins. We refer to the movement of a particular nutrient through an ecosystem, often changing from one form to another, as a nutrient cycle. Nutrient cycling, like all other processes, occurs because of energy forces including evaporation, precipitation, erosion, photosynthesis, herbivory decomposition, and so on, all run by the sun.

4.1 Limiting Nutrients

The study of nutrients in ecosystems was first undertaken systematically by the German chemist Liebig, who found that the growth of plants tended to be limited by only one element at a time. For example, if a plant had insufficient phosphorus relative to its needs, its growth would stop until phosphorus was added. At some point adding more phosphorus had no further effects, but at that time some other element, perhaps potassium, might be limiting the plant's growth, as could be determined by noting the growth response, or lack thereof, of adding potassium. This led to the formulation of Liebig's law of nutrient limitation, which states that the growth of plants tends to be limited by a single nutrient at any one time, that which is least abundant or available relative to the needs of the plant. Nutrient cycles at the global level were initiated by Vernadsky and greatly encouraged by the growth of atomic energy in the 1950s, which provided radioactive tracers that helped follow nutrient pathways, funding to do that research, and also a reason as to why we might be concerned about them—that is, if there were releases of radioactive elements into the environment.

Nitrogen is especially important because plants need it in large quantities and it is often restricted in its availability and energetically expensive to get into a useful form. Plants and animals use nitrogen extensively because it is, after carbon, the most important component of proteins. Plants extract it from the soil, and animals get it by eating plants or other animals. All organisms must concentrate the normally relatively rare nitrogen to get enough to build their proteins. Waste nitrogen is released from animals as ammonia or other compounds in their urine. Since N_2, ammonia, and nitrous oxide are volatile, nitrogen is different from most other nutrients in having a gaseous phase.

The cycle of nitrogen in ecosystems is also complicated because nitrogen is a useful and versatile atom with a valence state that allows for many complex interactions with other atoms. All organisms use nitrogen to make proteins. Some use ammonia as a fuel to gain energy. Others use nitrate for an electron receptor in the same way that humans use oxygen. Still others invest energy to take it out of the atmosphere for their own use. Even though nitrogen is presently about 80% of the atmosphere, plants cannot use it in this form, only after it is fixed (i.e., incorporated as nitrate or ammonia). In nature, this can be done only by the bacteria and blue-green algae. Thus, all members of all ecosystems are dependant on these two types of life for their nitrogen, or at least they were until about 1915, when humans learned how to fix nitrogen industrially through the Haber-Bosch process.

Evolution has found phosphorus to be an especially useful element, and hence it has a particular importance in ecosystems. Phosphorus is used by all organisms for their genetic material (DNA and RNA) and for energy-storage compounds (ATP), and in vertebrates for teeth and bones. It seems to be in a rather peculiar short supply in the world's biogeochemical cycles relative to the importance given it by evolution. Phosphorus tends to be especially limiting for the growth of plants in freshwater, and even where abundant it may be held very tightly by soils so as to be virtually unobtainable by plants. Phosphorus cycles rapidly between plants and the environment and is passed along food chains as one organism eats another (Fig. 3). When organisms die, they decompose, and we say that the nutrients such as phosphorus are mineralized (returned to their nonliving state). Phosphorus is easily dissolved in water, and in many respects the cycle of phosphorus at the ecosystem level is the cycle of water.

4.2 Redfield Ratios

It is not only the abundance of each nutrient that is important, but also their concentration relative to each other. The importance of this idea was first worked out by the oceanographer Alfred Redfield, who sailed around the world's seas on the first oceanographic ship, the *Challenger*, meanwhile taking samples of the oceans and its various life forms. Redfield's chemical analysis was a rather difficult undertaking, since the surface of most of the earth's seas are low in nutrients because the constant sinking of organisms and their feces tends to deplete nutrients in the surface of the sea. Nevertheless, Redfield was rather astonished to find that both the sea and the small plants of the sea had nearly constant ratios of nitrogen to phosphorus, about 15 atoms of nitrogen for each one of phosphorus, in both the living and the nonliving environments. Since we know that aquatic plants need roughly 15 atoms of N for each one of P, then we can determine whether the environment is N or P limited by whether it has more or less than this ratio. If the water is 20 to 1 it is likely to be P limited, and if it is 10 to 1 it is likely to be N limited. Likewise agricultural extension agents can analyze different soils and determine which nutrient is limiting, saving

the expense and environmental problems of pouring on unneeded nutrients.

5. STABILITY AND DISTURBANCE

A question that has intrigued many ecologists is the degree to which ecosystems are stable—that is relatively homeostatic or self-correcting. It seems to many early investigators that natural ecosystems tended to have self-correcting properties, so if they were disturbed they would bounce back toward their original conditions.

5.1 Succession

Hence earlier ecological studies tended to emphasized the equilibrium nature of ecosystems. The idea was that there was a strong tendency for ecosystems to "evolve" toward a "climax" state determined by the climatic conditions of the site. In this view, succession was an orderly process that would bring the system back to climax, a condition of stability with no more species change. Climax was considered the normal state of ecosystems, and considerable virtue was associated with this process, a sort of "mother nature knows best." The view is evolving that ecosystems are continuously subjected to disturbance, and are continuously responding in various ways to the various disturbances they are subject to. For example, tropical ecosystems were once thought particularly unchanging. Research has shown that many tropical forested ecosystems are continuously in disequilibrium—that is, recovering in some way from some externally imposed stress or pulse, such as a hurricane, a landslide, a drought or, locally, a tree fall.

5.2 The Role of Species Diversity

An unresolved issue in ecology is to what degree all of the different species found in an ecosystem are required for it's proper functioning. Twenty-five years ago, the idea that diversity (of species) and stability (of populations and ecosystems) were positively connected was very popular. At this time, the best that we can say is that certainly an ecosystem needs many species to function properly and that through coevolution many species are tightly linked to each other. But we do no know in a general sense whether ecosystems *need* all, or even most, of the plethora of species that are found there in order to continue their basic structure and function. At the same time, we are finding an increasing number of examples where animals once thought rather superfluous with respect to ecosystem function are in fact critical for some important function such as distributing or germinating the seeds of a dominant

plant. Species that have a disproportionate effect on the entire ecosystem are called Keystone species. An example is the sea otter of California-to-Alaska coastal waters, which maintains kelp beds by eating sea urchins that would other wise overgraze the kelp. Additionally we are understanding better that ecosystems themselves can be much more resilient than many of their component species, since if one species is knocked out, another (although perhaps one less desirable from a human perspective) can sometimes take over that function. This is an important question as all over the world humans are reducing the diversity of ecosystems, and they are especially impacting the large animals.

5.3 Disturbance

An important aspect of ecosystems that we have learned is that although we once thought of ecosystems as, generally, stable and focused on the tendency toward equilibrium that occurred through the process of succession, we now view ecosystems as much more transient phenomena, generally subject to, and responding to, external forces, which we normally term disturbances. For example, graduate students are often taught that tropical forests were "stable," due principally to a lack of winter and glacial-cycle impacts. In reality, many tropical forests, for example the Luquillo experimental forest in Puerto Rico, are routinely subject to three type of natural disturbances: tree falls, landslides, and hurricanes, so that the forest is almost always responding to, or recovering from, disturbances.

Some important nutrient cycling studies were done at the U.S. Forest Service experimental watersheds at Hubbard Brook, New Hampshire. Here entire watersheds were cut, and vegetation regrowth suppressed, to examine the role of the vegetation in determining nutrient retention by ecosystems (it was substantial). Even so, the scientists there also found that long-term trends in rainfall intensity were equally important in determining the nature of the ecosystem. In other words, even in a relatively undisturbed forest there was a large amount of what we might call disturbance introduced simply by the normal decade-scale cycles of drought and flood, and this greatly interfered with the evolution of the ecosystem toward what we might have once called mature. Thus, at the level of the ecosystem it is clear that both endogenous and exogenous factors are important in determining the structure of the ecosystems and the nature of nutrient movements.

5.4 The Role of Human Disturbance

We previously discussed the importance of natural disturbance in determining the structure and function of existing ecosystems. Unfortunately, often it has been frustratingly difficult to unravel the impact of natural factors on ecosystem structure and function because almost all ecosystems of the world have been heavily impacted by prior human activity. For example, it was widely believed that New England forests were in some kind of pristine condition prior to the American Revolution, or even prior to European colonization. Instead we now know that the New England landscape had been modified severely by the activity of both Native Americans and very early colonists.

Likewise Perlin has documented the intensive deforestation that has taken place in virtually all portions of the world over the past thousands of years due to human activities. The basic cycle, repeated over and over again, has been that initially human settlers had relatively little impact on the forested lands except to clear small areas for agriculture. Often this land was abandoned after fertility declined and a new patch cut while earlier patches reverted to forests. This was not too different from the patterns of natural disturbance. But then, characteristically, some metal was discovered. Huge areas of forests were cut to provide the charcoal to smelt the metal, and the net effect was extensive deforestation. Subsequently there tended to be an increase of agricultural production on these newly cleared and fertile lands, followed by large human population increases, and then substantial soil erosion, river and harbor sedimentation, and eventual agricultural and population collapse. For example, ancient Greece was deforested 4000 years ago and then recovered, only to be again deforested, recover, and be deforested again in relatively modern times. The use of chemical fertilizers has allowed agriculture to be maintained over a longer time period, so that the land is not abandoned to reforestation. Curiously, some few parts of the world, notably the Eastern United States and Western Europe, are now undergoing reforestation because the exploitation of fossil fuels has allowed the forests a respite, albeit perhaps only temporarily.

There are other ways in which people have and continue to impact natural ecosystems. Humans have changed the relative abundance of species through the introduction of new species and through the exploitation of natural populations. For example, the introduction of goats into the Canary Islands 800 years ago

resulted in wholesale destruction of the natural vegetation, and the unique flora and fauna of islands such as the Galapagos and Hawaii are being changed dramatically by human-caused introductions, many of them centuries old. Curiously the flora and fauna of the island of Puerto Rico seem to be much less impacted by invasive species, and when the vegetation is allowed to recover from human disturbance, native species predominate.

One consequence of all of this is that it is difficult for ecologists to measure what is "natural" in nature, for almost all nature that we have had an opportunity to observe is already quite different from what might have existed some tens of thousands of years ago. Meanwhile, climate change, at both a local and global level, are impacting all organisms in every ecosystem, subjecting them to different temperature and rainfall regimes and to different carbon and nitrogen levels than those within which the organisms evolved. We are learning that ecosystems can adapt surprisingly well to at least some of these changes, but we do not know how long this will continue into the future.

6. THE FUTURE OF ECOSYSTEMS

The natural ecosystems of the earth are tremendously and increasingly impacted by human activities. For example, Vitousek and his colleagues have estimated that fully 40% of the earth's primary production is directly or indirectly exploited by our own species, and others believe this proportion is higher. This is remarkable considering that we are but one of millions of species on this planet, and that about two-thirds of the planet is water and as such is difficult for humans to access. People are probably not doing anything conceptually different from other organisms in nature, which also tend to eat or otherwise exploit whatever resources are available as much as possible. Natural selection almost certainly has hardwired us for lust and something resembling greed. The difference is that agricultural, medical, and especially fossil fuel technology have allowed people to be enormously more effective at exploiting resources compared to other species, or indeed compared to our earlier selves. At the same time, the earth's ability to check our own population levels through predation and disease has been greatly reduced. The net result is that the human impact has grown enormously.

The consequences of this tremendous rate of exploitation are only beginning to be understood. They are not necessarily bad from the perspective of ecosystems, at least if we measure good and bad in terms of their biomass and productivity. For example, Nemani and his colleagues assessed the impact of changing climates and nutrient cycles on global vegetation and found that there had been a probable increase in productivity of ecosystems in the temperate regions and a decrease in the tropics. But in a conference on the sources and sinks of carbon, Sampson and his colleagues concluded that human activity was turning what had been natural sinks of carbon for most of the world's ecosystems into carbon sources, probably exacerbating the greenhouse effect. Although various scientists argue whether or not human activity has impacted the earth's climate to date, that is not really the issue. We have changed the concentration of carbon dioxide in the atmosphere by only about 40% so far. If civilization continues along its present path, the change could be 500 to 1000%. Thus, natural ecosystems, and the services that they provide, are likely to continue to decrease in area and naturalness, since the human population continues to grow—in fact, to increase more rapidly than ever before—and most of the earth's human citizens have increasing desires for material goods, which can come only from the earth itself. Young people reading this article will almost undoubtedly see a disappearance of most of the world's natural ecosystems during their lifetimes unless there is an extraordinary effort to reduce human impact or unless that occurs involuntarily.

7. CONCLUSION

Ecosystem science got a relatively slow start in America because of an early species-oriented, stamp collecting attitude toward the large, fascinating, and largely unknown diversity of nature in the new world. In addition, there was competition for funding, attention, and prestige from other levels of ecological and biological inquiry, a largely false sense of the power of formal mathematical analysis that came into vogue in ecology, and the fact that ecosystem studies often were expensive. But in the 1950s, ecosystem studies began to prosper, propelled in part by new techniques for studying the energetics of whole aquatic systems and also by curiosity and funding related to how radioactive materials might move through ecosystems if released by accident or war. Important studies of grasslands, forests, and lakes in the 1960s quantified many basic aspects of

ecosystems and began the process of constructing ecosystem models. In the 1970s, an ecosystems approach to watersheds in New Hampshire (Hubbard Brook) and North Carolina (Coweeta) showed how an experimental approach could be used to address many basic aspects of understanding ecosystems, and Howard Odum began his analyses of humans as components of ecosystems. The importance of ecosystems-level studies is becoming more and more obvious, and ecosystem studies have changed from a relatively obscure part of biology to a healthy and vibrant science all of its own. For example, the U.S. Forest Service in the early 1990s changed the entire focus of its management for our national forests from one based on timber yield to one focused on managing the forests as ecosystems. Another important trend is that ecosystem approaches are moving from the temperate latitudes increasingly to other regions, such as the tropics and tundra. One next phase, barely started, is to use ecosystem approaches to study cities and the relation of cities to natural or seminatural systems. Perhaps our understanding of how natural systems have evolved to prosper in the circumstances of relatively limited and stable energy supplies can give us some useful information as humans, presumable, will have to adapt to a more energy-restricted future.

Glossary

alternating current (AC) An electric current that alternates direction at regular intervals.
ampere (A) Unit of electric current. One ampere is a rate of flow of charge equal to 1 C/s ($I = Q/t$).
atom An atom consists of a dense, positively charged nucleus surrounded by a system of electrons equal in number to the number of protons in the nucleus. The atom is bound together by electric forces between the electrons and the nucleus.
atomic number The number of electrons (or protons) in a neutral atom.
coulomb (C) The metric unit of electric charge. In terms of the charge of the electron, the sum of the charges of approximately 6 1/4 billion-billion electrons equals 1 C.
direct current (DC) An electric current for which charges flow in one direction.
electric current Electric charges in motion. The ampere is the measuring unit.
electric field Qualitatively, a region of space in which an electric charge feels a force.
electric force A force between two objects that each have the physical property of charge.
electrical resistance The resistance offered by the structure of a conductor to the flow of electric charges.
hertz (Hz) Unit of frequency equal to one cycle per second. Named for Heinrich Hertz (1857–1894), a German physicist.
kilowatt-hour (kWh) A unit of energy equal to a power of 1 kilowatt (1000 W) acting for 1 h.
magnetic field Qualitatively, a region of space in which the pole of a magnet or a moving charge feels a force.
magnetic field line An imaginary line in a magnetic field along which a tiny compass needle aligns.
nucleus (of an atom) The positively charged central region of an atom. It is composed of neutrons and protons and contains nearly all the mass of the atom.
ohm Unit of electrical resistance. If a potential difference of 1 V across some electrical element causes a current of 1 A, the electrical resistance is 1 ohm ($R = V/I$).
Ohm's law If the electrical resistance of a device (e.g., a toaster element) does not depend on the current in the device, then it is said to obey Ohm's law.
potential difference The work required to move an amount of charge between two positions divided by the strength of the charge ($V = W/Q$). The volt is the measuring unit.
power Rate of doing work. The watt is the metric measuring unit.
transformer An electromagnetic device used to change the strength of an AC voltage.
volt (V) Unit of potential difference. If 1 J of work is required to move 1 C of charge between two positions, the potential difference between the positions is 1 V ($V = W/Q$).
voltage A common expression for potential difference.
watt (W) The metric unit of power. A rate of doing work of 1 J/s is a watt ($P = W/t$).

Electric charge is a property of matter in the same sense that mass is a property of matter. These two properties produce two distinct types of force. Two objects experience a mutual gravitational force because of the property of mass. We see the result of a gravitational force when a pencil is dropped and pulled toward Earth. An electric force is felt by each of two objects possessing the property of charge. Unlike the gravitational force, which always tends to pull masses toward each other, electric forces can tend to pull objects together or push objects apart. If the electric force is attractive, we say the charges acquired by the two objects are unlike. The charges are like when the two objects repel. Two unlike charges are distinguished by calling one positive and the other negative. A toy balloon acquires an electric charge when rubbed on one's hair. The charge on the

balloon is negative. Any charge repelled by the balloon is negative; any charge attracted is positive.

It is easy to relate to the property of mass because mass is a measure of the quantity of matter. Charge is a much more subtle property because we cannot see charge; we see only the results of forces produced by charge.

In 1784, Augustin de Coulomb discovered that the force between two charges labeled q and Q and separated a distance r obeys a law of the form

$$F = k\,\frac{qQ}{r^2}. \tag{1}$$

In the metric system of units charges q and Q are measured in Coulombs (C), r is measured in meters, and the constant k has the value

$$k = 8.99 \times 10^9\,\frac{\text{newton meter}^2}{\text{coulumb}^2}.$$

Electric charge, electric force, and energy associated with the electric force play roles ranging from the structure of atoms to the liberation of energy in either a nuclear-fueled or coal-fired electric power plant.

1. ATOMIC STRUCTURE

The charge acquired by rubbing a balloon as well as electric current in a wire has its roots in atoms, which are the basic structural components of matter. An elementary model of an atom incorporates features of an Earth–satellite system. Electrons are satellites and a nucleus acts like Earth. An electron has a mass of 9.11×10^{-31} kg and a negative charge of -1.60×10^{-19} C. A nucleus is positively charged and is much more massive than an electron. The mass of the nucleus is confined to a volume approximating a sphere of radius of approximately 1×10^{-15} m. The closest electron is approximately 1×10^{-10} m. In perspective, if the radius of the nucleus were approximately the thickness of a dime, the nearest electron would be approximately the length of a football field away. Having both mass and electric charge, electrons and a nucleus experience gravitational and electrical forces that tend to bind the electrons to the nucleus. However, the overwhelming binding is due to the electric force.

In a normal atom, the total negative charge of the electrons balances the positive charge of the nucleus and the atom is said to be electrically neutral. The number of electrons in a neutral atom is called the atomic number, which distinguishes different atomic species. For example, a carbon atom has 6 electrons and an oxygen atom has 8 electrons. Most electrical wires in homes are made of copper. Each atom of copper has 29 electrons. As the atomic number increases, the mass of the atom also increases. This results from the additional electrons and by an increase in the mass of the nucleus.

2. ELECTRICITY

A current is defined as "a steady and smooth onward movement, as of water." A steady movement of cars on a highway would be a car current. The rate at which cars pass a point on the highway is a measure of the car current. To determine the car current, one would count the cars, measure the time for the cars to pass, and divide the number by the time to obtain the rate in units such as cars per minute. If each car had two passengers, then multiplying the car rate by two yields a passenger current measured in passengers per minute.

An electric current is a flow of electric charges. In wires and appliances the flow is due to electrons because they are much freer than the positive charges in the nucleus. Electrons moving through a wire are analogous to cars moving on a highway. One cannot see the electrons but in principle one can stand at the edge of the wire and count the electrons passing by in a measured time interval and express the rate in units of electrons per second. Multiplying the electron rate by the charge per electron yields the rate at which charge flows in units of coulombs per second. As an equation,

$$\text{Electric current} = \frac{\text{coulumbs of charge flowing through a wire}}{\text{time required for the flow}}$$

$$I = \frac{Q}{t}. \tag{2}$$

Recording charge (Q) in coulombs and the time interval (t) in seconds yields coulombs per second as the units of electric current (I). A coulomb per second is called an ampere (A). If 100 C of charge flow by some position in a wire in 10 s, the current is 10 A. The electric current in a lit flashlight bulb is approximately 1A. If the bulb were on for 10 min, the total charge passing through the bulb in 10 min is

$$1\ \text{C/s} \times 10\ \text{min} \times 60\ \text{s/min} = 600\ \text{C}.$$

A force must be exerted on the electrons to cause them to flow through a wire just as a force must be applied to water to keep it moving through a pipe. The electric force has its origin in the force between

electric charges. Electrons pulled toward a positive charge create an electric current. Electric forces do work on the electrons just as work is done on an automobile pushed some distance by a person. It is the role of a battery in a flashlight or an electric generator in an electric power plant to supply electrical "pressure" for moving electrons. This electrical pressure is called a potential difference (voltage is a less formal word describing the same idea). A potential difference is analogous to a water pressure difference for moving water through a pipe. Potential difference is defined in terms of the amount of work done by electric forces on a charge as it moves between two positions:

$$\text{Potential difference} = \frac{\text{electrical work on the amount of charge moved}}{\text{amount of charge}}$$

$$V = \frac{W}{Q}. \tag{3}$$

Work (W) is measured in joules (J) and charge (Q) is measured in coulombs, making potential difference (V) joules per coulomb. A joule per coulomb is called a volt (V). If 100 J of work is done by electric forces on 1 C of charge when it moves between two positions, the potential difference between the two positions is 100 V. Batteries for most automobiles provide a 12-V potential difference between two terminals. If 2 C of charge flow between the terminals, electrical forces do 24 J of work on the 2 C of charge.

The notion of a difference in potential is very important. If a building is said to be 500 ft high, this probably means the difference in "height" between the top and bottom is 500 ft. Clearly, however, if the building were on top of a mountain, its height would be more than 500 ft relative to the base of the mountain. Potential differences, like heights, are also relative. The potential difference between the terminals in a household electrical outlet is 115 V. This means that one of the contacts is 115 V relative to the other contact. This other contact in a household outlet is at the same potential as any other part of the room, including a person in the room. You can touch this contact and not get an electrical shock because there is no potential difference between you and the contact. This contact is called ground because a wire connects it to a metal stake driven into the ground. Generally, this ground wire can be seen alongside an electric utility pole holding wires that bring electricity to a house. The other contact in an outlet is referred to as "hot." Electrical shocks occur when you touch both ground and the hot contact.

All electrical appliances have two electrical connections. To operate an appliance, an appropriate potential difference must be connected to these two connections. If two wires were connected to a flashlight bulb and the other ends of the wires touched to the terminals of a flashlight battery, the bulb would light. The lit condition signals a complete electrical circuit. It is complete in the sense that a complete (or closed) path is provided for the flow of electrons. Cutting one wire with a pair of scissors breaks the circuit and the light no longer glows. A switch is a device that allows opening and closing electrical circuits. A switch is analogous to a faucet that can be opened or closed to control the flow of water. An example of a water circuit is shown in Fig. 1. A pump pulls water from the container, forces it through a valve, past a water wheel, and back into the container. In a household electrical circuit, an

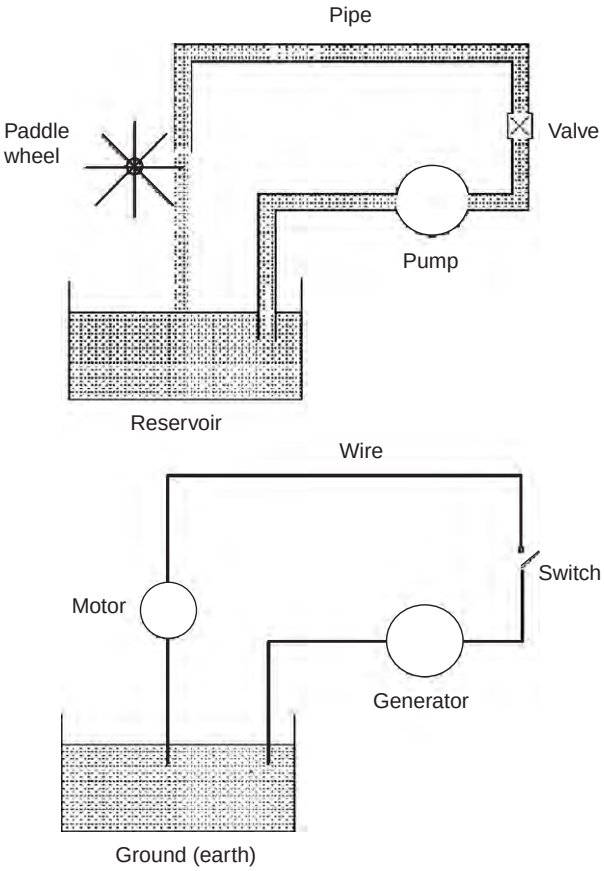

FIGURE 1 Schematic comparison of a fluid circuit and an electrical circuit. The water pump forces water to circulate through the water circuit. The electrical pump, a battery or generator, forces electrons to circulate through the electrical circuit. The sum total of electric charges never changes in the process, just as in the absence of leaks the sum total of water never changes in the water circuit.

electric generator provided by an electric utility pulls electrons from the ground, forces them through a switch, through a motor, for example, and back into the ground. The wire plays the role of a water pipe.

3. ELECTRICAL RESISTANCE

Electrons moving through a wire migrate through a network of atoms. This network impedes the flow, and we say the wire has electrical resistance. The resistance depends on the composition of the wire. For example, an aluminum wire having the same length and diameter as a copper wire offers more resistance than the copper wire. Just as water flows easier through short pipes than through long pipes, electrons flow easier through short wires than through long wires. Also, just as water flows easier through large-diameter pipes than through small-diameter pipes, electrons flow easier through large-diameter wires than through small-diameter wires. Accordingly, the resistance of a wire increases as the length increases but decreases as the diameter increases.

A current is produced in a wire when the ends are connected to a potential difference. The current increases if the potential difference (the electrical pressure) increases. If the resistance increases, the current decreases. This reasoning is modeled as an equation by writing

$$\text{Current} = \frac{\text{potential difference}}{\text{resistance}}$$

$$I = \frac{V}{R}. \tag{4}$$

Resistance has units of volts divided by amperes. This unit is called an ohm. If 1.5 A is produced in a bulb connected to a 12-V battery, the resistance of the bulb is

$$R = V/I = 12\,\text{V}/1.5\,\text{A} = 8\ \text{ohms}.$$

The resistance need not be constant. Doubling the potential difference across the bulb may produce a current of 2 A and a resistance of 6 ohms. If the resistance does not depend on the potential difference, the device obeys Ohm's law. Wires used for electrical conductors and heating elements in toasters and irons obey Ohm's law. Transistors do not obey Ohm's law.

In a household in which the potential difference is fixed at 115 V, the current in an appliance depends on its resistance. As the resistance decreases, the current increases. The energy used to overcome this electrical resistance appears as heat. For example, the heat liberated in a toaster is produced by electrons overcoming the electrical resistance provided by the metallic elements of the toaster.

4. ELECTRIC POWER AND ELECTRIC ENERGY

Like water pulled over a dam by a gravitational force, electrons moved by an electric force acquire kinetic energy as a result of work done on them. Electrons convert this energy in a variety of ways. In a lamp, the energy is converted to heat and light. In an electric motor, the energy is converted to mechanical rotational energy. The rate at which moving charges convert energy is called electric power:

$$\text{Power} = \frac{\text{energy converted in joules}}{\text{time required in seconds}}$$

$$P = \frac{E}{t}. \tag{5}$$

Electric power is expressed in joules per second, or watts. Electric clothes dryers use electric power in the range of a few thousands of watts; electric power plants produce power in the range of hundreds of millions of watts. Thousands of watts and millions of watts are usually expressed as kilowatts (kW) and megawatts (MW), respectively.

A useful relation for electric power follows from combining the equation for the definition of power, $P = W/t$, and the definition of potential difference, $V = W/Q$. Substituting for W in the equation $P = W/t$, we have $P = V(Q/t)$. Recognizing that Q/t is current I, we find $P = VI$. Power equals voltage times current is a general relationship for any electrical device. For a resistance, we can use $V = IR$ to arrive at $P = I^2R$ and $P = V^2/R$.

Companies that provide the voltage for forcing electrons through our appliances are often referred to as power companies. It is reasonable to expect that the companies are paid for power. However, they are actually paid for energy, not power.

Power is the rate of converting energy. A 100-W light bulb requires energy at a rate of 100 J/s regardless of how long it is on. However, the cost of operation depends on how long the bulb is lit. Using Eq. (5), it follows that energy, power, and time are related by

$$\text{Energy} = \text{power} \times \text{time}$$

$$E = Pt.$$

It follows that any unit of power multiplied by a unit of time yields a unit of energy. Watts (or kilowatts)

and hours are units of power and time. The watt-hour (or kilowatt-hour) is a unit of energy. It is peculiar because the units of time (hours) do not cancel the time units of seconds in power.

Table I lists the power requirements for several household appliances. Note that those involving the generation or removal of heat require the most power. These devices tend to have low resistance.

5. MAGNETIC FORCE AND MAGNETISM

We have discussed electric current and the idea that an electrical pressure is required to establish electric current. Nothing has been said about how the power company generates the pressure or how it is transmitted to homes and factories. To understand this important aspect of producing electricity, we must discuss some fundamentals of magnetic force and magnetism.

Images on a TV are produced by electrons impacting with the screen. The picture distorts if a magnet is placed near the face of a black-and-white TV. The distortion results from an interaction of the moving electrons with a magnetic field produced by the magnet. As a general principle, any moving charge "cutting" magnetic field lines experiences a magnetic force. In Fig. 2, magnetic field lines are directed from the N pole to the S pole. A wire moved vertically in the magnetic field "cuts" the magnetic field lines and all charges in the wire experience a force by virtue of moving in a magnetic field. However, only the free electrons in the wire acquire motion. If the ends of the wire are connected to a light bulb, for example, an electric current is produced in the circuit. Had the wire been moved horizontally parallel to the magnetic field lines, there would have been no current in the circuit. Work done by the agent moving the wire is responsible for the energy acquired by the electrons. This is the principle of an electric generator such as one might find on a bicycle or in an electric power plant. On a bicycle generator, the agent moving the wire is a wheel rotating wires mounted on the shaft of the generator. A large steam turbine is the agent in an electric power plant.

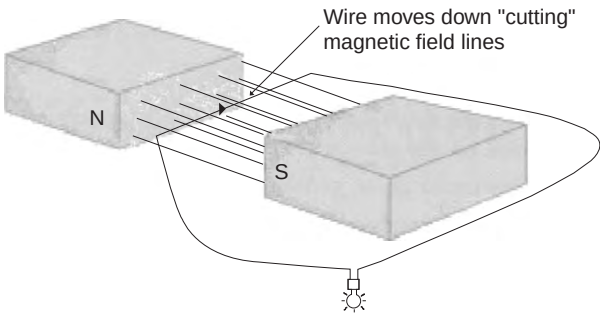

FIGURE 2 A current is established in a wire when it moves in a magnetic field so as to "cut" the magnetic field lines. If the wire is moved directly from the N to the S pole, no magnetic field lines are cut and no current results. The arrow indicates the direction in which electrons move in the wire.

The generator principle was illustrated by holding a magnet fixed and moving the wire in the magnetic field. A current would also be produced if the wire were held fixed and the magnet moved. As long as the wire cuts the magnetic field lines, a current results. If the wire were moved in a direction opposite to that shown in Fig. 2, the electric current changes direction. Cutting magnetic field lines with an oscillatory motion produces a current whose direction alternates. Such a current is called an alternating current (AC). The current produced by a battery is called direct current because the charge flows in one direction only.

6. ELECTRIC GENERATORS

A practical electric generator contains a coil of wire that is rotated in a magnetic field. To understand the operation, we examine a single loop as shown in Fig. 3. Metallic rings, called slip rings, are mounted on the shaft of the rotating loop and the ends of the loop are bonded to the slip rings. Metal contacts, called brushes, rub against the slip rings. The loop, slip rings, brushes, and connected electrical device form an electrical circuit for a current. The magnet produces a magnetic field whose field lines are directed from the N pole to the S pole. Only the sides of the loop labeled A and B are able to cut magnetic field lines. The two segments of the coil labeled A and B always move in opposite directions. Accordingly, the current is always in opposite directions in these two segments. The maximum current results when the wires move perpendicular to the magnetic field lines. There is no current in the circuit when the wire segments move parallel to the magnetic field lines. When the segment designated A in Fig. 3 is in the upmost position of its rotational path, it is moving horizontally to the right. Because the magnetic field lines are directed to the right, the wire is instantaneously moving parallel to the magnetic field lines. At this instant, there is no current in the circuit. As the loop rotates, the segments begin cutting the magnetic field lines and a current develops in the circuit. When the portion of the loop designated A has moved one-fourth of a turn down, instantaneously it moves perpendicular to the magnetic field lines. In this position, the electron current is a maximum. The electron current decreases to zero when the coil makes another one-fourth turn. As the coil rotates further, the electron current increases and changes direction. It reaches a maximum when the coil makes a third one-fourth turn. Finally, the electron current decreases to zero when the coil returns to the initial starting position. A plot of electron current versus position of the coil, or equivalently time since the position depends on time, is shown in Fig. 4. The cycle of current and time shown in Fig. 4 repeats with each revolution of the coil. The number of cycles produced each second is called the frequency. A cycle per second is called a hertz (Hz). In the United States, the frequency of the AC voltage produced by commercial electric power plants is 60 Hz.

When a toaster is plugged into an AC household outlet, the current produced in the wires of the toaster continually changes in magnitude and direction. Nevertheless, the current causes the toaster wires to warm. Otherwise, one would not be able to toast bread. Household voltage is usually labeled 120 V, even though the voltage is continually changing. The 120-V rating means that the voltage is as effective at producing heat as a 120-V battery connected to the toaster. The 120-V AC label on a light bulb is the effective value of an AC voltage needed to power the bulb.

A generator that provides electricity for a headlamp on a bicycle functions very much like the one illustrated in Fig. 3. Mechanical energy is provided by the bicycle wheel rubbing against and rotating a shaft connected to the coil of the generator. The magnetic field is provided by a magnet. This type of generator produces approximately 5 W of electric power. Although the generator in a commercial electric power plant is much larger in size and often produces

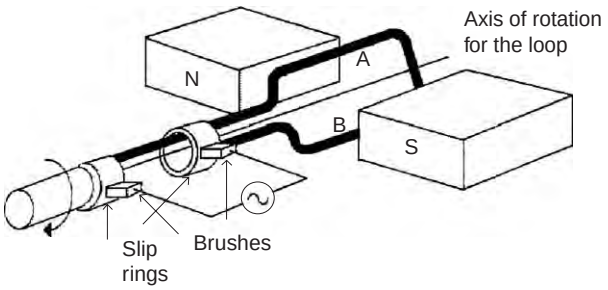

FIGURE 3 Principle of operation of an AC generator. A current develops in the rotating coil when it moves through the magnetic field created by the magnet. The slip rings rotate with the coil and make electrical contact with the brushes that are connected to an electrical device, such as a light bulb or a motor.

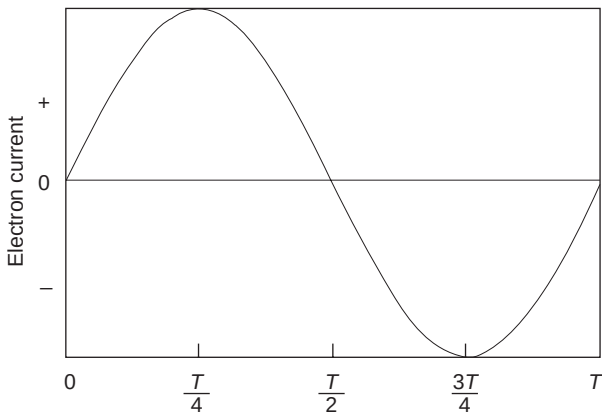

FIGURE 4 Plot of induced current in the rotating coil of an AC generator. Positive and negative currents are used to distinguish the two directions of charge flow. $T/4$, $T/2$, $3T/4$, and T denote times for one-fourth of a rotation, one-half of a rotation, three-fourths of a rotation, and a full rotation of the coil, respectively.

1 billion watts of electric power, the basic physical principle is the same. The commercial generator uses a steam turbine for the input mechanical energy and a massive stationary coil with a circulating electric current to provide the magnetic field.

7. TRANSFORMERS

An AC generator and a battery both deliver energy to such things as light bulbs connected to them. If a light bulb requires 12 V and one has a single battery that can provide 2 V, it is difficult to use the battery to power a device that can change the voltage from 2 to 12 V. If AC voltages are involved, it is reasonably easy to tailor voltages using an apparatus called a transformer. Transformers play very important roles in the transmission of electric power and in adapting voltages for industrial and household uses. The transformer principle is straightforward.

An electric current produces a magnetic field proportional to the current. If the current is constant, as would be the case if a battery were connected to the ends of a wire, the magnetic field is constant. The direction of the magnetic field lines depends on the direction of the current. If the battery is replaced by an AC source, the magnitude of the magnetic field changes as the current changes and the direction of the magnetic field lines changes when the current changes direction. There exists in the vicinity of the wire a changing magnetic field. If a coil of wire is placed in this changing magnetic field, an alternating current develops in it because the magnetic field lines as they change cut the wires of the coil. It is much like changing the magnetic field lines by moving a magnet. This principle is used in transformers to change the size of an AC voltage. The small black box often connected to an electrical outlet and to a portable computer to recharge the computer's battery is a transformer that typically reduces the outlet voltage from 115 to 20 V.

A transformer has two distinct coils of wire wound onto an iron core (Fig. 5). One of the coils, the primary, is connected to an AC voltage such as at the outlet in a house. The other coil, the secondary, is connected to an electrical device such as a light bulb. The AC current in the primary coil produces magnetic field lines that are guided into the secondary coil by the iron core. The interception of the magnetic field lines by the secondary coil produces a current in the secondary coil. The ratio of the primary and secondary voltages is equal to the ratio of the number of turns of wire in the primary and secondary coils of the transformer:

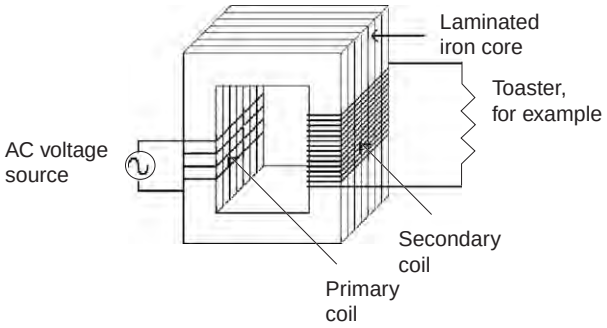

FIGURE 5 Essentially, a transformer consists of two coils of wire (primary and secondary) and an iron core to guide the magnetic field lines from the primary coil to the secondary coil.

$$V_s/V_p = N_s/N_p. \tag{6}$$

Door chimes in houses often require 6 V for operation. Suppose that the voltage available at an outlet is 120 V. If a transformer has 20 times more turns on the primary than on the secondary so that $N_s/N_p = 1/20$, then the secondary voltage will be 6 V when the primary voltage is 120 V. The primary is connected to the available 120 V and the secondary is connected to the chimes.

The secondary of a transformer delivers electric power to whatever is attached to it. This electric power has its origin in the electrical source connected to the primary. The principle of conservation of energy prohibits obtaining more power in the secondary than was supplied in the primary. Transformers tend to warm, indicating that some of the power supplied in the primary appears as heat so that the secondary power is always less than that in the primary. In a well-designed transformer, the efficiency for energy transfer is approximately 99%. The ability of a transformer to tailor voltages and its very high efficiency makes it an extremely useful device.

Glossary

coal combustion products (**CCP**) Solid waste left after burning the carbon and hydrocarbons in coal; made up of flyash, bottom ash, slag, and sulfur dioxide scrubber sludge. CCP are often used as construction materials.

direct cooling The transfer of waste heat from power plants to water bodies using water-to-water heat exchangers. This approach does not consume significant amounts of water (most is returned) but can cause significant impacts on aquatic species due to contact with screens or pumps.

electromagnetic field The combination of electric and magnetic fields that surround moving electrical charges (e.g., electrons), such as those in electric currents. Electromagnetic fields apply a force on other charges and can induce current flows in nearby conductors.

indirect cooling The use of a closed loop water system to reject waste heat to the atmosphere. A significant amount of water is evaporated in this process, which must be replaced, but total flows are less than with direct cooling, and water bodies are not heated.

radionuclide An isotope of an element that is radioactive, that is, a radionuclide undergoes spontaneous fission (splitting), releasing energy when it does so. The energy released from radionuclides can cause various health effects, including increased risk of cancer.

submergence Permanent flooding of land behind (upstream from) a dam.

Electric power is simultaneously one of the cleanest energy technologies and one of the dirtiest; it has virtually no environmental impacts at the point of use, but generation and transmission create enormous impacts. This article provides an overview of the environmental impacts of electricity, the most important of which are air pollution, water use, solid waste, and land use.

1. ACTIVITIES

Most of the environmental impacts of electricity are associated with generation and transmission, including equipment manufacture and construction, fuel supply, fuel combustion, and waste disposal. Currently, electric power systems rely on fossil (coal, oil, and gas) powered generation for to ensure adequate electricity is always available and to follow load; but if fossil generation is limited in the future, other technologies will be needed. If so, the environmental impact of the entire system, including the manufacture and use of new technologies such as energy storage, must be considered. Here, only direct effects are discussed.

1.1 Generation

Enormous quantities of fossil fuels are used to generate electricity, so even relatively minor contaminants found in them (especially in coal) lead to very significant emissions of pollutants such as sulfur dioxide (SO_2), nitrogen oxides (NO_x), carbon dioxide (CO_2), toxics such as mercury (Hg) and hydrogen chloride (HCl), and radionuclides such as uranium (U) and thorium (Th). If electricity generation occurs near the point of use, emissions of carbon monoxide (CO) may be an issue.

Another major environmental impact of fossil and nuclear fuel electricity generation is water use, which includes consumption, impacts on aquatic species, and discharge of heat into nearby water bodies. Electricity generation by coal and nuclear plants also creates significant solid wastes that must be dealt

with. The majority of the environmental impacts of nuclear technologies occurs before and after generation, especially in fuel production and spent fuel disposal. Nuclear power plants are also vulnerable to accidental release of radionuclides.

Aesthetic concerns are also important; many people find electricity generation and transmission equipment unpleasant to be near or even to look at. While aesthetic concerns may seem relatively unimportant compared to health and environmental quality issues, they can be more difficult to resolve than pollution (which generally has a technical solution).

Renewable electricity generation technologies usually have quite different impacts; they typically create little or no emissions or waste during generation, but their manufacture may have important environmental impacts and they often require the use of large land areas to collect relatively diffuse renewable energy resources. This is especially true of hydroelectric power, which can require flooding vast areas. Fuel cells may also fall into this category because while they emit only water, producing the fuel cells and manufacturing and delivering hydrogen fuel may have significant environmental impacts. In this entry, however, only the direct impacts of operation are considered.

1.2 Transmission, Distribution, and Storage

The primary environmental impacts of transmission and distribution systems are associated with land use and aesthetics, but their scales are quite different. Distribution systems are ubiquitous in developed areas where they affect land use little (if at all), and are largely ignored by the public. In highly urbanized areas, electricity distribution infrastructure may be largely underground. The public often strongly opposes proposals to build transmission lines, especially when they will be close to population centers or highly visible. One reason for this opposition is concern about possible health effects of electromagnetic fields (EMFs), although it is very uncertain what (if any) risk EMFs create. On the other hand, transmission systems reduce the amount of generation capacity that's needed for a reliable system and allows for power plants and their emissions to be located far from populated areas, which tends to decrease their health and aesthetic effects.

Renewable energy sources are often located far from demand centers (cities and factories), extensive transmission systems may be needed to deliver renewable power from where it's available to where it is needed. In addition, wind and solar energy are intermittent (they are not always available—such as on a calm night), so if they are to supply electricity whenever consumers need it, these technologies need some sort of energy storage. Nuclear power plants may rely on storage in the future as well; it can be hard to adjust reactor power up and down rapidly (over the course of a few hours) to follow demand.

Energy storage is extremely challenging, only two practical methods now exist—pumped storage and compressed air. Pumped storage facilities are like hydroelectric dams; energy is stored by pumping water from a lower reservoir to a higher one, and withdrawn by letting it flow back down through turbine generators. At compressed air energy storage facilities, electrically driven compressors fill caves or other underground formations with pressurized air to store energy, which is released later through a turbine. Neither of these technologies is widely used, and the environmental impacts of significant deployments of them are not well known.

1.3 End Use

There are essentially no environmental impacts of electricity in its end-use phase. Thus, as electric technologies replaced end-use fuel consumption for heating, cooking, lighting, and mechanical work, many environmental problems disappeared at the cost of introducing environmental impacts from electricity generation and transmission. This has helped homes and workplaces in many countries around the world become much cleaner and safer since the start of the 20th century, vastly improving public health and environmental quality. The only exception is the potential risk of EMF effects from household and workplace exposures, especially appliances.

2. IMPACTS

2.1 Air Pollution

2.1.1 Gases: SO_2, NO_x, and CO_2

Electricity generation causes a significant fraction of anthropogenic emissions of three major air pollutants, CO_2, NO_x, and SO_2, although the fraction varies significantly around the world, as shown in Table I. Anthropogenic emissions of SO_2 are relatively large compared to natural emissions of sulfur into the atmosphere, and are highly concentrated in the northern hemisphere. Electricity sector

SO_2 emissions are expected to grow in the future and become a larger fraction of anthropogenic emissions due to more use of coal for power production, compared to flat or declining uses in other sectors. In contrast, electricity sector NO_x emissions are relatively small compared to anthropogenic and natural NO_x emissions. Power sector NO_x emissions can have important effects because they are often concentrated near populated areas and because the nitrogen cycle can be significantly altered by relatively small perturbations. In the future, NO_x emissions from electricity generation are expected to grow, but not as fast as other sources, especially transportation.

The environmental effects of these emissions from power plants are diverse, including acidification, reductions in visibility (also called haze), and eutrophication. Acidification is a change in an ecosystem's natural chemical balance caused by an increase in the concentration of acidic elements and can lead to severe damage to trees and the elimination of fish species from lakes and streams. Eutrophication is excessive plant growth due to the addition of compounds like NO_x, which leads to noxious algae and loss of fish and other aquatic wildlife. Visible haze is increasingly viewed as an important issue in parks and other natural areas, and it is driving some regulatory processes to control power plant emissions.

The most important human health impacts of SO_2 and NO_x emissions are their contributions to urban air pollution. In photochemical smogs, increased concentrations of ozone, polycyclic aromatic hydrocarbons, and fine particles (less than 2.5 micron diameter) can lead to increased morbidity and mortality. These compounds have many sources, but anthropogenic NO_x is among the most important.

Emissions of CO_2 from the electricity sector are not due to fuel contamination, CO_2 is the intended result of the combustion of fossil fuels. Unfortunately, it is also the primary cause of climate change.

2.1.2 Smoke and Particulate Matter

One of the main environmental impacts that electricity has helped lessen over the past century is smoke in urbanized and industrial areas. Smoke is a combination of unburned carbonaceous material (both solid and gaseous), nonburnable ash, sulfur

dioxide, nitrogen oxides, and trace amounts of metals. In the early 20th century, cities like Pittsburgh and London could experience dustfall of 10 to 30 g/m^2 each month. This material was certainly a nuisance and possibly a health hazard as well. Electricity replaced industrial boilers for mechanical work and in some cases as a heat source, reducing some of the smoke burden.

At first, however, electric power plants simply changed the location and character of smoke, or as it has come to be known particulate matter (PM) emissions. Early power plants had little or no PM controls and some power plants in developing countries lack them. In the 1960s, power plants in North America and Western Europe began to be fitted with PM control equipment and now virtually all coal-fired power plants in industrialized countries capture 99% or more of fly ash. In the United States, electricity generation accounts for about 1% of anthropogenic PM emissions of 10 microns diameter or greater (PM-10). In contrast, electricity generation contributes between 15 and 45% of PM emissions in some cities in India.

The greatest health risks of PM are due to the smallest particles, those 2.5 microns and smaller (PM-2.5). These fine particles also scatter visible light, causing haze. PM-2.5 can be emitted directly but are also formed in the atmosphere from gaseous emissions, especially SO_2 and NO_x. Electricity generation contributes similar fractions of direct PM-2.5 as it does PM-10, but it is a much larger contributor to global SO_2 and NO_x emissions and therefore to secondary PM-2.5 in the atmosphere. However, fine particles may have different health risks depending on their chemical composition, so the importance of electricity sector emissions to the health impacts of PM-2.5 pollution is not completely clear.

2.1.3 Toxics

Because many coals contain toxic contaminants and almost two-thirds of global coal production goes to power electricity generation, the sector has substantial toxic emissions. Petroleum products and to a much lesser extent natural gas, contain some toxic contaminants as well. These pollutants are persistent (i.e., they do not degrade) and some of them, notably mercury (Hg), bio-accumulate. The most important compounds that coal-fired power plants may emit include Hg, hydrogen chloride (HCl), sulfuric acid (H_2SO_4), and hydrogen fluoride (HF). These materials are can cause health and environmental effects at lower concentrations than more conventional pollutants like NO_x, and can be a significant local problem. Table II contains approximate annual global emissions of metals from worldwide electricity production and shows how these emissions compare to global anthropogenic emissions and of global natural emissions. Natural emissions of these metals are very small, so electricity generation creates very large perturbations to natural flows.

Geothermal resources (hot water and steam) can contain significant amounts of some of these toxics, as well as the toxic gas hydrogen sulfide (H_2S). In installations with very small emissions these may be vented to the air, in larger facilities they are reinjected into the ground along with most of the water or steam that has been withdrawn, and so they are. However, the contribution of geothermal electricity to all toxics emissions is trivial compared to that of fossil fuels.

Except for Hg and Se, most metals in coal tend to be captured by the fly ash, and their ultimate fate corresponds to that of the ash from the power plant. Many of these metals can also be captured in SO_2 scrubbers, and if so, their environmental impact is then largely determined by the final disposition of scrubber sludge. However, up to two-thirds of the Hg that enters a power plant in the coal remains a gas and escapes to the atmosphere. Controlling Hg emissions may include the conversion of gaseous Hg in power plant exhaust into compounds such as HgCl that can be more easily captured. Another

strategy may be to inject a sorbent (such as activated carbon) into the exhaust gas to capture the Hg and allow the particle control device to remove it.

Probably the most important public health impact of toxic emissions from electricity generation is neurotoxicity risk to unborn children of Hg. The primary exposure route is through consumption of fish by pregnant women, since aquatic bacteria create the most harmful form (methlymercury), which then accumulates in edible fish such as bass and perch. By 2002, Hg contamination had caused almost all U.S. states to warn women of child-bearing age to limit consumption of some fish from some water bodies. Wildlife may also be at risk due to Hg exposure, especially fish-eating birds and mammals.

As a liquid at typical temperatures, Hg can be transported very long distances through deposition and revolatization. Thus, Hg is a global pollutant, and for many countries more than one-third of Hg deposition originates outside of their borders. The hemispheric temperature gradient drives deposition toward the poles, although most Hg emissions occur in northern midlatitudes, health and ecological effects in the Artic may be most severe.

2.1.4 Radionuclides

Radionuclides present a human health risk by increasing the risk of cancer, genetic changes, and birth defects, and present a similar risk to wildlife. Globally, the background radiation dose is typically about 2.5 milli-Sievert (mSv) per year, of which about one-third is from cosmic radiation and two-thirds from naturally occurring radionuclides, mostly uranium (U), thorium (Th), and especially potassium (K). Medical equipment can add measurably to this amount (for instance, 0.5 mSv/yr. in the United States, on average), as can lifestyle choices (e.g., flying in airplanes frequently). Nuclear power plants are often designed to give a dose of no more than about 0.05 mSv/year (about 2% of background) to the most exposed nonworker group.

Radionuclide contaminants in coal used to generate electricity total about 1.5×10^{14} disintegrations per second (or Becquerels, Bq) each year. The isotopes most important isotopes (of U, Th, and K) are solids by the time they leave the combustion chamber, so radionuclide emissions and exposure from coal generation are dependent on PM controls and solid waste disposal. Significant direct contact with ash or poor disposal techniques may create a slight hazard, but radionuclide concentrations in most coal ash are lower than in many soils and building materials (e.g., limestone). Interestingly, the total radiation doses due to coal-fired electricity and due to nuclear electricity are virtually identical under normal operating conditions (unless the fuel is reprocessed, in which chase the nuclear electricity dose more than doubles).

Nuclear power presents the unique problem of potential accidental release of radionuclides. Operating reactors contain significant amounts of radioactive Iodine (I-131), which tends to be absorbed readily by the body and concentrated in the thyroid, increasing the effective dose to that gland. This radionuclide has a short half-life (about 8 days) and so is essentially eliminated as a risk 2 months after a release. Nonetheless, I-131 can cause sufficient genetic damage during this short period to induce thyroid cancers later. Iodine tablets are an inexpensive way to minimize exposure in case of accidental release.

Almost a dozen nuclear reactors have suffered meltdowns since the mid-1940s, in addition to fires and other accidents. Most of these accidents were associated with experimental or weapons reactors, but two large electric power reactors have had catastrophic meltdowns, Three Mile Island Unit 2 (TMI-2) in 1979 in the United States and Chernobyl RBMK Unit 4 in 1986 in the Ukraine (which was part of the Soviet Union at the time of the accident).

The TMI-2 accident resulted in a release of 6×10^{11} Bq I-131 to the environment and resulted in a dose of less than 1 mSv to the closest neighboring civilians. The containment system prevented further releases despite most of the core melting to the bottom of the steel reactor vessel. The TMI-2 accident has had no observable effect on the health of either workers at the plant or the public. However, the total does for the United States was 20 to 40 person-sieverts, which will cause one or two excess cancer deaths in the United States. Cleanup of TMI-2, which will be completed some time after 2010, will eventually cost about $1 billion, more than the plant's construction cost.

The Chernobyl accident was far worse; inadequate design, incompetent operation, and negligent disaster management combined to cause a large steam (thermal) explosion that exposed the core directly to the environment and caused great human suffering. Contemporary reports talk of a scarlet glow in the sky that could be seen 10 km away due to the light of the red-hot core being reflected in the clouds. The accident released large quantities of radioactive gases and particles, including 3% to 4% of the fuel. The greatest risk was from the release of isotopes that are readily taken up by the body,

including 1.7×10^{18} Bq of Iodine (I-131) and 8.5×10^{16} Bq Cesium (Cs-137).

About 200 tons of fuel escaped as liquid metal from the concrete cavity in which the core sat and mixed with other building material to form several piles that are now crumbling into dust. This dust presents a significant potential radiation risk, as does the 20,000 liters of contaminated water under the remains of the reactor. The reactor is contained within a massive but unstable "sarcophagus" that was constructed quickly and under extremely difficult conditions. To date, cleanup of Chernobyl has cost more than $3 billion; more will likely be needed to replace the sarcophagus and for continued monitoring and cleanup.

More than 30 employees and emergency response personnel working onsite were killed due to radiation exposure during the first several days of emergency response to the accident, and more than 100 other workers were hospitalized with acute radiation sickness. Evidence has been found that considerable numbers of neighboring civilians probably also had some acute radiation sickness, but this was not acknowledged by Soviet officials at the time of the accident.

In the subsequent decade, approximately 800,000 people were involved in cleanup of Chernobyl, most of whom received <25 mSv, but one quarter of whom received >200 mSv. Among these workers, increased (approximately double) rates of various cancers have been observed, as well as genetic damage (although it is not clear if these have hereditary implications). Evidence of genetic mutations in the DNA of children of cleanup workers is mixed. One of the more common problems that Chernobyl cleanup workers have faced is psychological distress, which has caused various neurological symptoms.

Average exposure to the public was lower but still significant. Most of these doses were from I-131 and so were delivered primarily to the thyroid. Most people received doses below 20 mSv, but some went as high as 1000 mSv, with small children and infants being most affected. People in this age cohort who lived within a thousand kilometers of the plant at the time of the accident have experienced about a five-fold increase in thyroid cancers (typically nonfatal), probably totaling a few thousand through their lifetimes. Some researchers have found evidence of additional leukemia among this group as well, while some have found no relationship. There is some evidence of increases in birth defects in places as far away as Berlin and Greece. Estimates of the overall effects are difficult to calculate, but it appears that the Chernobyl accident will cause between 10,000 and 30,000 fatal cancers, most in the Ukraine and Belarus.

Approximately 325,000 people were evacuated or relocated from the vicinity and the area within 30 km of the site is now a permanent exclusion zone. Two of the other reactors at the Chernobyl site operated until 2000 but are now shut down. The area around the site has become economically and socially depressed due to migration and other reasons. Local ecosystems were severely affected immediately after the accident, but are recovering without observable damage (although the extent of any genetic damage has not been determined).

About a dozen reactors with the same design as the reactor in Chernobyl (RBMK) exist elsewhere in the former Soviet Union, but all have received operational and engineering changes that make a repeat extremely unlikely. All other nuclear plants in the world are more similar to the TMI-2 design with massive steel containment vessels and other features (especially negative coefficients of reactivity for temperature and voids) that make an accident exactly like the one at Chernobyl impossible. However, the root causes of both the TMI-2 and Chernobyl accidents were a combination of design flaws, operating errors, and equipment failures, which can afflict any complex system. For instance, in 2002 a massive hole was found in pressure vessel of the Davis-Bessie reactor. Several inches of steel had corroded away without being noticed, leaving only a thin layer of stainless steel in place. No accident occurred, but this new type of situation demonstrates that the complexity of nuclear power plants continues to be a safety challenge.

2.2 Water Use

Water is consumed during virtually all forms of electricity generation, although fossil and nuclear plants that use steam turbines generally use far more than other technologies. Water is used to cool the plant, to make up feedwater, in emission control equipment, for ash handling, and for cleaning. By far the greatest volumes are used in cooling, although most of these withdrawals are returned to the water body (but at a higher temperature). In industrialized countries, water use by electricity generation be significant. In the United States, for example, 708 electricity generating plants (half of the installed capacity in the country) use cooling water, making up about half of all large industrial uses of cooling water in the country. These power plants have a combined average flow of 10,000 m^3/s. About half are located

on lakes and reservoirs, a quarter on streams and rivers, and a quarter on oceans and estuaries. Discharge temperatures can be as high as 40°C.

Cooling can be either direct or indirect. In the direct approach, cooling water enters a once-through system with heat exchangers that condense turbine exhaust steam to make return feedwater. All the waste heat goes into the water body, but little water is actually consumed. In addition to heating water bodies, electric power plants with direct cooling kill many marine organisms that come in contact with cooling water systems. Organisms may enter the cooling water system (entrainment) or be trapped on screens (impingement). For example, estimates for individual nuclear power plants in the 1600 to 2200 MW size indicate annual losses of 3 billion to 4 billion larvae, equivalent to 23 million adult fish and shellfish, or 17 to 45 tons of adult fish (creating observable changes in populations).

In the indirect approach, a closed loop of water absorbs heat from the steam heat exchanger to a cooling tower and gives up heat to the atmosphere, partially evaporating. This water must be made up with input from a nearby source. Tall (100 m) natural-draft cooling towers may be used (wet cooling); however, they are unsightly and may cause a visible plume or fog. Dry cooling replaces the cooling tower with finned radiators over which air is blown with fans. Hybrid systems combine wet and dry cooling. The water use and efficiency implications are shown in Tables III and IV. Hybrid cooling also tends to cost less than indirect wet cooling or air cooling and have less visual impact than wet cooling towers.

Overall, direct cooling involves larger flows of water, resulting in larger numbers of marine organisms killed and significant heating, while indirect cooling consumes larger amounts of water.

Technologies that do not use a steam cycle (and thus require little cooling), such as gas turbines, need little water. However, if water or steam injection is used for NO_x control, gas turbines can consume considerable amounts of water. Flue gas desulfurization to control SO_2 emissions also requires a considerable amount of water; a 1000 MW unit burning 1.5% sulfur coal would need approximately 0.1 m^3/s for this purpose alone. All solar electricity technologies need some water for cleaning, and those that use sunlight to drive a steam cycle may need cooling water as well.

Large dams can also impact water quality by vastly changing natural flow regimes in terms of flow timing, volume, turbidity, and temperature. Such changes can have very large impacts on riverine species as well as on terrestrial species that depend on aquatic sources of food. Of course, large dams pose insurmountable barriers for species that spawn in rivers and streams but live most of their lives in the ocean, such as salmon.

2.3 Solid Waste

Besides nuclear waste, the major solid wastes created by electricity production are coal combustion pro-

ducts (CCP), which consist of flyash (ash that leaves with the flue gas and can leave the stack), bottom ash (ash that falls to the bottom of the combustion chamber), slag (ash that has melted and resolidified), and sludge from flue gas desulfurization scrubbers. The ash and slag consist of impurities of silica, iron, alumina, and other incombustible matter that are contained in the coal, while the sludge is largely gypsum ($CaSO_4$). Some ash is also produced by petroleum coke or fuel oils. Many toxics are solids by the time they leave the combustion chamber (exceptions include Hg, Cl, and F) and end up wherever the ash goes.

Assuming 10% ash content on average, about 500 million metric tons of CCP are created each year. Most of this ash is dumped in large landfills; sometimes a small valley will be dammed and ash slurry pumped behind the dam until filled. Increasing pressure to protect the environment in addition to increasing interest in controlling costs have led the electricity and coal industries to find alternative uses for CCPs. The largest use is in making cement and concrete; followed by wallboard (gypsum), road construction materials, mine fill, blasting grit, soil additive, and structural fill. Importantly, the use of CCP avoids the need to mine or otherwise produce raw materials for these products. In Europe, almost 90% of CCP finds a use, while only about one-third is in the United States.

Environmental regulations have made the reuse of CCP more difficult. First, low NO_x burners increase the unburned carbon in the ash, which concrete manufacturers limit to 6%. Second, NO_x reduction systems that inject urea or ammonia into the flue gases can contaminate the ash, creating handling difficulties. Looking ahead, requirements to produce renewable fuels may lead to cofiring of biomass and coal, which will add simple organic salts to the mostly alumino-silcate CCPs. The importance of this change has yet to be determined.

Power plant operators have learned how to optimize their scrubbers to produce high-quality production by forcing the oxidation of calcium sulfite and adding chemicals that help stabilize the dry mass. Gypsum can be used to make wallboard or cement. It can also be used to mitigate acidification and acid mine drainage due to its alkalinity, or as a fertilizer and soil enhancer in some locations.

Petroleum fuels do create small amounts of ash, which will have more vanadium and nickel. Ash and slag from the combustion of municipal solid waste (MSW) contains much higher quantities of toxics, as well as potentially valuable metals (like copper). The solid waste from fluidized bed combustors will contain unreacted limestone and products of SO_2 and Cl capture, mostly as calcium compounds.

2.4 Land Use

All forms of electricity production as well as electricity transmission require large equipment and considerable amounts of land. High-voltage transmission lines can have a number of important land use implications and the siting of transmission lines in industrialized countries has become extremely difficult. However, transmission lines are necessary to use some resources effectively, and they can reduce the cost of system operation by allowing distant systems to share resources. Land use is the major environmental impact of renewable technologies. Good locations for hydropower and wind turbines are rarely located at demand centers (e.g., major cities), necessitating long-distance transmission and the associated environmental effects.

The amount of land different electricity technologies require depends on how the calculation is done. Key questions include these: Are the impacts of fuel production and transportation included? (Natural gas production can be very disruptive to wilderness areas and biomass may require vast areas for planting.) Are the impacts of waste disposal included? (Nuclear waste storage removes some areas from other uses.) Are the impacts of pollution measured in area? (Coal fired power plants can case acidification across large regions.) Are the impacts of associated transmission included? (Wind power will often have to be transmitted long distances.)

2.4.1 Aesthetic, Cultural, and Equity Concerns

Many people find electric power plants and transmission towers ugly and undesirable to live or work near. For this reason, property near power plants or power lines have a lower value than comparable properties not near power lines. Electricity infrastructure is typically prohibited in parks, wilderness areas, scenic areas, and so forth as well as historic or culturally important locations. An important and related aspect is equity: Why should one community accept a power line (or power plant) when that facility will serve another community? This problem can create tensions between urban dwellers and rural/suburban dwellers.

Concerns about aesthetics and equity are among the largest challenges facing developers of wind power farms and transmission systems. This is exacerbated by the fact that many of the best

potential wind energy sites are highly visible and prized mountain ridges. This problem has forced many new installations offshore.

As income levels rise, the desire for political freedoms and preferences for environmental amenities tend to rise as well, suggesting that aesthetics and equity will play larger roles in electricity projects in the future. This trend may boost technologies that can reduce the visual impact of transmission systems, such as more compact high-voltage direct current transmission systems and underground cables. It may also boost small, distributed generation technologies, which typically are connected to an underground gas distribution system and may require fewer transmission lines.

2.4.2 Land Submergence and Relocation

The environmental impact of hydroelectric facilities differs greatly from other types of electricity generation in that it often requires the submergence of large land areas and relocation of residents and other ecosystem inhabitants. This may be true of both facilities that use impoundments (dams) and run-of-river facilities, since the latter are often built downstream of a dam and rely on moderated river flows of the dam. Unlike other renewable energy sources that utilize a lot of land for energy collection, submerged land is lost completely, along with rivers and creeks. However, a new, lake-like reservoir is created, with its own amenities. Dams can also change the aquatic ecosystems dramatically. Importantly, dams can reduce the hazard of flooding, which can be considerable for settlements in floodplains.

Globally, about 45,000 large dams (>15 m high or 5 to 15 m high with a reservoir of 3 million m^3) exist, along with 800,000 smaller ones. About 100,000 dams worldwide generate electricity, mostly the larger ones. (The remainder are used for irrigation or water supply only.) The total area covered by reservoirs is 0.5 Million km^2, less than 1% of the land used for human habitation and agriculture. Although dam construction in North America and Europe has largely halted (or even reversed), several nations in Africa, Asia, and Latin America have considerable potential and are involved in large-scale dam development.

Reservoirs can submerge homes, farmland, wilderness, polluted sites (possibly liberating the pollutants), cultural features, and appealing landscapes, especially dramatic river valleys. Larger hydroelectric projects tend to have larger reservoirs, but submerge less land per unit of capacity. Dams under 100 MW generally require over 200 hectares per MW of capacity (ha/MW), those from 100 MW to 500 MW less than 100 ha/MW, and those above ,000 MW less than 50 ha/MW.

Relocation of large numbers of people can be very difficult and expensive, and finding new homes (and possibly farms) for them may cause environmental stress. There are often tensions between different groups, such as between urban dwellers (including elites) who will typically get most of the power from a hydro project and rural dwellers who will be displaced. Tensions between different ethnic and political groups have arisen as well. In addition, dam construction often reduces flood risk, inducing settlement on floodplains for the first time. Dams also reduce sediment loads downstream, which can weaken dikes and levies. These conditions can worsen outcomes when flood control measures of dams fail, which does occasionally happen.

2.4.3 Wilderness and Wildlife

Electric power systems can have major impacts on wilderness and wildlife, mostly because fuels or hydroelectric facilities can be located in wilderness areas or because electric power systems in different areas may find it beneficial to interconnect themselves to share resources. In particular, dams and wind turbines can affect wildlife. Submergence of habitat is the most obvious impact. In addition, the roads and power lines needed to construct, maintain, and connect hydroelectric facilities sometimes run through wilderness areas, fragmenting them. The vegetation below power lines must be trimmed, burned, or controlled with herbicides, and there must be access roads for maintenance, all of which have environmental impacts. These effects may reduce the habitat for threatened species, or cause new species (including threatened species) to move into an area. Birds are known to strike transmission towers and lines, but the numbers doing so are usually not very large, and proper routing and design can reduce bird deaths.

Birds have also been known to strike wind turbines, sometimes in large numbers. This problem can be greatly reduced by modern designs that spin slower and by not placing wind turbines in areas that birds use heavily as flight corridors.

Underground and underwater electric cables are becoming more common, most often due to space restrictions, such as in major cities, and partly because of aesthetic concerns. These cables are filled with dielectric oil and are armored. Breaks that leak the dielectric oil are rare and are usually identified quickly. Underwater cables are typically laid 1 or 2 m

below the seafloor using a mechanical plow or hydraulic jet to create a trench, which is then filled in. This alters the seabed, and there are concerns that it might have permanent effects on fisheries and marine wildlife. Trawling and other fishing techniques, repair of the cable, and retrieval at end of life must all be considered.

2.5 Electromagnetic Fields

When electricity is generated, transmitted, or used, electromagnetic fields (EMFs) are created as a direct consequence. These fields can induce small electrical currents in the body, which have been suspected of causing cancer and other health effects. This idea remains controversial, however, since the currents induced by EMFs seem far to small to cause such effects, leading to a suspicion that contact currents and not EMFs may account for the observed effects.

The main sources of exposure to EMFs are wiring and appliances in the home and workplace, and electric power lines (both transmission and distribution). The use of electricity increased for 100 years without any observed environmental effects from EMFs until a 1979 study reported that children living near power lines might have an increased risk for developing cancer. Since then, studies of human populations, animals, and isolated cells aimed at understanding the potential health effects of EMFs have been conducted, but experts are divided about their interpretation.

Three types of scientific evidence have been examined in the effort to understand the possible health effects of EMFs: human epidemiological studies, mechanistic (test-tube based) research, and animal toxicology. The epidemiological studies have shown a small risk of increased childhood leukemia, and possibly adult brain cancer, amyotrophic lateral sclerosis, and miscarriage. No evidence for other health risks has been found. However, epidemiological research can only show associations, it cannot determine cause and effect. The mechanistic and toxicological research has never found any consistent effect. The failure of these two approaches means scientists cannot explain how EMFs might cause health effects.

The degree to which experts believe that EMFs present a health risk depends on how they weigh these three lines of inquiry. Generally, however, scientists who study EMFs feel they is cannot be recognized as entirely safe, sometimes listing EMFs as possible carcinogens. If there is an effect, the risk probably falls just within the range that is considered sufficient to warrant minor regulatory action in industrialized countries. Various bodies have set voluntary guidelines that are designed to limit the induced current density in the body to $10\,mA/m^2$, sometimes reduced to $2\,mA/m^2$ for exposure to the general public. Exposure in the home is typically less than $0.01\,mA/m^2$, while contact with electrical appliances (e.g., razors, electric blankets) can create currents up to $30\,mA/m^2$.

2.6 Other Impacts

Electric power systems can affect nearby people and the environment in a number of less obvious ways. Some equipment creates noise, including wind turbines, transformers, and power lines. There is some concern that this noise could limit the suitability of land under wind turbines for wildlife or livestock. Wind farms can occupy from 4 to 32 ha/MW of capacity, although they typically only use a small percentage of that land for towers and other equipment, leaving the rest free for other uses. Wind turbines can interfere with television and radio signals. Corona effects on transmission system components can create electrical interference, but this is a highly localized effect.

Transmission lines can interfere with other infrastructures and with aircraft, possibly a significant problem in areas where aerial application of herbicides is used. Wind turbines and tall exhaust stacks can also affect aircraft. Dams will change a regions hydrology and may induce excess seismicity. Geothermal electricity production will generally cause subsidence, although this is usually controlled by reinjection of the highly saline water and steam that is brought to the surface for electricity production.

10. Electricity Use and the Environment

Glossary

alternating current This current is produced when flows of electrons are made to shift directions in a constant pattern. It is easier to transmit long distances than direct current, and it is the form of electricity in most homes and businesses.

arc light An early, brilliant form of illumination produced by passing an electric arc between two carbon rods.

direct current This current is created when electricity moves in one direction along a wire. It was most common in the late 19th century; for example, it was used in Thomas Edison's first light and for early streetcars. It still has many applications, for example, in batteries.

incandescent light Light produced from an enclosed bulb by heating a filament until it glows.

In the 19th century, electricity was at first exotic, and then a luxury. Since then it has become a necessity, but paradoxically both the level of demand and the level of use vary considerably from one nation to another. The telegraph (1838), telephone (1876), and broadcast radio (1919) at first spread slowly; as with many later applications, consumers needed time to discover their uses. An interconnected electrical system grew rapidly from c. 1880, with lighting followed in rough sequence by commercial establishments (such as department stores), public buildings, monuments, streetcars, railways, subways, factories, homes, airports, farms, and stadiums. The precise sequence of adoption and degree of penetration varied from one nation to another, particularly in rural areas. Likewise, the intensity of use varied. In c. 1960, Norway, Canada, and the United States consumed more than twice as much per capita as England and France. Continually improved generating efficiencies did much to meet increasing demand while lowering the cost per kWh, until reaching engineering limits in the 1970s. Since then, new efficiencies have been in the appliances and light bulbs consumers use. Nevertheless, rising demand for electric power creates environmental problems that alternative energy sources such as wind mills can only partially solve.

1. INVENTING AND PROMOTING ELECTRIFICATION

Until the many practical applications of electricity that became available in the late 19th century, no single energy source could provide light, heat, and power. Electricity's versatility made it an enabling technology that allowed people in all walks of life—including architects, designers, homemakers, industrialists, doctors, and farmers—to do new things. These new and often unanticipated uses found for electricity mean that its history must include far more than such matters as dam construction, the extraction of fossil fuels, or improvements in dynamo efficiency. One must also consider energy history in terms of demand. Consumers have been an active force behind the expansion of electricity use. If one considers the rapid increase in electricity demand from the middle of the 19th century to the present, one is struck by how this increase parallels the growth of the middle class, the expansion of cities,

the development of mass consumption, and increased demands on the environment. The uses of electricity are more than mere applications; they are inseparable from rising demand, which at times has outstripped the capacity of utilities and led to major programs in demand side management. Indeed, the same pattern repeated itself with the electric light, the electric iron, or the electric vacuum cleaner and a host of appliances and later applications. A new device first became a luxury for the rich, then a desirable item of conspicuous consumption for the middle classes, and, within little more than a generation, a necessity for all.

Practical applications were only possible in the 19th century and after. The understanding of electricity was so rudimentary in the late 18th century that Benjamin Franklin, a clever self-taught amateur in the American colonies, made an important contribution to knowledge by discovering that lightning and electricity were the same thing. The phenomenon of electricity had remained a curiosity since classical times, when static electricity was known but scarcely investigated. Few scientists focused attention on it until after the invention of the Leyden jar (1746), which facilitated a century of experiments that prepared the way for practical applications. Charles Coulomb, Michael Cavendish, Benjamin Franklin, Luigi Galvani, Alessandro Volta, Humphrey Davy, and Andre Ampere developed a rich store of observation and theory that made possible Faraday's studies of electromagnetic induction, which in turn made possible the dynamo (1831). When Faraday was asked whether his experiments would ever result in tax revenue, he boldly declared that they would.

Indeed, during the next half century a series of industries and businesses emerged based on the special properties of electricity. Its movement was so rapid as to be instantaneous, a property exploited by the telegraph, various alarm systems, and the telephone. It could produce electrolysis, making possible metal plating. Electricity could also produce light when passed through certain conductors, eventually making possible arc and incandescent lighting. Electricity provided a way to transmit power over considerable distances, allowing falling water or burning coal to be translated into motive force by distant electric motors. Electricity could also be used to produce precisely controlled heat without fire or the consumption of oxygen, leading to applications in baking, enameling, and industrial heating and burning. Each of these innovations was eventually incorporated into devices used in the home and on the farm.

Given the many potential uses of electrification, it might seem that its adoption was virtually automatic. Such was not the case. As late as 1912, less than 3% of electrical power was residential, whereas almost 80% was used in manufacturing, with the remainder used commercially. Although it might be tempting to treat the history of electrification as the story of inventors producing a stream of practical devices, it was a far more complex developmental process that included government, manufacturing, marketing, and several different groups of consumers. Utilities quickly discovered that large, urban customers were far more profitable than smaller customers in suburbs and the countryside. The spread of electrical service therefore moved from larger to smaller customers, and from urban to rural, in a series of distinct stages. This process began in the 1870s in Europe and the United States and has since spread throughout the world. However, even in the early 21st century electricity has by no means become the dominant source of lighting or power in every location, and in most cases other sources of heat are more economical. If the world's capital cities are electrified, some of the countryside remains in darkness, as revealed by satellite photographs. Indeed, even in the nations in which the process began—England, France, Germany, and the United States—in 1900 almost all factory power still came from falling water or steam, and less than 5% of all homes had electricity. Although in retrospect electrification might appear to have been a steady and inevitable process, closer inspection reveals uneven growth, at times thwarted by competition from gas, coal, and other energy forms. In general, electricity replaced gas for lighting because the incandescent bulb was safer and cleaner than an open flame and because it was more like daylight. In contrast, gas remains a strong competitor to electricity for heating and can also be used for air-conditioning. Yet such generalizations do not apply universally because energy use was inflected by local conditions and by social class. For decades, English workers clung tenaciously to gas lighting, leaving electricity to the middle and upper classes. In contrast, wealthy Swedes were reluctant to give up traditional forms of lighting that they considered genteel, whereas Swedish workers more rapidly embraced the electric light. In 1931, less than 30% of British homes were wired, and few were all electric, at a time when 90% of Swedish homes had been wired. In the United States, most urban but few rural dwellings were electrified by that time, and wiring was less a marker of social class than of geographical location.

From a technical standpoint, electrification was not a unified process that spread like ripples in a pond from certain nodal points. Rather, there were several interrelated processes, which began at many different locations, driven not only by utilities but also by the demands and interests of consumers. Particularly in the early decades, separate systems developed to serve different needs, including small stand-alone generating plants for some hotels, department stores, theaters, and wealthy homes and large, direct current power houses owned by street railways. Until the 1930s, many factories also had their own power stations.

The degree of such fragmentation varied, being considerably greater in Britain than in the United States, for example. In the early 20th century, London had 65 electrical utilities and 49 different types of supply systems. Anyone moving within London risked entering a new grid because there were 10 different frequencies and 32 different voltage levels for transmission and 24 for distribution. Once consumers had converted all the lamp and appliance plugs and made other appropriate changes, they discovered that each utility also had its own pricing system. In the United States, where utilities worked harder to coordinate their systems and interconnect their lines in order to achieve economies of scale, consumers still faced considerable inconsistencies in plug and socket sizes. These were only ironed out in the 1920s with the help of the federal government. Even today, as every tourist knows, the electrical current and the plugs needed to access the system vary among the United States, Britain, and continental Europe, and these three different standards have been reproduced throughout much of the rest of the world.

The large electrical manufacturers, which sold generating equipment and provided technical expertise to new markets, exported these standards. With so many potential customers, the manufacturers did not attempt to enter all markets. Rather, each focused on certain regions, to a considerable degree based on political spheres of influence and colonial empires. For example, General Electric (United States) sold lighting and traction systems to Brazil and much of Latin America, whereas in most cases General Electric (United Kingdom) transferred the same technologies to the British Empire. German and Austrian electrical expertise spread throughout central Europe and the Nordic countries. To some extent, France developed its own systems but relied heavily on investment and partial ownership from the United States.

On the demand side, in all the industrial countries the middle classes developed a demand for electrification in many guises. On the supply side, the electrical industry was an expansive investment opportunity that was more important and longer lasting than the Internet bubble of the 1990s. Between 1875 and 1900, electrical equipment makers and utilities formed the most dynamic sector of the American economy, growing from a few small adjuncts to the telegraph companies into a $200 million industry. After 1900, it grew into a colossus that was inseparable from the health of the national economy. The electrical industry's potential was early recognized by J. P. Morgan and other leading investors who financed Edison's work. Once commercial development began, a flurry of mergers reduced the field from 15 competitors in 1885 to only General Electric and Westinghouse in 1892. Before this time, railroads had been America's largest corporations, demanding the greatest capital investment, but they were a mature industry compared to the emerging electric traction companies, local utilities, and equipment manufacturers.

2. THE TELEGRAPH, ALARM SYSTEMS, AND THE TELEPHONE

The invention of the telegraph in 1838 heralded the first widespread practical application of electricity. However, potential consumers were not certain what to use the telegraph for. Conceived and patented by Samuel F. B. Morse, the telegraph astounded incredulous crowds, and the first telegraph offices often provided seating for the public, who could scarcely believe that it was possible to sever language from human presence. Twenty years after its invention, when thousands of miles of lines linked the United States, the *New York Times* declared that "the telegraph undoubtedly ranks foremost among that series of mighty discoveries that have gone to subjugate matter under the domain of mind" (August 9, 1858).

However, even the inventor of the telegraph did not understand its enormous commercial potential, and he tried to sell it to the federal government. Many European countries chose to make the telegraph part of the postal service, but the U.S. Congress refused, and only after 5 years granted Morse $30,000 to build a line from Washington to Baltimore. People seemed to have little use for it, however, and even when the first line connected New York, Philadelphia, and Washington business still developed slowly. Six months after it started operation, the line averaged less than 2000 words a day, and it was generating

only approximately $600 a week. By 1848, the telegraph linked Chicago to New York, however, and grain traders with immediate access to information soon made fortunes trading in midwestern wheat. In less than a generation, Western Union became one of the largest corporations in the United States. During the same years, newspapers realized the commercial value of Mexican war news and formed an association that inaugurated the wire services. As these examples suggest, the potential of the various forms of electrification was only gradually understood.

During the second half of the 19th century a series of technologies based on the telegraph, such as burglar alarms, stable calls, and door bells, familiarized people with the idea that a current carried over wires could be instantaneously transmitted to virtually any point. However, other practical applications were few because most electricity still came from inefficient batteries. Further use of electricity was limited until large and efficient generators became available in the 1870s. Until then, "impractical" electric lighting was confined to special effects in theaters.

Like the telegraph, the invention of the telephone (1876) at first seemed a curiosity, and Alexander Graham Bell was unable to sell his invention even to Western Union. Setting up on his own, Bell concentrated on businessmen and wealthy households and did not expand service widely until his patent ran out and competition emerged in the 1890s. It took more than a generation before phone companies realized that people wanted phones not just for business and emergencies but also for gossipy conversations. Even so, the telephone took a long time to become a necessity to consumers compared to the electric light. Only after World War II did most American homes have telephones. Even then, they were all black, heavy apparatuses that the subscriber did not own but leased. They were not stylish elements of décor that varied from one home to another but utilitarian objects that were engineered to last decades. In contrast, a greater variety of models were marketed in Europe, despite the fact that universal service only came to some countries during the 1960s, and Spain and Portugal only achieved it at the end of the 1980s. On the other hand, during the 1990s Europeans adopted mobile phones far more quickly than did Americans.

Again, as late as 1919 the U.S. government failed to see the broadcasting potential of radio, understanding it only as a superior form of the telegraph, for wireless point-to-point communication. In the early 1920s, a few amateurs initiated the first public radio broadcasts. Yet even when the potential of a device is grasped, not all societies have made the same choices about how to embed electrical technologies within the social structure. Should suppliers be public or private or a mix of the two? Should pricing encourage extensive or intensive use of a system? What is the best balance between regulation and open competition? Between 1880 and 1900, such questions had to be answered first with regard to public lighting and then street traction systems.

3. PUBLIC LIGHTING

In both Europe and the United States, regular public electric lighting appeared first in the late 1870s as a spectacular form of display in city centers and at expositions and fairs. The first installations were arc lights, which shed a powerful glare over streets and the insides of some stores. Department stores and clothiers quickly adopted such lights because they were cleaner, brighter, and safer than gas and because they proved popular with customers. By 1886, 30 miles of New York's streets had arc lights, installed approximately 250 ft apart. In 1879, Thomas Edison demonstrated his enclosed incandescent bulb, which had a softer glow that was well suited to most indoor and domestic settings. Both arc and incandescent lighting competed with already existing gas systems until the first decades of the 20th century. Edison recognized that his light, its distribution system, and its cost had to be designed to complete with gas. For as much as a generation, some new buildings had both systems. The Edison system was rapidly adopted wherever convenience and fissionability were highly valued, and it spread rapidly into the wealthiest homes, the best theaters, and the most exclusive clubs in New York, London, Vienna, and Paris. However, 20 years after its introduction, the electric light was almost entirely restricted to public places. Less than 1 home in 10 had been wired, and the average person encountered electricity at work, in the street, and in commercial establishments.

From its inception, the public understood lighting as a powerful symbolic medium. The history of lighting was far more than the triumph of the useful. Before gas and electric streetlights people had to find their way with lanterns, and the city at night seemed fraught with danger. Public lighting made the city safer, more recognizable, and easier to negotiate. However, mere functionalist explanations cannot begin to explain why electric lighting had its origins in the theater or why spectacular lighting emerged as a central cultural practice in both Europe and the

United States between 1885 and 1915. As early as 1849, the Paris opera used an electric arc lamp to create a sunrise, and showmen of every description seized on the new medium to attract crowds. During the 1870s, thousands of people turned out to see the first arc lights in Cleveland, Boston, London, and Paris. The new light fascinated them not only because it was so much brighter than existing gas but also because it seemed to violate the natural order. For the first time in history, light was separated from fire. It needed no oxygen. It was unaffected by the wind. It could be turned on in many places simultaneously at the turn of a switch. In 1883, Niblo's Garden featured "novel lighting effects by the Edison Electric Light Company," which included an illuminated model of the Brooklyn Bridge and chorus girls with lights flashing from their foreheads as they flourished electrically lighted wands. Promoters and public alike demanded ever-greater public displays as use far exceeded necessity.

Intensive lighting became a form of symbolic expression at not only theaters but also world's fairs and other public events. Every exposition attempted to outdo all previous efforts by escalating both the scale and the completeness of displays. Intensive arc lighting at Chicago in 1894 gave way to thousands of incandescent lights at Omaha (1898), arrays of colored bulbs in Buffalo (1901), and artificial sunrises and electrical fireworks in San Francisco (1915). Many fairs made illuminated towers their central symbols, notably Buffalo's Electric Tower, San Francisco's Tower of Jewels, and New York's Trylon and Perisphere in 1939. Electricity became more than a theme; it provided a visible correlative for the ideology of progress, and it was placed at the apex of an evolutionary framework, as opposed to "ethnological" villages—compounds representing the life of Mexicans, Cubans, blacks in the Old South, Filipinos, or Africans in the jungle—where the visitor could see staged versions of earlier forms of social evolution. Electrification thus became embedded in a social Darwinist ideology of racial superiority, as darkness represented the "primitive," whereas artificial light exemplified Christianity, science, and progress. At the Buffalo Pan-American Exposition, "the strongest, crudest colors" were nearest the entrances, and there was "a progression from warm buff and ochre walls … through more refined and brilliant hues to … ivory white, delicate blue, greens, and gold" on the central tower.

During the same years, electrical advertising signs spread from a few isolated installations in approximately 1890 to nearly ubiquitous evening displays. Particularly in the United States, main streets became "great white ways" that were more alluring at night than during the day. In each nation, particular locations became famous tourist attractions because of their advertising signs, notably New York's Times Square and London's Piccadilly Circus. In these public squares, the electric sign, the spotlight, and even the streetlight became economic weapons. The competition for attention did not create the majestic serenity of an exposition, dominated by beaux-arts architecture bathed in white light. Commercial lighting produced a potpourri of styles and colors flashing against the night sky. Thousands of individual decisions produced this electric landscape, but it nevertheless had an unanticipated collective impact. Literally millions of lights seen together, particularly from a distance or from the top of a skyscraper, had a strong popular appeal. Electric lighting was also used to dramatize important monuments. One of the most effective early displays was the lighting of the Statue of Liberty in 1886, which made the statue stand out against the darkness of the New York harbor. In the following decades, search lights would be permanently trained on many of America's most important symbols, including many skyscrapers, the White House, Niagara Falls, Old Faithful, Virginia's Natural Bridge, and Mt. Rushmore.

Between 1880 and approximately1920, dramatic lighting transformed the night city into a scintillating landscape that was a startling contrast to the world seen by daylight. Street lighting, illuminated buildings, and electrical advertising simplified the city into a glamorous pattern that signaled more than the triumph of a new technology. By 1920, spectacular lighting had become a sophisticated medium of expression that governments and corporations used to sell products, highlight public monuments, commemorate history, encourage civic pride, and even simulate natural effects.

4. INDUSTRIAL APPLICATIONS

Industry found many uses for electricity, and from 1880 to 2000 it used the preponderance of power in most nations during any given year. Factory electrification began with lighting. Munitions plants and flour and cotton mills quickly adopted electric light because it was far safer than any other form of illumination. Printers, artists, and others whose work required accuracy and true color relations found gas inferior to incandescent light. Factory owners soon realized that light made possible the construction of

large interior spaces without regard for windows. However, if lighting came quickly to the factory, adoption of electric drive required a generation. Existing steam and water power functioned well and cost a great deal to replace. These power sources could not easily be transmitted over more than a few hundred feet, but there were other alternatives. In 1891, to transmit water power 2 km or less, wire rope cost half the price of electricity. At that time, electricity was only cost competitive for networked power systems more than 5 km long. For example, high-pressure hydraulic transmission was a well-established alternative. Introduced by Joseph Bramah in Dublin in 1795, it was applied to cargo handling in many British ports and to centralize urban hydraulic power supply. Hydraulic power was also applied to heavy industry, such as steel production, and water motors using a city water supply could drive small appliances requiring less than 2 horsepower as well as church organs and many elevators in commercial buildings. Milwaukee alone had 600 hydraulic elevators connected to the city water system. Power from illuminating gas also briefly flourished in the 1890s. Clean, safe, compressed air, however, was the most successful alternative to electric power and was well developed in Paris, where in 1899 more than 100 miles of pipe supplied 24,000 horsepower to a wide variety of customers.

Nevertheless, electricity proved so versatile and generation costs declined so quickly that after 1900 it was in the ascendant. An investigation by the Franklin Institute showed why it was preferred. Interestingly, savings in energy costs were considered to be of no great importance since power usually comprised only 1–3% of a workshop's budget. Furthermore, electrical equipment was somewhat more expensive than the familiar mechanical drive, but savings in maintenance and depreciation offset this expense. Electricity's advantages were primarily in creating freedom in the location of machinery, improvements in lighting and ventilation, cleanliness (there were no overhead oil drippings from shafting), reductions in shutdowns, greater precision of electrical equipment, and increases of 20–30% in output as a result of all these factors.

Adoption of electricity in industry varied considerably by nation, however, with the United States taking the lead, closely followed by Germany. Although accurate statistics are difficult to obtain, in 1928 one British expert estimated that 73% of manufacturing power was electrical in the United States compared to 67% in Germany, 48% in Britain, and less for other European countries. Britain particularly lagged behind in iron, steel, and chemicals, but this gap was partly closed during the 1930s, when its economy performed better than that of the United States.

Electricity's versatility extended into virtually all areas of manufacturing. For example, electrolysis enabled silverware manufacturers to coat materials with silver. In coal mines and rock quarries, electric drills were far less cumbersome to move around than drills driven by compressed air or steam. By 1920, many steel rolling mills had installed electric drive and controls that made it possible for one man to guide steel from the ingot furnace to the finished rail. An observer noted, "Every motor replaced a man, but the work is done better and more quickly." In food processing plants, aluminum factories, brass foundries, and potteries, electric furnaces and ovens produced no smoke, consumed no oxygen, and maintained high temperatures precisely. Such factories reduced spoilage and increased throughput.

Electric motors proved especially useful in moving materials, particularly in mines and other closed environments. Electric motors were also adapted to overhead hoists and cranes, and these began to move their loads more freely once overhead drive shafts were removed in favor of electric drive. Indeed, by 1920 electricity had become the basis for a revolution in factory design, brightening and opening up the work space and making possible new work flows, most notably on the assembly line, where electrically powered machines were arranged in combinations that were impossible using older power-delivery systems. This is not to say that electrification necessarily led to a particular form of mass production. Rather, it facilitated experiments and new designs. At the same time, electrification altered the siting requirements of factories, which no longer had to be immediately accessible to rushing streams or coal supplies. Indeed, after the successful demonstrations of alternating current in the 1890s, the short practical transmission range of direct current no longer placed a limit on where power could be delivered. Whereas early generating plants such as Edison's Pearl Street Station in New York had to be near the city or town to reach customers, during the 20th century power stations increasingly were located on the edge of the city or in the countryside. Because transmission lines could reach virtually anywhere, factories and businesses could also move away from railroads and canals to the edge of town or along main highways. Thus, electrification was used to transform both factory layouts and the location of industry.

From a worker's point of view, incandescent lighting reduced the danger of fire, reduced pollution, and made it easier to see, but it also made possible round-the-clock shifts. Furthermore, as electric motors and cranes provided more horsepower to production, they made possible radical changes in the layout of production, most strikingly in the development of Henry Ford's assembly line in 1912, an innovation partly anticipated by Edison's experiments with automating iron mining in the 1890s. The assembly line was literally impossible in any complex industry before machines were freed from the rigid organization required by overhead drive shafts and given the flexibility of electrical devices.

The connection between electrification and mass production at times has been overlooked by historians, who have emphasized scientific management, particularly the work of Frederick Winslow Taylor. It is true that Taylor systematized work and made tasks such as shoveling more efficient. In contrast, Ford's assembly line used electrified machines to eliminate shoveling altogether. Taylor retained piecework, a concept that makes no sense on the assembly line, where all share the same pace. Taylor maximized efficiency in existing production technologies; Ford transformed the means of production. Taylor saved time; Ford sped up time. In 1914, after Taylor imposed his system on the Packard Motor Company, its 4525 workers produced 2984 cars a year, less than 1 per man. This was essentially artisanal production of a luxury vehicle. Ten years earlier, well before the assembly line, Ford produced 12 cars for every worker. By 1914, 13,000 Ford employees, using conveyor belts, electric cranes, and 15,000 specialized machine tools, manufactured 260,000 cars or 20 per worker. Ford's system outperformed Taylor's by more than 2000%.

5. ELECTRIFIED TRANSPORTATION AND THE CITY

As industrial plants grew larger and became concentrated in cities, the urban scale expanded and electricity supplied many forms of transportation. Indeed, it made possible faster and easier movement not only at the street level but also into the sky and down into the earth. The Columbian Exposition of 1894 introduced visitors to electric boats and electrified trains and even installed some electrified moving sidewalks. Although similar sidewalks are found in few places outside airports today, a closely related technology, the escalator, has become almost ubiquitous in department stores and large public buildings.

The clean and quiet electric car initially seemed to be a promising form of urban transportation. A French coach builder, Charles Jeantaud, introduced an electric car in 1894, but it never sold well. In contrast, many American inventors enjoyed initial success, including an "Electrobat" introduced in Philadelphia in the same year. The early leaders were two Hartford-based firms, Pope Manufacturing, which made 500 vehicles in 1897, and the Electric Vehicle Company, which made 2000 electric taxis and several electric trucks the following year. For approximately a decade such vehicles were almost as numerous as fledgling gasoline cars. Even Henry Ford bought an electric car for his wife Clara in 1908. Such vehicles were easier to control than gasoline cars, and with their slower speeds (25–30 mph) and shorter range (60–80 miles) they seemed ideal for women making social calls or shopping but not for men, who demanded faster, long-distance transport. The electric car could easily strand drivers in the countryside, far from any recharging station, and even if one were found recharging took hours. If electric trucks and cars largely disappeared after the early 1920s, however, smaller electric gaffle trucks, golf carts, and indoor delivery vehicles held a niche market. Eight decades later, electric vehicles are still being designed and tested, and hybrid cars are now sold that switch automatically from gasoline motors to electric drive, depending on driving conditions.

Other forms of electric transportation were more widely adopted. Vertically, the elevator made the skyscraper practical, as it carried executives to their preferred offices high above the streets. These offices had electric lights and telephones, their plumbing was supplied with water by electric pumps, and their air could be heated or cooled electrically. The electrified office literally detached executives from the noises, smells, and temperatures of the street.

Horizontally, electric trolleys made a much larger city feasible. In the 1890s, streetcars were faster and cleaner than horsecars, and they could be stopped more precisely and climb steeper grades than cars pulled by steam. Electric cars could easily be lighted at night and heated in winter, and overall their operation cost less than any alternatives. Real estate promoters often invested in or owned traction companies, whose spreading lines defined much suburban and regional development, especially in new cities such as Minneapolis and Los Angeles but also in older metropolises, such as Boston, Copenhagen, or Amsterdam. By

1902, large cities averaged more than 200 trips per citizen per year, and Americans alone took 4.8 billion journeys by streetcar.

In the larger cities, notably Paris, New York, Budapest, and London, the technology of the electric tram was adapted to underground use. Construction began in the 1890s, and millions of commuters and shoppers were literally hidden from view. The subway showed that electric light, power, and ventilation made possible an entire new urban setting beneath the pavement. New department stores added several brightly lighted basement stories, and underground arcades connected some buildings. In Toronto and Montreal, where winter temperatures prevail, such urban designs became particularly popular.

Electrified transport transformed the city, bringing an unprecedented number of rural and urban consumers to the center, which stimulated new forms of entertainment. Vaudeville theaters and movie houses were able to fill thousands of seats several times a day, and new sports arenas (electrically illuminated) drew even larger crowds to see professional baseball, football, and basketball. Traction companies drew some of the crowd to their own amusement parks, which consumed some of their excess electrical output on evenings and weekends. The technology of electrical traction was the basis of the roller coaster, the subterranean tour, and many other rides. Trolley parks spread rapidly after 1888, and by 1901 more than half of all street railway companies operated at least one (often several). These typically generated as much as 30% of the line's overall traffic as well as provided a market for electricity. The trolley made the city the center of an easily accessible network, from the downtown shopping district to streetcar suburbs, the amusement park, and the fringe of rural hamlets on interurban lines.

Urban electrification was not merely a matter of improving existing structures. The electrified city had a fundamentally different built environment than the city before it. At the center were large office buildings, department stores, theaters, and brilliantly lighted public buildings accessible on an expanded scale reaching miles further into surrounding countryside. Practical electrical lighting, elevators, and air-conditioning likewise made it possible to create self-enclosed environments, including the later developments of indoor sports stadiums and shopping malls. The modern city is unimaginable without electricity, which enabled enormous changes its in design.

Yet these changes were by no means the same in all cultures. In the United States, where the automobile became a central form of transportation in the 1920s, the electrified city was quickly modified, sprawling out into the suburbs. In contrast, European cities retained mass transit and bicycles for a generation longer, and as a result the electrified cityscape developed and became naturalized. The urban landscape made possible primarily by electrification (i.e., without intensive use of the automobile) is therefore far more visible in a city such as Oslo than in Los Angeles.

6. PERSONAL USES OF ELECTRICITY

The public became excited by electrical medicine well before Edison had perfected his incandescent light. Electricity seemed to be a mysterious fluid that permeated living organisms, leading Walt Whitman to write of "the body electric." Electricity seemed capable of recharging the body, helping it to overcome a host of diseases and conditions. Neurasthenia and neuralgia became fashionable complaints apparently caused by lack of nerve force, and millions bought patent medicine cures for electrical imbalances. Respected doctors hooked their patients up to generating machines and passed currents through diseased limbs or sought to (re)animate sexual organs. Patent medicines such as Dr. Cram's Fluid Lightning claimed to contain electricity in liquid form so that one could ingest it and revitalize the whole body. By the mid-1890s, magazines such as *Popular Science Monthly* asked, "Is the Body a Human Storage Battery?" So many believed the answer was yes that electrical devices were mass marketed. The *Sears and Roebuck Catalog* for 1901 sold electric belts designed to restore men's sexual powers and to help either sex restore lost energies. Some electrotherapeutic electric belts retailed for as much as $40 and promised a "triple silver plated battery of great power, silver plated nonirritating electrodes, and a very powerful electric sack suspensory." Women bought electric corsets fitted with "magnetic steel" with the expectation that they could mould their figure to any desired form. Even the U.S. Congress had a cellar room in the Capitol building fitted with an electrical medical apparatus. The *Electric Review* noted, "The members say it is splendid after they have exhausted their brain power by speechmaking or listening. A great many members take electricity, and some go to the basement of the Capitol for it every day during the season."

Although these "uses" of electricity are clearly bogus, other applications just as clearly were not. By

the 1890s, it was firmly established that ultraviolet light, either from the sun or from arc lights with special filters, could kill bacteria, and in 1896 Niels Finsen discovered that lupus could be cured by repeated exposure to ultraviolet rays. He won the Nobel Prize for this work in 1903, and such successes seemed to be only the beginning. The Belgian chemist Ernest Solvay proposed that electrical stimulation might accelerate plant growth and increase the yield of crops. Similar ideas inspired experiments by the Nobel Prize-winning chemist Svante Arrhenius. He "tested the effect of electrical stimulation on the growth of children," who, he reported, grew 20 mm more than those in the control group.

When prestigious scientists made such claims, the gullibility of laymen is not surprising, and the enthusiasm for electrical cures lasted well into the 20th century. Despite the efforts of the American Medical Association to discredit them, people bought electrical cures in the 1920s and 1930s. For example, thousands of people paid $60 for an I-ON-A-CO electric collar in hopes of rejuvenation. As this popular faith in electrical medicine suggested, people regarded electricity to be a magical fluid, a nerve-tingling "juice," or an invisible tonic that could restore normal health. From the 1880s until 1920, when few people had wired their homes, electrical medicine offered direct contact with the mysterious force that was transforming work and public life. For approximately half a century, the body literally became the contact zone where men and women explored electricity's possible meanings.

By the time the electrical medicine craze was over, electricity had begun to be used to enable the body in many ways as battery technology improved. Small, lightweight batteries could deliver small but constant amounts of power for a year or more, and starting in the 1950s they first made possible electric watches and hearing aids, and later pacemakers and a host of ingenious medical devices. Slightly larger batteries combined with the new transistors made possible radios that could be carried in a shirt pocket. Consumers have not given up on using electrical devices to reshape their bodies. Some still buy electric belts, advertised on TV in the wee hours of the morning, and attach electrodes to their stomachs with the expectation that they can effortlessly tone up their muscles and look thin. Millions of people pay to use private gyms with Stairmasters and other electrical devices that tell them how long the workout has lasted, monitor heartbeat, and count calories lost.

By the 1990s, improved batteries, weighing less and lasting longer, had become an assumed part of most people's everyday life. They drove electric toothbrushes, cordless drills, and other tools. They powered tiny portable radios, disc players, mobile telephones, and palm desktop computers. They had become essential to thousands of children's toys, even if they were not usually included with those toys when purchased. In outer space, satellites and exploring machines relied on solar-powered batteries to keep them operational for years. In little more than a century, electrical devices had penetrated into the most intimate parts of the body and reached millions of miles into space and, in the process, extended human sight and hearing.

7. DOMESTIC ELECTRIFICATION

In the 1880s, the few domestic consumers of electricity were almost exclusively wealthy, and they chose the new form of illumination as much for its social prestige as for convenience. Some even bought personal generating plants, especially in the countryside. Utilities did not focus on domestic customers until after a generation had passed, during which time a host of appliances appeared that made higher levels of consumption possible. Electric lights alone did not create much demand, but with the marketing of electric irons, fans, toasters, coffee makers, and other devices after 1900, the domestic consumer became more interesting. In the United States, gas continued to supply the vast majority of light and heat to private residences until after 1910, with the major shift to electricity occurring between 1918 and 1929. In Britain, the change occurred later, and as late as 1919 less than 6% of all homes were wired.

In the decade before World War I, the new profession of home economists championed the electrified house, but the domestic market only became particularly attractive to utilities once their overall load curve peaked in the day, creating a need for compensating night demand from homeowners. However, the conversion to electricity was neither automatic nor easy, and in many areas gas remained the stronger competitor, for example, in refrigerators until at least the end of the 1920s and in stoves and home heating until the present. Furthermore, it was not always easy to determine what the consumer would buy. Electric Christmas tree ornaments were a success in the United States but less so in some European countries. Even today, most Scandinavians prefer to put lighted candles on their trees. Electric cigarette lighters caught on in automobiles but not in the home. The air-conditioned bed never sold well,

although there was limited success with electric milk warmers for babies.

Given the uncertainties of public demand, could the electrical utilities create this demand in practice? In Chicago, Samuel Insull showed other utilities that it was possible to build up the load through innovative pricing policies designed to attract a wide variety of customers, whose variable energy use evened out the demand curve and permitted production efficiencies. His variable pricing persuaded large customers, such as factories and traction companies, to abandon their own power systems, creating daytime demand that decreased at night. This created the generating capacity for a large domestic market, where use peaked after working hours.

In addition to Insull, Henry L. Doherty in Denver was another innovator in promotion. Their salesmen marketed electrical devices systematically, selling door to door. They also employed extensive newspaper advertising, built model electric homes that were extremely popular in approximately 1920, and paid for follow-up demonstrations by home economists in schools and at public events. Many people were afraid to use an electric iron, for example, and salesmen were trained to educate consumers and to dispel their fears of the new technologies. They emphasized cleanliness, comfort, convenience, and economy of operation—themes particularly appealing to those responsible for public buildings, especially schools. By approximately 1915, educators were convinced that the air temperature should be 68–70° and that sickness could be controlled through good ventilation. Schools also prepared a new generation of consumers. Students experienced the superior light, heat, and ventilation that electricity made possible, and in class they learned about the scientific background of the new domestic technologies. There were also gender-specific classes: newly invented home economics for girls and shop for boys. Additional domestic appliances made the home an even more attractive market as vacuum cleaners and washing machines became common during the 1920s, followed by radios, stoves, electric phonographs, and refrigerators in the 1930s.

The widespread adoption of labor-saving machines soon spread in Europe. In Britain, by the late 1920s domestic power consumption had outpaced commercial use. France lagged slightly behind and experienced the appearance of electric kitchen appliances as Americanization, although its level of consumption nevertheless was only 40% that of the United States as late as 1937. In that year, Norwegians and Canadians were by far the most avid domestic consumers. They faced long, cold winters but possessed ample hydroelectric resources and as a result used more than twice as much electricity per inhabitant as the United States and four times as much as Germany. Although electrification spread more slowly in some areas than others, once it entered the home it was seldom removed, and by the 1930s it had begun to be seen as a necessity.

U.S. consumption continued to double every decade. *Fortune* noted in a 1969 article on the dangers of brown-outs and utility overloads that "the American likes his home brilliantly lit, of course, and he has a passion for gadgets that freeze, defrost, mix, blend, toast, roast, iron, sew, wash, dry, open his garage door, trim his hedge, entertain him with sounds and pictures, heat his house in winter, and—above all—cool it in summer."

The European pattern of development was much different than the American pattern. In part because of the denser population and in part because electricity was more often considered to be a state service rather than a private business, lighting was widely dispersed because it seemed fair to do so, although the cost was generally higher than in the United States. As with gasoline, the expense of the service discouraged Europeans from adopting a wide range of appliances during the first half of the 20th century. Since approximately 1960, however, the patterns of consumption have converged, and by 2000 a French or German home had much the same repertoire of electrical appliances as one would find in Canada or the United States. Nevertheless, differences remain. What are considered normal and acceptable levels of illumination in many European homes may seem dim to American visitors. Many a temporary resident complains that the owners must have removed most of the floor lamps. In fact, Scandinavians prefer a living room that is dim by American standards. They generally find it cozy to have only small pools of light and a few candles.

8. RURAL ELECTRIFICATION

One of the most striking changes in the past two centuries is the shift away from agricultural life, which rural electrification abetted, although it had begun long before. In 1800, approximately 90% of all Europeans and Americans were farmers; today, farmers comprise less than 4%. Half the United States was still rural until the 1920 census, so much of the decline had little to do with electricity. However, the disappearance of millions of additional farmers was due in large part to the increased

efficiency brought by electrification. Although the scale and organization of individual farms changed continually for 200 years, rural electrification exemplifies the substitution of capital equipment for labor, bringing both reductions in waste (e.g., through refrigeration) and improvements in productivity using such devices as milking machines, incubators, and electric pumps.

Not all applauded these developments. British thinkers, such as G. M. Trevelyan, Vaughan Cornish, and Patrick Abercrombie, developed environmental ideas about the relationship between man and nature. Such thinkers believed that periodic experiences of wilderness could assuage the wounds of urban civilization and therefore attacked the march of electrical pylons across the countryside. In contrast, most agrarians in the United States embraced electrification as a way to reverse flight to the city by bringing new amenities to farmers and small towns. John Crowe Ransom, for example, realized that electrification could make farming more attractive, and Herbert Agar argued that it could bring some urban amenities to the countryside and help preserve the Jeffersonian ideal of equality and independence.

Although the long view makes the process of electrification seem rational and even inevitable, in fact rural electrification was long ignored by utilities, unless prodded by government. Some of Edison's early utilities were in smaller cities, but he quickly realized that the distribution costs for scattered customers were too high. Indeed, the costs were much higher for direct current than for alternating current, which only became commercially available in the 1890s. After that time, in places where rural services were nationalized or subsidized, such as in New Zealand, the countryside was rapidly brought into the grid. In the United States, however, where power was largely privately controlled, more than 90% of all farmers still did not have electricity as late as 1935. Although equipment manufacturers and hardware stores advertised electrical wares to farmers in magazines and displayed appliances at county fairs, few people could buy them because before the 1930s private utilities used most of their resources to electrify urban homes and sponsored few experimental rural projects. The long distances between farms, with only three or four customers per mile, made transmission costs high, and farmers had little money due to the long agricultural depression that persisted throughout the 1920s.

For utilities, this rural poverty was not an incitement to action but a caution against expansion. As a result, by the 1930s electricity had become naturalized as a normal part of daily life in cities, creating a vivid contrast with a countryside still plunged in darkness. New Deal politicians, encouraged by Franklin D. Roosevelt, made rural power a national issue and created a Rural Electrification Administration (REA) that established rural cooperatives throughout the United States. Indeed, one of the selling points for this program was that the nation had fallen behind the successful efforts in Europe to provide electricity to the entire population.

Organizing farmers into REA cooperatives and getting electric lines to their homes were only first steps. A self-sustaining cooperative required higher electrical consumption, and REA coops soon were being visited by "utilization experts," Washington's bureaucratic term for salesmen. Their mission was to convince farmers to buy motor-driven equipment and larger appliances. Customers who never installed more than a few electric lights did not create enough business to enable coops to repay government loans. Washington agencies at first misjudged the farmers, however, and the utilization experts initially pushed heavy farm equipment. In practice, however, only dairies and chicken ranches discovered immediate advantages of electrical equipment. Raising wheat, tobacco, cotton, and many other crops could be done profitably much as before. However, the farmhouse was quite a different story. Farmers adopted washing machines and refrigerators more quickly than urban consumers, and they did so for sound economic and practical reasons. Cities had laundries, but in the country all washing had to be done by hand after water was pumped from a well and heated on a stove. Little wonder half of the REA's customers in the first 3 years bought washing machines, which had a much higher priority than indoor toilets. A 1939 study of the first cooperative in Indiana showed that after 2 years of service 68% had washing machines, whereas only 10% had utility motors; 45% had vacuum machines but less than 1% had bought any machines for agricultural production. Only during World War II did farmers purchase large amounts of such equipment due to manpower shortages and high crop prices. Productivity and profits rose.

Rural electrification was not implemented to drive people off the land but to keep them there by bringing to the country the amenities enjoyed by the city. Paradoxically, however, rural electrification meant fewer farmers were needed. In the United States, people as diverse as Henry Ford, Frank Lloyd Wright, Lewis Mumford, southern Agrarians, and New Dealers all agreed on the desirability of rural electrification

as a means to regenerating life in the countryside. However, in practice relocation programs and rural electrification instead helped make farmers so productive that many became redundant. In the United States, 40% of the population was on the farm in 1930, 15% remained in 1950, and there was only 8.7% by 1960. The percentage kept declining for the rest of the century and fell below 2% in 2000. This transformation cannot be attributed to electrification alone, of course, because mechanization of farm work and transport also played a role. As farmers moved out, however, others began to move beyond the suburbs into the countryside. Although some were hobby farmers, most wanted to escape the city, but they demanded the urban amenities that only electricity made possible, such as indoor running water, washing machines, vacuum cleaners, radio, and television. After 1975, migration into rural America was greater than out-migration, and the trend shows no sign of abating. Thus, rural electrification underlay not only the decline of the farm but also the deconcentration of cities and suburbs.

Most European countries did not repeat this development to nearly the same degree. During most of the 20th century, cities remained more attractive to most citizens, and until at least 1965 those who commuted were more likely to use bicycles, trains, and trolleys than automobiles. At the same time, European Union subsidies made it possible for a higher percentage of farmers to remain on the land, and national land legislation, notably in The Netherlands, often discouraged sprawl into the countryside. In Europe, where rural electrification was first realized, the electrified city remains the focus of life far more than in the United States, suggesting how much cultural values shape the consumption of electricity. Indeed, overall in the 1990s, a North American family was using twice as much energy as its Western European counterpart.

9. AIR-CONDITIONING

The skyscrapers of Dubai or Mexico City would not be habitable without air-conditioning, which has transformed possibilities of life in large areas of the world that are hot during much of the year. Stuart Cramer coined the term air-conditioning in 1904. He developed humidity controls for Southern textile factories, where excessive dryness made threads break easily, creating havoc in production. Cramer focused on ventilation and humidification more than cooling. Willis Carrier, a Cornell engineering graduate, did the most to promote the acceptance of a precisely controlled indoor environment. His Carrier Air Conditioning Company (1908) sold devices that could regulate both a room's humidity and its temperature, and these spread rapidly from textile mills to food processors and breweries.

Engineers used air-conditioning to increase their authority and control in factories. They first insisted on control of the building and later over the activities within. At times, the new technology displaced skilled workers whose tacit knowledge of materials and their response to different atmospheric conditions previously had been crucial to production of such varied things as textiles, macaroni, candy, beer, and cigarettes.

In the 1920s, air-conditioning spread into stores, skyscrapers, theaters, restaurants, and trains, familiarizing the consumer with its benefits and making people more accustomed to an enclosed, artificial environment. By the 1930s, many firms saw enormous potential for domestic sales and began a fierce competition for a market that only developed after World War II. Many early domestic machines did not regulate humidity but focused on cooling only. As a result, the public perception of air-conditioning remained confused, and in 1938 less than 1 home in 400 used it in even one room. After World War II, however, the industry overcame consumer resistance by working with builders and architects and by achieving economies of scale in producing the equipment.

Air-conditioning was not merely something added to existing structures; its use transformed housing design. Builders partially offset the cost of air-conditioning by eliminating attic fans, window screens, sashes, and high ceilings. New homes were often designed to minimize the purchase price, not the operating costs. Sealed windows combined with the heat produced by appliances, television, and the modern kitchen made air-conditioning a necessity, and the resulting electricity demand eventually helped create the national energy shortages of the 1970s.

In 1955, the federal government adopted a temperature policy that in effect required air-conditioning in most of its new buildings. The Federal Housing Association also permitted new mortgages to include it. Two forms of air-conditioning competed in the marketplace. Selling to both home and workplace, the Carrier Corporation led old engineering firms committed to central systems, whereas General Electric and other appliance manufacturers sold smaller units designed for individual rooms. Central systems began to predominate in hot

cities such as Las Vegas, Dallas, and Bakersfield by the 1960s. Air-conditioning reached 24 million homes by 1970. Thereafter, it rapidly changed from being a luxury to a necessity, creating enormous summer demand for electricity. At office buildings such as the United Nations headquarters, floor-to-ceiling windows increased air-conditioning costs by 50%. By 1982, just after the end of the energy crisis, most office towers and more than 60% of all homes had some form of air-conditioning, half of which were central systems for cooling the entire structure. This was high market penetration considering that this technology was unnecessary in areas such as the Pacific Northwest, the northern tier of states, higher elevations generally, and many coastal communities.

10. ELECTRICITY USE AND THE ENVIRONMENT

Compared to burning wood or coal, electricity seems to be a clean and odorless form of energy. Indeed, for generations electricity provided a better alternative to older, more polluting technologies. Unlike gas and kerosene lamps, electric lights left no soot. Clean electric trains eliminated the cascades of soot from steam locomotives. In factories, electric motors emitted far less oil and raised far less dust than overhead drive systems. Hydroelectric plants create energy with no smoke, but unfortunately falling water provides less than 5% of U.S. energy needs and even less in some other nations. Generating electricity in coal-fired power plants causes pollution, even if it is often invisible to consumers. Such plants are usually located far from the sites of consumption, but their smoke, and the acid rain that eventually results, falls on distant consumers.

Fortunately, during the 20th century utilities developed economies of scale, transforming a larger percentage of coal into energy. Gas-fired plants are even more efficient. During the 20th century, the production of electricity became increasingly efficient, which lowered prices and reduced pollution. In New York City, for example, the average residential customer in 1930 paid $29.23 for 404 kilowatt-hours (kWh) of electricity per year, slightly more than 7¢ per kilowatt-hour. By 1956, the average New Yorker's consumption had almost quadrupled to 1536 kWh, but the cost had only doubled to $61.09. For the nation as a whole by that date, the average consumer used much more, 2969 kWh, but paid only $77.19 for it. Electricity became cheaper because engineers found ways to extract more from a ton of coal or barrel of oil. By the 1970s, however, it was difficult to achieve further production efficiencies. Thereafter, the most cost-effective savings lay not in production but rather in more efficient consumption.

Industrial research therefore focused on developing highly efficient products, notably light bulbs, motors, washing machines, stoves, and refrigerators. As a result, during the two decades after 1973 total U.S. energy use increased only 10%, an achievement based more on technological ingenuity than on changes in lifestyle. People did not use fewer appliances, but their new devices were more efficient. Home refrigerator manufacturers tripled the energy efficiency of refrigerators during these two decades, and by the 1990s washing machine electricity use had been halved. However, efforts to become more efficient resembled the mad queen in Alice in Wonderland, who had to run as fast as she could just to stay where she already was. Even greater efficiencies or lower per capita consumption will be necessary in the 21st century as electricity reaches all the world's population. Recognizing this, in 1994 the World Energy Council proposed the idea of national limits in electricity use. It noted that annual electricity use per capita higher than 6 MWh did not seem to improve life expectancy. It therefore suggested that the 30 highest consuming nations should reduce electrical consumption to this level, whereas the rest of the world should not allow consumption to rise higher than this level. Even if these targets are achieved, however, the increased use of batteries in toys and other consumer products poses another environmental problem because the discarded batteries contain highly poisonous materials. The public tends to discard them in ordinary dumps, allowing lead, cadmium, and other toxic wastes to filter into the groundwater.

Overall, demand for electricity poses environmental problems that lay at the heart of the quest for sustainable development. However, whereas coal and oil-fired power plants contribute to global warming and acid rain, new forms of wind mills, solar power, and passive solar heating promise not only to reduce pollution but also to decentralize power production, moving it closer to the consumer. In the future, as in the past, production of electricity will prove inseparable from its use.

Glossary

centrifugal The motion away from the center of rotation. Centrifugal fans, pumps, and compressors use centrifugal action to create pressure differences that result in the flow of fluids.

harmonics Electrical voltages or currents with frequencies that are integral multiples of the fundamental frequency, e.g., 150 cycles/second is the third harmonic in a 50-cycle system.

power factor The ratio between real power (measured in watts or kilowatts) and apparent power (the product of the voltage times the current measured in volt-amperes or kilovolt-amperes), expressed either as a decimal fraction or a percentage (0–100%). In the case of pure sinusoidal waveforms (i.e., not distorted by harmonics), the power factor is equal to the cosine of the phase angle between the voltage and current waves in an AC circuit. This value is known as the "displacement" power factor (because it deals with the displacement in time between the voltage and current). If the power factor is less than 1, more current is required to deliver a unit of real power at a certain voltage than if the power factor were 1. In the case of waveforms that include harmonics, the harmonic current adds to the total current without contributing to the real power, so the power factor is reduced. This higher current is undesirable because the energy lost to heat in the wires supplying power is proportional to the square of the current. In motors and other inductive loads operating in AC circuits, the current wave lags behind the voltage wave.

three-phase alternating current (AC) The flow of electrons back and forth along the conductors making up a circuit; the frequency of the alternation is 50 cycles/second in most of the world and 60 cycles/second in North America. Three-phase AC circuits have three conductors, each having an alternation at the nominal frequency, but the voltage waveforms in the three phases are offset from each other by 120° (equally out of phase around the 360° cycle).

Electric motors, devices that convert electrical energy to mechanical energy, power a wide range of applications in all sectors of the economy. Electric motors take over half of the world's electrical energy as their input. In this article, how the most common types of electric motors work, their development and application, and their trends in energy efficiency are described.

1. HOW ELECTRIC MOTORS WORK

All electric motors convert electrical energy into mechanical energy, typically in the form of a rotating shaft; they operate through the interaction of magnetic fields. The operation of the most important motor types is described in this section.

1.1 Induction Motors

1.1.1 Squirrel-Cage Induction Motors

The vast majority of the motors used in industry are squirrel-cage induction motors (Figs. 1 and 2) due to their low cost, high reliability, and fairly high efficiency. These motors also use more of the total electrical energy than any other motor

type in homes and buildings. The three-phase induction motor, invented in the 1890s, is composed of three sets of stator (the stationary part of the motor) windings arranged around the stator core (a stack of steel laminations with slots for the windings).

There are no electrical connections to the rotor (the rotating part of the motor), which means that there are fewer wearing parts to maintain and replace. When the three stator windings are fed by a three-phase alternating current (AC) supply, a rotating magnetic field is generated, the rotating speed of which is determined by the frequency of the power supply and by the number of magnetic poles of the motor. If the motor is fed by 60 Hz and has two pairs of poles as in Fig. 1, the speed of the rotating field will be 1800 revolutions per minute (rpm). When the rotating field crosses the squirrel-cage rotor (so named because the cylindrical shape of the conducting rotor bars resembles a squirrel cage), the variable magnetic flux induces currents in the rotor bars (hence the name induction motor), which leads to a pulling torque in the direction of the rotating field. The rotor accelerates to a speed close to the speed of the rotating field speed (synchronous speed), but never is able to reach it. If the two speeds were equal, there would not be a change in the magnetic flux (of the stator relative to the rotor), and thus no induced currents, and therefore no torque. The induction motor speed decreases by a few percent when the motor goes from no load to full-load operation. The full-load speed is a function of the motor design and power and is usually in the range of 94–99% of the synchronous speed; the difference is the "slip." Figure 2 shows the typical construction of a squirrel-cage induction motor. The rotor squirrel cage, detached from the steel laminations can also be seen.

1.1.2 Wound-Rotor Induction Motor

Large induction motors can also have a wound rotor. As the name suggests, these motors feature insulated copper windings in the rotor, similar to those in the stator. This type of induction motor was once used in industrial applications in which the starting current, torque, and speed needed to be precisely controlled. In such applications today, squirrel-cage motors with variable-speed drives are much more commonly used.

1.2 Synchronous Motors

Synchronous motors, as the name implies, rotate at a constant (synchronous) speed. The rotor of this type of motor is a wound rotor, which receives the excitation (magnetizing) current from its excitation system (a separate direct current source with controller). Synchronous motors, although they are more costly and require more maintenance compared

to induction motors, are used in applications requiring constant speed (such as in the textile fiber and paper industries), a high degree of operating efficiency, and a controllable power factor. The last two factors are particularly important above 1000 kW. Synchronous motors are often used in large plants to drive the central air compressor. A large synchronous motor can be used to control the power factor of the whole plant, compensating the lagging power factor of a large number of medium and small induction motors.

1.3 Motor Efficiency

It must be emphasized when considering the energy efficiency of electric motors that the motors are part of a system. The loads (cooling, movement of fluids or materials, etc.) imposed on the system are worthy of attention, as well as the motor-driven process or equipment designed to meet those loads: both influence to a large extent the overall efficiency (units produced or service provided/kilowatt-hour) of the system. Automatic controls in industry and other sectors can reduce labor intensity and thus increase productivity, as well as increase energy efficiency.

1.3.1 Motor Losses

Part of the electrical energy supplied to the motor is not converted into useful mechanical energy, ending up instead in losses released to the outside of the motor in the form of thermal energy (Fig. 3). There are four different kinds of losses occurring in a motor: electrical, magnetic, mechanical, and stray. These losses can be reduced by using quality materials as well as by optimizing the design. The electrical losses are of the type I^2R (the product of the square of the electrical current I and the resistance R of the stator and rotor), and they increase rapidly with the motor load (because current and load are roughly proportional). These electrical losses can be decreased by increasing the cross section of the stator and rotor conductors. Magnetic losses occur in the steel laminations ("iron") of the stator and rotor. They can be reduced by increasing the cross section of the iron in the stator and rotor and by using thinner laminations and improved magnetic materials. Mechanical losses are due to friction in the bearings, ventilation, and windage (air-drag) losses. They can be decreased using low-friction bearings and improved fan design. Stray losses are due to leakage flux, nonuniform current distribution, mechanical imperfections in the air gap, and irregularities in the air gap flux density. They can be reduced by optimal design and careful manufacturing.

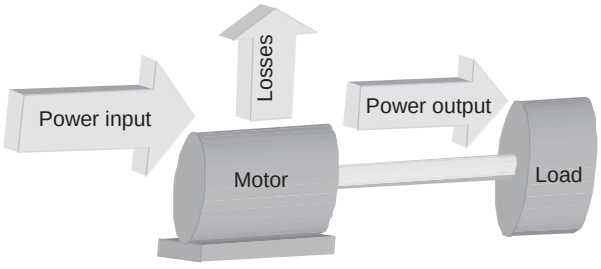

FIGURE 3 Power flow in a motor system (efficiency = output power/input power).

1.3.2 Energy-Efficient Motors

After World War II and until the early 1970s, there was a trend to design motors that minimized the use of raw materials (namely copper, aluminium, and silicon steel). These motors, although inefficient, had lower initial costs and were more compact than previous generations of motors, but due to their low efficiency, their running costs were higher. By the mid-1970s, electricity prices started escalating rapidly. Most of the large motor manufacturers started offering a line of energy-efficient motors in addition to standard-efficiency motors. Efficiency improvements have now been achieved in the standard motor range. There is competition in the market based on motor efficiency. Energy-efficient motors (EEMs) feature optimized design, more generous electrical and magnetic circuits, and higher quality materials. Incremental efficiency improvements are still possible with the use of superior materials (e.g., amorphous silicon steel) and optimized computer-aided design techniques. EEMs typically have 30–50% lower losses (this translates into 2–10% better efficiency, depending on motor horsepower) compared to the equivalent standard motors. EEMs normally carry a price premium of around 20–25% in relation to standard motors. This translates into a price premium of $5–22/kW (U.S. dollars). In a new application, and for a motor with a large number of operating hours, the payback time is normally under 2 years.

Because the reduced losses result in lower temperature rise in the motor, the lifetime of the motor winding insulation, of the bearings, and of the bearing grease increases. Reliability therefore increases, leading to less down time and reduced maintenance costs. Lower losses also provide the following advantages:

- Better tolerance to thermal stresses that typically result from stalls or frequent starting.

- Increased ability to handle overload conditions.
- Better resistance to abnormal operating conditions, such as under- and overvoltage or phase unbalance.
- Higher tolerance to poorer voltage and current wave shapes (e.g., harmonics).
- The ability to use smaller cooling fans, allowing quieter motor operation.

1.3.3 Proper Motor Sizing and Selection

Motors rarely operate at their full rated load. Field tests in the United States and Europe indicate that, on average, motors operate at around 60% of their rated load. Induction motor efficiency typically peaks near 75% of full load and is relatively flat down to the 50% load point. Motors in the larger size ranges can operate with reasonably high efficiency at loads down to 30% of rated load. In Fig. 4, the efficiency and power factor values at partial load points are shown. The adverse effect of the reduction of power factor due to oversizing is often neglected. Motor oversizing is a major reason for the low power factor of some industrial operations. Unless the reactive power is compensated for each motor, the additional line losses from higher currents due to oversizing are an additional incentive for proper motor selection. The original equipment manufacturers (OEMs), who are responsible for choosing the motor in the first place, as well as the users, who influence the buying phase or the replacement of failed motors, should consider that the design criteria leading to oversizing can result in higher first and operating costs, especially when a motor has a working point far below 100% of rated power. Oversizing can also lead to an increase in the mechanical power used by the load. The operating speed is dependent on the applied load, and the loading imposed on a motor is in turn dependent on its size. For example, a 25% loaded 100-kW motor could be replaced by a 50-kW motor with a 50% load factor or a 25-kW motor with a 100% load factor. The oversized motor operates at higher speed, due to having a smaller slip. For centrifugal fans and pumps, even a minor change in the motor's operating speed translates into a significant change in imposed load and annual energy consumption. For most fans, the belt drive between the motor and the fan can be changed to obtain the correct fan speed; most pumps are direct drive, so the motor size, slip, and efficiency must all be carefully considered to make the best selection.

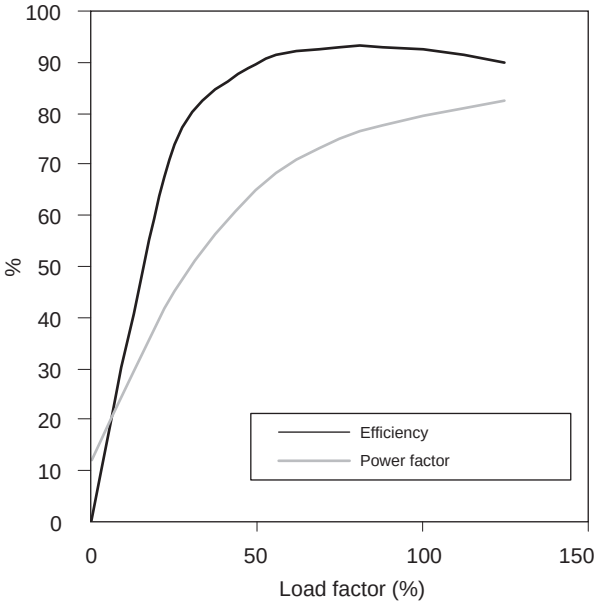

FIGURE 4 Typical efficiency and power factor versus motor load.

2. DEVELOPMENT OF ELECTRIC MOTORS AND THEIR ROLE IN INDUSTRIALIZATION

2.1 Early Motors

The first practical electric motors date back to the late 1800s. They were driven by direct current (DC) supplied by nearby generating plants. The early DC systems were superseded by alternating current, due to the ease of transmitting AC power generated centrally and to the simplicity of the AC induction motor, which was invented in the 1890s. Soon, DC motors were relegated to niche roles, especially when speed and motion control were needed (e.g., elevators and electric transportation).

2.2 Motor Evolution

2.2.1 Effect of Materials and Technology

The ability of the original motor winding insulation systems to withstand high temperatures was limited, so motors needed to be large, efficient, or both in order to keep the insulation from being damaged. As synthetic insulation materials were developed in the mid-20th century, higher operating temperatures were acceptable, allowing motors to be designed with lower operating efficiency, as noted in Section 1. In the 1970s and later, with renewed interest in efficiency, special steels were used in the magnetic

core to reduce energy losses there; computer-aided design and other techniques were used to design and build more efficient motors. The advent of inexpensive power electronics in the late 20th century made controlling the speed of AC motors easy and made DC motors with permanent magnets practical and efficient in applications ranging from residential furnace fans to drive motors for electric cars (see Section 4). Ongoing work includes motors that use high-temperature superconductors in the windings to further increase efficiency and motors that are extremely small (so-called nanomotors, because their size is on the scale of a nanometer).

2.2.2 Energy and Labor Considerations

For most of the 20th century, decreasing electricity costs and the evolution in insulation materials together put downward pressure on motor first cost and efficiency. Decreasing motor first cost and increasing labor rates meant that repairing motors in the United States and Europe gave way to simple replacement, especially for small motors. The electric motors that drive factory and construction equipment have been fundamental contributors to increases in worker productivity.

2.3 Role in Industrialization

2.3.1 Fluid Motion

The movement of fluids (collectively, liquids and gases) is the largest application for electric motors throughout the world.

2.3.1.1 Fans Fans are used for moving air at relatively low pressures; they are sized from a few watts for cooling small computers to megawatts for forcing combustion air through boilers at electric power plants. Fans are commonly used in systems that heat, cool, and ventilate buildings in which people live, learn, and work.

2.3.1.2 Pumps Pumps are used for moving liquids, most commonly water; they are sized from a few tens of watts for circulating water for heating homes to tens of megawatts for supplying drinking water to large cities. Industry uses large numbers of pumps for moving cooling water and a wide variety of liquid chemicals.

2.3.1.3 Compressors The most common use of compressors in industry is for making compressed air for operating air-powered (pneumatic) tools and processes. A very common type of compressor through all sectors of the economy is the refrigeration compressor, used for ice making, air-conditioning, and food refrigeration. The scale of these compressors ranges from below 100 W for small household refrigerators to over 1 MW for large building air-conditioning systems.

2.3.2 Materials Transportation

Electric motors power conveyor belts, slurry pipelines, and pneumatic and air-blown systems used in the transport of all types of materials.

2.3.3 Materials Processing

In industry, materials are processed by a wide variety of electric motor-driven equipment such as grinders, saws, drills, crushers, stampers, shears, and lathes.

2.3.4 Transportation

Electric motors are widely used throughout the transportation sector. Electric railroad locomotives and diesel–electric locomotives both use electric motors in the low-megawatt size range. Likewise, streetcars and subways typically use DC motors, though there is a trend toward the use of AC induction motors with inverter drives. Electric and hybrid electric automobiles use AC induction motor/inverter drives or permanent magnet motors in the range of tens of kilowatts. Elevators, escalators, and people movers provide vertical and horizontal transportation in buildings, all powered by electric motors. Many ships are propelled by electric motors, supplied by onboard generating plants.

3. CURRENT STATUS OF END-USE APPLICATIONS OF ELECTRIC MOTORS

3.1 Common End Uses

3.1.1 Industrial Sector

In the industrial sector, motor-driven loads use about three-quarters of the total sector electricity use (74% of 2007 TWh/year for the United States and European Union combined). Common end uses are dominated by pumps and material processing, with air compressors and fans making significant contributions (see Fig. 5).

3.1.2 Commercial Sector

In the commercial sector (known as the tertiary sector in Europe), 37% of the electricity is used in

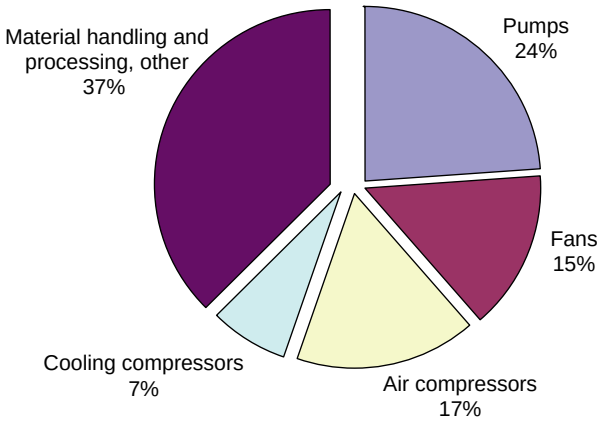

FIGURE 5 Industrial sector motor electricity use in the United States and European Union. Data from Nadel *et al.* (2002) and the University of Coimbra.

motor systems (out of a sector total of 1540 TWh/year for the United States and European Union combined); the dominant end uses are fans, air-conditioning, and refrigeration (see Fig. 6).

3.1.3 Residential Sector

In the residential sector, the dominant end uses in the United States are space conditioning (heating, fans, and air-conditioning) and refrigeration; motor-driven end uses require 38% of the residential sector's total of 1192 TWh/year (see Fig. 7). In Europe, a slightly higher fraction of the residential electricity is estimated to flow into motors.

3.2 Evolving End Uses

3.2.1 High-Performance Motion Control

In many industrial applications (e.g., robotics), there is increasing use of high-performance permanent-magnet or switched-reluctance drives (see Section 4 for more on these drives). With the advent of vector drives (inverters that separately control the speed and torque of AC induction motors), many applications (e.g., elevators) that were the stronghold of DC motors are giving way to simpler and more efficient AC motors.

3.2.2 Increasing Use of Speed Control

The cost of inverters for speed control (see Section 4) is continuing to decrease, and the reliability is increasing as the circuitry becomes more integrated (more functions on fewer components). As a result, the controls are becoming standard in many applications in homes, commercial buildings, and industry

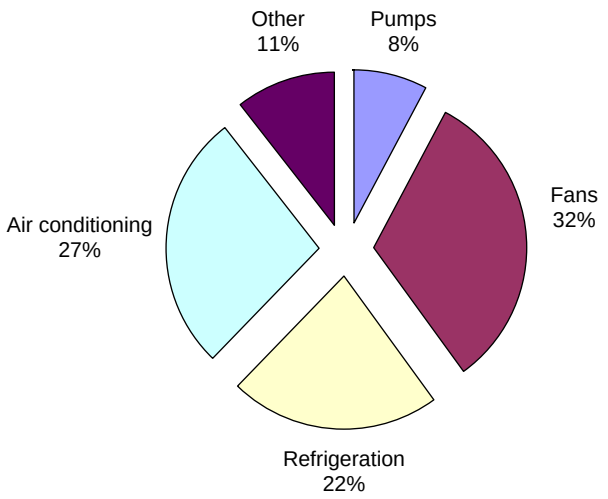

FIGURE 6 Commercial (tertiary) sector motor electricity use in the United States and European Union. Data from Nadel *et al.* (2002) and the University of Coimbra.

that formerly used on/off cycling or throttling to match output to load. Examples include residential furnace fans, ventilation fans, and air-conditioning compressors in office buildings, and many industrial applications. A continuing challenge is the control hardware and especially software to take full advantage of the improved process control and energy-savings opportunities offered by speed control.

3.2.3 Electric Transportation

3.2.3.1 Rail Due to the availability of powerful and compact inverters, there is an increasing tendency to use AC induction motors with inverter drives rather than DC drives. In the future, high-speed rail will include magnetic levitation trains (using magnetic repulsion to float the cars above the

guideway) that use a linear motor to propel the cars along the guideway.

3.2.3.2 Road Electric and hybrid electric vehicles use sophisticated water-cooled drives that include regenerative braking to increase energy efficiency. Some designs use AC induction motors and some use permanent-magnet motors. These will continue to evolve as hybrid vehicles move from internal combustion engines to fuel cells as the primary power source.

3.2.3.3 Air The National Aeronautics and Space Administration in the United States is flying unmanned airplanes powered by numerous electric motors that gather their electricity from onboard solar–electric panels and fuel cells. These can fly at very high altitudes for long periods and could eventually perform many of the functions of satellites at much lower cost.

4. ENERGY EFFICIENCY TRENDS

4.1 Technology

4.1.1 Permanent-Magnet Motors

In the last decades of the 20th century, new technologies led to the introduction of new motor types that have some performance and efficiency advantages over induction motors. Permanent-magnet (PM) motors have a stator winding configuration similar to the three-phase induction motors, but they use permanent magnets in the rotor instead of a squirrel cage or wound rotor. The permanent-magnet rotor tracks with synchronism the stator rotating field, and therefore the rotor speed is equal to the rotating magnetic field speed. A wide variety of configurations is possible, and the two-pole version can be seen in Fig. 8. Motors of this sort have output ranging from about 100 W up to 100 kW. The key advantage of the permanent-magnet motor is that no excitation power is required for the rotor and therefore its efficiency is higher, compared to the induction motor. Early permanent-magnet motors, besides being very expensive, suffered from the tendency of the magnets to be demagnetized by the high stator currents during starting, and from a low maximum allowable temperature. Much improved versions using rare-earth magnets have been developed since the 1970s to overcome these problems. Rare-earth alloys (neodymium, iron, and boron),

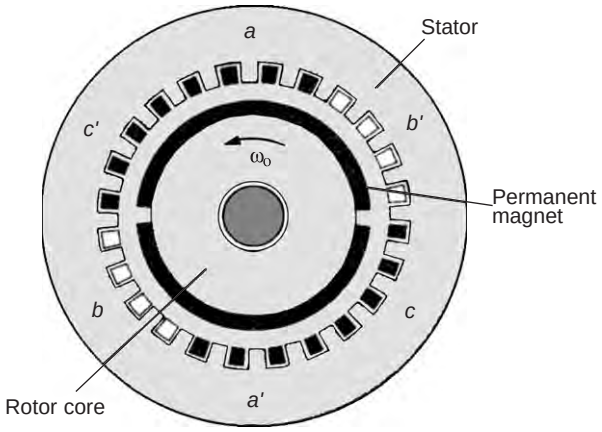

FIGURE 8 Permanent-magnet motor: two-pole version. See text for discussion.

developed in the mid-1980s, have allowed an increase in performance with a decrease in costs. For starting from a fixed-frequency supply, a rotor cage is required; such motors are referred to as "line-start" motors. Because there are no electric and magnetic losses in the rotor, there is less heating than in a conventional motor, so higher specific outputs can be achieved. The rotor inertia can also be less than that of an induction motor rotor, which means that the torque/inertia ratio is better, giving a higher acceleration. The torque-to-weight ratio, the steady-state efficiency, and the power factor at full load of PM motors are in most cases better than those of the equivalent induction motor, and they can pull in to synchronism with inertia loads of many times rotor inertia.

Although better efficiency and low-speed performance can be obtained with permanent-magnet synchronous motors, there would need to be a significant reduction in the cost of rare-earth permanent-magnet material for these motors to the replace induction motors in most applications. Permanent-magnet motors are in most cases used with electronic speed controls, normally called brushless DC (BLDC) motors. In the BLDC motor, the stator winding currents are electronically commutated (switched) by digital signals from simple rotor position sensors; these motors are also known as electronically commutated motors (ECMs) The stator winding also creates a rotating field that creates a rotating torque by pulling the permanent-magnet rotor. This combination permits the motor to develop a smooth torque, regardless of speed. Very large numbers of brushless DC motors are now used, particularly in sizes below 10 kW. The small versions (less than 0.75 kW) are

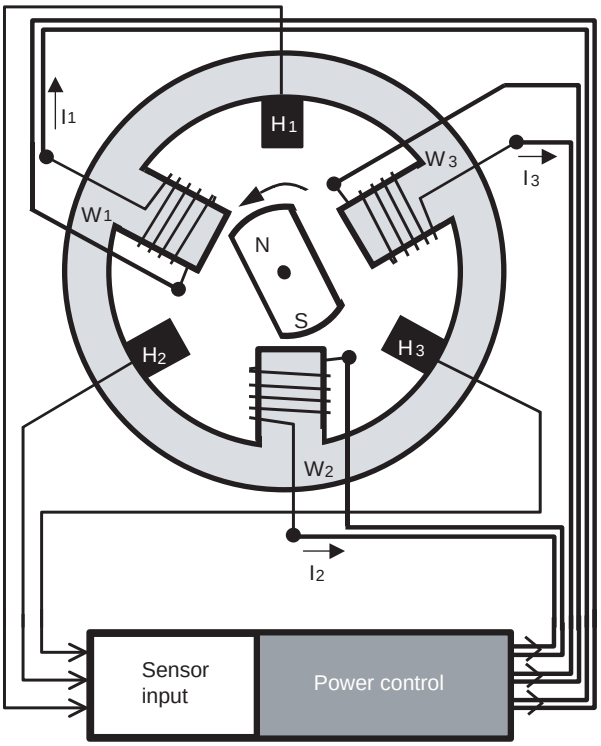

FIGURE 9 Control system scheme of a brushless DC motor. H_1, H_2, and H_3 are magnetic position sensors.

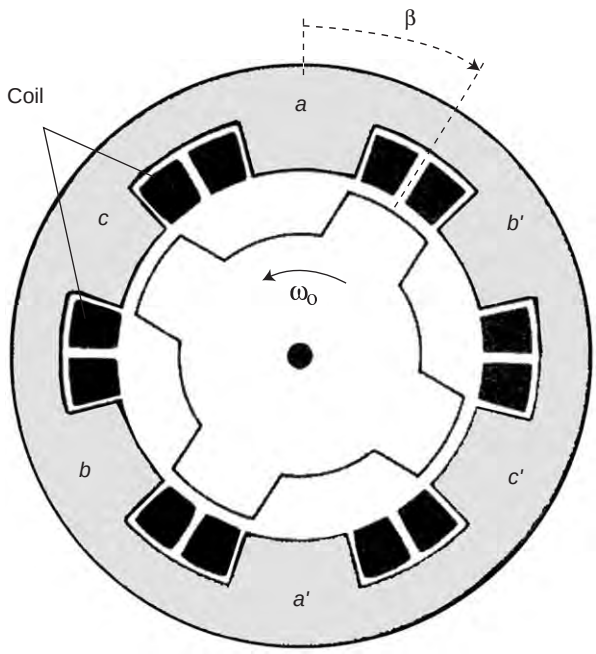

FIGURE 10 Switched-reluctance motor configuration.

increasingly made with all the control and power electronic circuits integrated at one end of the motor. The typical stator winding arrangement and the control scheme are shown in Fig. 9.

Many brushless motors are used in demanding servo-type applications (e.g., robotics and high-performance systems), in which they need to be integrated with digitally controlled systems. For this sort of application, complete digital control systems that provide torque, speed, and position control are available. New applications such as energy-efficient elevators with direct-drive (gearless) permanent-magnet motors are also entering the market.

4.1.2 Switched-Reluctance Motor

The switched-reluctance (SR) drive is a recent arrival (ca. 1990s) on the drives scene, and can offer advantages in terms of efficiency, power density, robustness, and operational flexibility. The drawbacks are that it is relatively unproved, can be noisy, and is inherently not well suited to smooth torque production. Despite being recent, SR technology has been successfully applied to a wide range of applications, including general-purpose industrial drives, traction, domestic appliances, and office and business equipment.

In the switched-reluctance motor, both the rotor and the stator have salient (protruding) poles. This doubly salient arrangement proves to be very effective as far as electromagnetic energy conversion is concerned. The stator has coils on each pole, the coils on opposite poles being connected in series. The rotor, which is made from machined steel, has no windings or magnets and is therefore inexpensive to manufacture and extremely robust. The example shown in Fig. 10 has six stator poles and four rotor poles, and represents a widely used arrangement, but other pole combinations are used to suit different applications. The motor rotates by energizing the phases sequentially in the sequence a–a', b–b', c–c' for clockwise rotation or a–a', c–c', b–b' for counter-clockwise rotation, the "nearest" pair of rotor poles being pulled into alignment with the appropriate stator poles by reluctance (the alignment of a metal object with a magnetic field) torque action. In this way, similar to PM motors, the rotor synchronously tracks the stator rotating magnetic field.

As with the PM motor, the SR motor has no electric or magnetic losses in the rotor. Therefore, the overall efficiency is generally higher compared to induction motor efficiency. The SR motor is designed for synchronous operation, and the phases are switched by signals derived from a shaft-mounted rotor position detector. This causes the behavior of the SR motor to resemble that of a BLDC motor.

Because the direction of torque in a reluctance motor is independent of the direction of the current, it means that the power converter can have fewer switching devices than the six required for three-phase bipolar inverters used in BLDC motor. Some of the early SR motors were deemed to be very noisy, but improved mechanical design has significantly reduced the motor noise.

4.1.3 Speed Controls

Most induction AC motors operate at fixed speed. However, most motor applications will benefit if the motor speed is adjusted to match the process requirements. Motor speed controls are the devices that, when properly applied, can tap most of the potential energy savings in motor systems. Motor speed controls are particularly attractive in applications in which there is a variable fluid flow. In many centrifugal pump, fan, and compressor applications, the mechanical power grows roughly with the cube of the fluid flow; e.g., to move 80% of the nominal flow, only half of the power is required. Centrifugal loads are therefore excellent candidates for motor speed control. Other loads that may benefit from the use of motor speed controls include conveyers, traction drives, winders, machine tools, and robotics.

Conventional methods of flow control used inefficient throttling devices such as valves, dampers, and vanes. These devices, although they have a low initial cost, introduce high running costs due to their inefficiency. Several speed-control technologies can be used to improve motor system operation. Electronic variable-speed drives (VSDs) are discussed in detail here because they are the dominant motor speed-control technology.

As was mentioned in Section 1.1, the speed of the rotating field created by the induction motor stator windings is directly linked with the frequency of the voltage applied to the windings. Electronic variable-speed drives can produce variable-frequency, variable-voltage waveforms. If these waveforms are applied to the stator windings, there will be a shift of the torque–speed curve, and the same slope of the linear operation region of the curve. In this way, the motor speed is proportional to the applied frequency generated by the VSD (Fig. 11). Figure 12 shows the general configuration of most VSDs. The three-phase alternating current supply is initially converted to direct current, then filtered, and, finally, the DC/AC inverter converts the DC voltage to the variable voltage and variable-frequency output applied to the motor. The adjustment of the motor speed through the use of VSDs can lead to better process control,

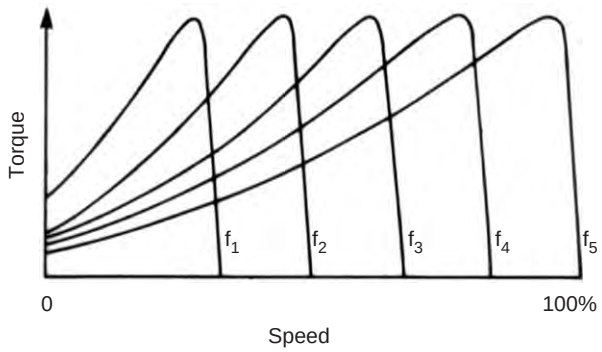

FIGURE 11 Speed–torque curves for an induction motor ($f_1 < f_2 < f_3 < f_4 < f_5$ and $f_5 =$ normal line frequency).

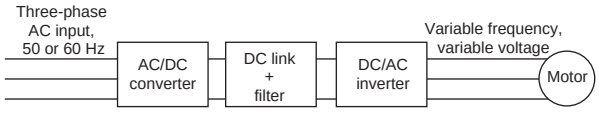

FIGURE 12 General configuration of inverter-based variable-speed drives.

less wear in the mechanical equipment, less acoustical noise, and significant energy savings. However, VSDs can have some disadvantages, such as electromagnetic interference (EMI) generation, current harmonics introduction into the supply, and the possible reduction of efficiency and lifetime of old motors.

There are five basic types of power electronic VSDs: two voltage-source (pulse-width modulation and six-step) types, two current-source (force-commutated and load-commutated) types (typically for large motors), and cycloconverters (typically for large-motor, low-speed applications). Of these, the pulse-width-modulated VSD has come to dominate the market.

4.1.3.1 Pulse-Width-Modulated VSDs The pulse-width-modulated (PWM) voltage source inverter is widely accepted as giving the best overall performance below power levels of 1 MW. The PWM inverter maintains a nearly constant DC link voltage, combining both voltage control and frequency control within the inverter. The objective of the sinusoidal PWM is to synthesize the motor currents as near to a sinusoid as economically possible. The lower voltage harmonics can be greatly attenuated, and therefore the motor tends to rotate more smoothly at low speed. Higher order harmonic motor currents are limited by the motor inductance (the tendency to resist changes in current). Torque

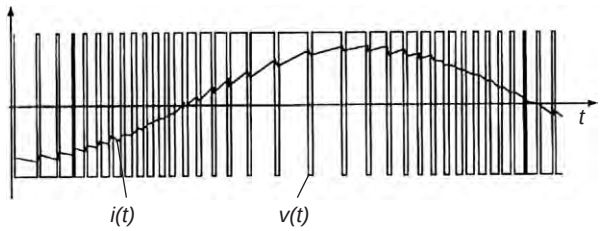

FIGURE 13 Illustration of a sinusoidal pulse-width modulation technique.

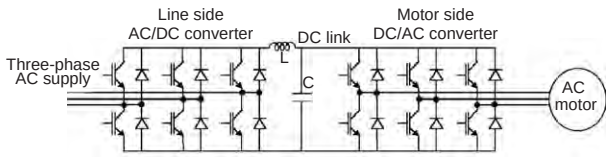

FIGURE 14 Power circuitry of a voltage source inverter pulse-width modulator with regenerative capacity and power factor control. Whereas conventional VSDs use diode rectifiers in the input stage, regenerative units use insulated gate bipolar transistors (IGBTS) at both the input and the output stages to allow bidirectional power flow.

pulsations are virtually eliminated and the extra motor losses caused by the inverter are substantially reduced (see Fig. 13).

The advantages of the PWM VSD are the good displacement power factor throughout the speed range, low distortion of the motor current, wide speed range, and, with proper circuitry, regeneration capability, which allows the motor to absorb energy from the load, generate electrical power, and feed it back into the electrical supply. When the power rating is large and/or when the motor may have to operate for long periods of time in the regenerating region, the line-side converter can be modified to allow regeneration, feeding power back to the line by reversing the direct current in the DC link. New (ca. 2000) PWM circuitry (Fig. 14) allows for the braking energy to be injected back to the source. This feature can be a way of saving a significant amount of energy in applications with high speed/high inertia (e.g., centrifugal separators) and/or long time operations in the braking mode (e.g., elevators, downhill conveyor belts).

4.2 Policies to Promote Energy-Efficient Motor Technologies

Experience from many energy-saving initiatives around the world shows that the most successful programs to achieve the potential savings are based on a combination of technical information, financial incentives, voluntary agreements, and, in some cases, the use of regulation. Strategies involving education, technical support, financial aid, and legislative standards can be pursued.

4.2.1 Education and Training

More education on energy efficiency is needed on many fronts. The information gap should be filled through several means:

- Media, including advertising, trade press releases, direct mail, electronic mail, Web site, and exhibitions; the mix of these depends mainly on the available budgets, with care taken to examine the possible impacts.
- Publications, including a selection of materials from short and simple introductory leaflets and brochures to guides, handbooks, journals, and software; detailed technical information may be needed to satisfy more experienced personnel. Literature should be issued and distributed by manufacturers, trade associations, distributors, energy agencies, etc.
- Training and workshops.
- Dissemination of educational materials, not only through existing energy agency databases and via the media (paper-based products, software programs, and Internet information), but also third parties such as trade associations and equipment suppliers, groups with tremendous potential leverage.

4.2.2 Provision of Technical Assistance

Decision support tools, such as user-friendly software tools, are required for more standardized comparison of efficiency and economics of system configurations. These include support tools for product selection, such as the U.S. Department of Energy's Motor Master and (for Europe) the European Database of Energy-Efficient Motors (EURODEEM) for motors, guides that help users to select particular equipment for an application.

On-site assessment and assistance can provide motor users with information describing their savings potential. Energy-saving publications frequently use comprehensive measurements to ensure the reliability of the figures presented, but in practice most site personnel will have the time and resources only for much simpler measurements. Demonstration projects and pilot actions can be very helpful. One key factor that limits the adoption of energy-efficient technologies is the scepticism about their viability. People doubt equipment durability, performance, and real savings. There already are many demonstration projects and case studies on the

application of EEMs and VSDs; additional demonstration projects aimed at new technologies as well as easier access to the results of existing actions are needed.

4.2.3 Financial Tools

Tax incentives, including tax reduction and accelerated depreciation on efficient equipment, e.g., with VSDs, would be very effective measures to promote efficiency. Another market mechanism for improving energy efficiency involves the development of the energy service company (ESCO) industry. Energy service companies are often privately owned, nonregulated organizations that contract with a utility or an end user to assess, finance, and install energy conservation measures. The financial mechanism used by ESCOs for encouraging the use of their services is performance contracting. The ESCO takes as payment a share of the energy cost reduction, based on either engineering estimates or measurements. Yet another mechanism, rebates, is now seen primarily as a short-term measure to help stimulate the market for energy-saving products; this served in North America as a very useful precursor to legislation on minimum motor efficiency standards.

4.2.4 Efficiency Standards

The establishment of minimum efficiency standards for motors, for end-use devices, and for motor systems is an important market transformation tool. These standards are particularly effective for OEMs, obliging them to incorporate efficient devices in their equipment. A case in point in the United States is the mandatory motor minimum efficiency standards (Energy Policy Act), enforced in October 1997, as well as minimum efficiency standards for appliances dominated by motor use (e.g., refrigerators and air conditioners).

Glossary

cascading failure A disruption at one point in a network that causes a disruption other points, leading to a catastrophic system failure.

critical infrastructure protection (CIP) Activities and procedures designed to avoid, prevent, detect, resist, and recover from deliberate attacks on electric power systems.

distributed generation (DG) Electricity production near point of use, typically with small (<10 MW) generators using natural gas. One form of embedded generation.

energy management system (EMS) System of sensors, actuators, communications, and computation hardware and software used to operate an electric power system. Key functions include generation scheduling and control, transmission system analysis and control, and operator training.

outage A temporary suspension of electric service; a loss of electric power.

security The ability of electric power systems to withstand accidental, sudden disturbances such as electric short circuits or unanticipated loss of system elements.

stress Electric power system conditions more severe than those considered in reliability planning analysis, that is, outside of typical operating conditions in industrialized countries. These may include deliberate attacks, multiple failures, persistent failures (or attacks), and conditions that make system restoration difficult (i.e., a lack of spare parts).

survivability The ability of a system to fulfill its mission in a timely manner, despite attacks, failures, or accidents by detecting, resisting, and recovering from attacks. Survivable systems are likely less vulnerable to stress.

The rise of terrorism around the world and the persistence of inadequate investment or maintenance in some areas have given rise to concerns about how to safeguard key infrastructures (energy, communications, banking, roads, etc.). Electric power systems are among the most difficult to protect because of their complexity. The concept of critical infrastructure protection is still relatively new and is likely to evolve over time, possibly away from a "guards, gates, and guns" defensive approach and toward a design approach that yields systems that are inherently harder to successfully attack. Such survivable systems may feature distributed intelligence, control, and operations.

1. DEFINING THE PROBLEM

Deliberate attacks on electric power systems occur around the world, although their character and magnitude vary greatly. In the industrialized world, such events are small and infrequent; they pale in comparison to the largest weather-related events. Modern war-fighting includes tactics and weapons designed to damage electric power systems, but preparation for war is outside of the power system planning processes. Thus, attention paid to deliberate attacks on electric power systems is relatively scarce. However, the growth of terrorist acts within

 © 2004 Elsevier Inc. All rights reserved.

developed countries since the late 20th century has raised concerns about critical infrastructure protection (CIP) for power, fuel, telecommunications, transportation, and other systems.

Even less attention is paid to the reconstruction of power systems damaged by conflict and in places where political tensions may result in frequent deliberate attacks in the future. The most obvious terms for these issues, reliability and security, have different, well-established meanings in electricity system planning. Thus, we will use CIP to refer to activities and procedures designed to avoid, prevent, detect, resist, and recover from deliberate attacks on electric power systems. The understanding of the CIP implications for electric power systems is rather limited, and the ability to manage the threat of deliberate attacks even more so. Significant research and development efforts are expected over the coming decade, with subsequent deployment of new approaches and technologies.

Electricity cannot be stored economically, so generation and consumption must be matched at every instant. In addition, electric power systems must be managed so that several other parameters (including voltage, reactive power, and frequency) remain within specifications at all times. Not only can these parameters change extremely quickly, electric power systems are typically large interconnected grids that are vulnerable as a system due to the possibility of cascading failures in which a small number of failures in a network cause other failures, leading to widespread disruption and outages. Another key feature of electric power systems is that they are inherently vulnerable to attack since they extend over great distances, often through relatively isolated areas. Further, transmission systems are extremely complex with many custom-designed and hard-to-replace components, including transformers, switches, and relays. These components are monitored and operated by technicians both in the field and at central control centers using electronic systems while other groups form electricity markets that use different computer networks. These applications open up the possibility of cyber attack on electric power systems.

To better understand CIP, it is necessary to introduce three key concepts. The first is reliability and how electric power system planners have dealt with normal failures in the industrialized countries. The second concept is stress, and why planning for reliability must change when the system is under stress. The third concept is cascading failures of the electric power system and how they relate to reliability planning and stress.

1.1 Reliability

These constraints make CIP a greater challenge in electric power systems than in any other part of the energy sector. However, the necessity of dealing with these constraints during normal operations has result in a long history of reliability planning, which includes consideration of both normal operation under reasonable expectations of intended operating conditions (adequacy) and of limited disturbances due to weather and occasional equipment failure that are unplanned but not unexpected (security). These conditions fairly well describe most conditions in high-income countries, but they do not describe a variety of situations now considered important in both high- and low-income countries (see Table I). Frequent deviations from intended operating conditions in industrialized countries is defined as a condition of stress, which includes deliberate attacks, multiple failures, persistent failures or attacks, and conditions that make system restoration difficult (e.g., a lack of spare parts). Cascading failures are still largely excluded since stress is a planning concept and concerned with improving reliability under stress, not an operating concept, unless the stress is directly linked to a change in the probability and magnitude of cascading failures.

Generally, reliability concepts are thought of first when CIP is considered by the electric power industry. However, traditional concepts related to electricity reliability may not be appropriate for achieving protection of critical infrastructures from deliberate attack. There are two main reasons for this; first, the assumptions made in reliability analysis about single point failures may not be realistic; second, some attack modes do not necessarily result in service outages, which is the focus of reliability planning.

In the past, reliability concerns have been handled from the supply side under the fairly restrictive assumption of a single mode failure. The goal that planners adopted was to protect generators and transmission and distribution networks from the ill effects of an equipment failure or natural disturbance (e.g., a tornado). Thus, practice is to have available at all times more capacity than actually needed in order to deliver power to the end users under both normal and a limited set of abnormal conditions. The reserve capacity typically required under the single failure mode assumption is sufficient for the largest single generator or transmission system component to fail without causing either damage to other equipment or a loss of power to any customers. This rather brute force, reliability-through-redundancy approach has

TABLE I

Modes of Disturbance in Electric Power Systems

Mode of disturbance	Possible causes	Likely characteristics	Likely impacts
Weather related damage[a]	Hurricanes, tornadoes, floods, ice storms	Random, not repeated, not targeted, regional	Impacts T & D primarily. No long term impacts on failure probabilities, magnitudes, or durations; recovery only hampered by environmental conditions
Equipment failure[a]	Trees, animals, or vehicles contacting power lines, unanticipated wear	Single events occur randomly, but at a known, acceptable rate	Reduces the equipment available to the system by one component; managed to obtain desired balance of cost and reliability
System-wide direct conflict damage	Civil war (e.g., Bosnia), guerilla movement	Persistent, system-wide, impacts all levels of system	Both failure probabilities and magnitude of damage high, recovery difficult and expensive due to continuing conflict
Regional direct conflict damage	Regional insurgency	Persistent but localized, impacts all levels of system	Failure probabilities and magnitudes increase in affected region, recovery difficult
Localized direct conflict damage	Terrorism or sabotage	Targeted, repeated (lower frequency), less damage per attack on average, less damage to large generators	Failure probabilities increase, magnitudes do not increase greatly except for the most extreme acts, recovery relatively unhampered
System-wide indirect conflict damage	Civil war (e.g., Bosnia), guerilla movement	Mobility hampered, increased nontechincal losses creating financial problems	Failure probabilities increase, magnitudes of failures do not increase, recovery more difficult
Regional indirect conflict damage	Regional insurgency	Regional mobility hampered, increased nontechnical losses, financial problems	Failure probabilities increase, magnitude of failures do not increase, recovery more difficult
Lack of investment in new capacity	Capital access, investment uncertainty	Units need to be run more often and for longer as reserve margins decline, transmission system strained	Possible increase in failure rates over time
Poor maintenance	Capital and spare parts access		Failure rates increase over time, repair times increase

[a] These disturbances are part of reliability planning. All others are stress conditions.

proven effective in the past, but its efficacy is challenged both by the advent of restructuring and the potential for terrorist or other military attacks.

The rationale for a supply-side approach to reliability was that by protecting the electricity supply system; the concerns of most end users would automatically be accommodated. These concerns were quantified with reliability indices. However, these indices do not differentiate among the very different needs of the end users, nor are supply-side measures alone likely to meet the needs of all customers. For instance, a sag in voltage that lasts no more than a fraction of a second would go unnoticed by most end users but could be a serious event for some. Eliminating such sags from the supply side is difficult, if not impossible. Similarly, procedures for measuring indices ignore outages less than a minute long, even though a few milliseconds of lost power may be sufficient to interrupt or damage electronic equipment.

No matter what the cause, power outages impose significant costs on electricity users, while there are

significant costs to electricity companies for avoiding outages. Lowering outage rates raises electricity costs, especially for high levels of reliability. Choosing an acceptable level of outages based on supply costs as well as the costs of outages is a key decision for power system planers and regulators. For instance, typical average outage rates in the Untied States are 1.4 outages per year, and a total time without power of about 3.5 hours per year. About half of the time without power is due to problems with the local distribution system and about half are associated with the transmission system.

In the past, a balance between outage costs and reliability costs has been struck through a political/legal process of some sort, whether by a Ministry deciding on power system design and prices or by a public service commission setting rates for private power companies who operate within a set of (usually voluntary) reliability guidelines. While this approach has been effective, it has also served the interests of utility managers in both public and private systems. In public systems, reliability through redundancy meant higher budgets and more employees, generally seen as markers of status in government bureaucracies. In private systems, reliability through redundancy served shareholders by tending to increase the size of the ratebase, and thus profits.

However, it is not clear how this balance will be struck if and when privatization and competition are used to guide most investment and operating decisions in the power sector. Voluntary reliability requirements could be harder to implement, although competition may lead to flexible, lower cost alternatives. CIP adds a new concern to this balancing act; actions to prevent or mitigate deliberate attacks may raise the cost of electricity service directly through new expenses or indirectly by limiting the flexibility of firms to innovate or economize. Minimizing cost increases due to CIP is an important goal—protecting a country's homeland security should not slow its economic growth unduly. A further complication will be deciding who pays for what fractions of the cost of CIP. This will be an area of research, development, politics, and practice for some time.

1.2 Stress

Stress differs from the modes of disturbance analyzed in typical reliability planning in several important ways, as seen in Table I. Since electrification occurred first in industrialized countries and has been studied most extensively there, analysis of the electricity sector reflects conditions in industrialized countries. Typical conditions in low-income countries have not been well studied. In addition, deliberate attacks on infrastructure have not been a significant concern in industrialized countries until relatively recently, so these conditions have not been well studied either. This article focuses on deliberate attacks, which will include one or more of the following general characteristics (to different levels of intensity).

1.2.1 Coordination of Attack

Unlike equipment failures or even extreme weather events, deliberate attacks are not short-term, random events. Both militaries and terrorists alike have the capabilities to coordinate attacks and intentionally maximize damage to the system. For example, the Farabundo Marti National Liberation Front (FMLN) was able to interrupt service to up to 90% of El Salvador at times and even produced manuals on disrupting electricity systems. Attacks can also be repeated as system components are repaired.

1.2.2 Scope of Impacts

The failure of distribution equipment within a half mile of the customer is the cause about half of the outages in the United States. However, in conflict situations, remote transmission lines, generating stations, and transformer substations can also become primary targets or be impacted by indirect damage stresses. The nonconflict stresses discussed earlier (e.g., poor access to spare parts) would also have a wider scope of impacts.

1.2.3 Persistence of Outage

Deliberate attacks may not be single events, and they may occur under conditions (or create conditions) that make restoration of service and repair more difficult. Alternatively, conditions could be created that make even necessary routine maintenance more difficult. When outages do occur, a number of factors can cause them to persist for days or even longer. Such factors would include risks to personnel, impeded transportation of personnel and parts, lack of funds for replacement parts, absence of technical expertise, and the possibility of subsequent sabotage. Long outages are not considered normal by electricity planners in industrialized countries (a sustained interruption is generally classified as one that lasts more than 1 hour, there is no classification level for longer outages).

1.3 Cascading Failures

Large-scale blackouts result from cascading failures, which occur when equipment failure or other disruption cause further failures or disruptions in large portions of the power grid. These events are relatively rare but potentially very costly. Reliability planning is meant to avoid creating situations in which a cascading failure is even possible while accepting that some localized (normal) outages will occur. However, such cascading failures do occur in industrialized countries and are not unique to stressed systems or to concerns about CIP. Reliability improvements may reduce the probability of cascading failures but will not eliminate them, and it may be difficult to determine the precise impact of reliability improvements on the frequency and size distribution of cascading failures.

Changes in electricity system planning to account for stress should reduce the higher incidence of normal outages that would otherwise be expected under these conditions. Avoiding cascading failures is still a goal, but planning for stressed systems is considered with wider impacts of stress and over much longer timescale than any individual cascading failure. In some places, rolling blackouts may already be the norm rather than the exception. These are not the result of cascading failures but are imposed in a controlled fashion on a regular basis due to inadequate generation. In fact, cascading failures may not even be a major concern for many stressed systems. In a tightly coupled, interconnected, and generally well-functioning system like in the United States, cascading failures are a real possibility and concern. On the other hand, the infrastructure in many places may be only loosely interconnected, which may make widespread cascading failures less likely. As a result, electric power systems under stress may or may not suffer cascading failures at a higher rate depending on the context, but they will suffer more and possibly longer localized outages.

2. TURNING OUT THE LIGHTS

One of the primary concerns for CIP in electric power systems is preventing outages, particularly large blackouts. There is much to be learned from the study of past outages. Contingency planning, spare equipment preplacement, emergency preparedness training, and temporary personnel transfers tend to be the keys to recovery from large outages. Power companies often loan trained workers in emergencies under fairly informal arrangements, knowing that they are likely to need to make such requests themselves someday. Several aspects of successful management of electric system outages have been identified: planning, training, analysis, and communications. However, communication during and after an event might be difficult, especially if, as discussed later, the attack is not on the physical part of the electric power system but on the information technology (IT) components.

The experience of several high-profile outages reinforces the need for planning and leadership. One of the largest such event in U.S. history was the Great Northeastern Blackout of 1965, which shut down New York, as well as much of Ontario and New England after an equipment failure. New York City was blacked out for an entire night, and about 30 million people were directly affected. The National Opinion Research Center studied this event and discovered the following:

> *An outstanding aspect of public response to the blackout was the absence of widespread fear, panic, or disorder. There is probably little question that this absence is largely due to the ability of individuals to interpret their initial encounter with power loss as an ordinary event…. Of equal importance in maintaining order was the rapid dissemination of information about the blackout.*

A smaller outage in New York City in July 1977 was far more troubling. Although outright panic did not emerge, there was considerable looting in some parts of the city. At the time, crime had been increasing and there was a general sense of insecurity in New York City. Some of the looting occurred due to poor response by the police, leaving some areas of the city more vulnerable. The 1977 blackout was frightening in ways that ordinary electricity outages are not, suggesting that there *can* be troubling social responses to turning out the lights. In contrast, the August 2003 blackout in the northeastern United States, the largest outage to date, did not generate terror. Commentators who had lived through both the 1977 and 2003 events noted that a more positive attitude in New York pervaded the second time.

There are three primary concerns in protecting the electric power system from an intended failure: physical security, cyber security, and fuel security. Each will be discussed in turn.

2.1 Physical Security

Many CIP concerns are about possible disruption of electric service, or turning out the lights. In places where deliberate attacks on the power system and

interruption of service are frequent, both everyday life and economic development can be damaged. However, it is not clear if an attempt to turn out the lights would permit terrorists to create widespread panic or the shock associated with violent attacks on symbolic objects that cause loss of human life. Electricity customers in most industrialized countries lose power for an average of couple of hours per year. For the most part, individuals and society cope with these outages well. Power companies respond rapidly to restore service, and facilities that have special needs for reliability (e.g., hospitals and airports) typically have backup generators.

There is some experience with large physical damage from natural forces. For example, in January 1998 an ice storm struck southeastern Canada, New York, and New England, felling 1000 transmission towers and 30,000 distribution poles while sending thousands of tree branches into power lines. This event left 1.6 million people without power, some for more than a month. Almost a quarter-million people had to leave their homes to take shelter and at least a dozen people died (mostly due to loss of heat or suffocation from faulty temporary heating setups). Insurance claims reached approximately $1 billion Canadian. This event, although massively destructive, did not cause panic or shock.

It is difficult to imagine a terrorist organization amassing the capability to accomplish damage on this scale, but a terrorist attack could nonetheless be larger and more long lasting than typical equipment- or weather-related problem, and multiple attack modes could be coordinated for maximum effect. Critical points exist in the electricity infrastructure (especially among transmission and substation assets) where attacks could cause more damage. A U.S. National Research Council panel found that "a coordinated attack on a selected set of key points in the system could result in a long-term, multistate blackout." Furthermore, the ability of the electric power sector to deal with coordinated attacks on the system is lacking. As noted by the U.S. National Electricity Reliability Council, "most (electricity sector) members do not have in place business recovery plans that include procedures for dealing with widespread, well-planned attacks on physical facilities. Likewise, they do not include procedures for dealing with deliberate attempts to hamper repair and restoration activities."

High-voltage transformers have been long identified as a key vulnerability in electric power systems, but due to the cost of stockpiling, few spares are available. It might be possible to develop modular, flexible transformers, but this goal is frustrated by the tendency of different power companies to insist on unique standards and often on customized equipment for every situation. The trend toward restructured markets may exacerbate this problem, as noted by a U.S. National Research Council panel, "Deregulation has encouraged efficiency, invested-cost utilization and return on investment rather than redundancy, reliability and security. For the same reasons, power companies keep fewer spares on hand." Other problems have also been identified. Spares are often kept at the substation site, increasing the possibility that an attack will also result in damage to the spares. If spares have to be ordered from the manufacturer, the customized nature of the transformers may mean the units could take a year or more to manufacture. Delivery could also be lengthy given that transformers are increasingly being manufactured in a small number of countries (e.g., China).

Even so, it is not clear if a highly successful physical attack on an electric power system would have the same social effect as terrorist attacks that claim lives or focus on symbolic targets. Responses would likely include outrage and a sense of vulnerability, but evidence from large-scale blackouts indicates that panic and shock do not generally ensue.

2.2 Cyber Security

Traditionally, information technology (IT) in the electric power sector has been considered less vulnerable to attack (at least by outsiders) than the transmission grid. This is partly because power sector IT systems often consisted of dedicated systems without interconnection to other computer networks and with built-in redundancies. However, systems may be more vulnerable to attack due to their use of dialup modems and the Internet. For instance, in January 2003 an Internet-transmitted computer virus infected and disabled several computers at the Davis-Bessie nuclear power plant, although this problem apparently presented no safety concerns.

In the electricity industry, energy management systems (EMS) monitor and control the production, transmission, and distribution of electrical energy. This includes scheduling and controlling generators and monitoring and analyzing the transmission network in order to provide power while maintaining reliability of the system. Competition is leading to more and more use of electricity markets to make decisions about what power plants will be operated when. Since markets are typically open, it may be

impractical (or simply expensive) to verify the identity and reliability of all participants, exacerbating the problem.

Concern about EMS arises because of their use of open protocols, increased use of intelligent devices, and lack of encryption. Remote systems receiving control signals from the control center often do not verify such signals for authenticity. Instead of relying on traditional means to protect these systems, information security typically has relied on uncommon, often proprietary protocols and the need for considerable hard-to-obtain knowledge about operating systems and so forth. However, such measures are insufficient, particularly when one considers the insider threat problem. An employee with the proper knowledge could create serious problems and face minimal resistance from the system due to lack of encryption and authorization requirements.

2.3 Fuel Security

Electric power systems vary in how vulnerable they are to fuel supply disruption. Four major fuels are used: coal, natural gas, uranium, and renewables (wind and water). Each has a different vulnerability to deliberate attack. Several important distinctions between fuel distribution and electricity transmission systems are relevant. First, it is possible to store fuel but not electricity. Second, system stability concerns in electric power systems have no real analog in fuel supply systems. Third, fuels usually have a number of alternate delivery paths, while electricity transmission systems often have few, and some electricity generators can switch fuels. Fourth, almost all of the components of electricity transmission and distribution systems are aboveground, while much of the natural gas delivery system is buried.

2.3.1 Coal

Coal is the fuel least vulnerable to deliberate attacks because it is produced in many locations, can be shipped by multiple means, and can be easily stored. In addition, coal supply systems are made up of large and relatively robust capital equipment. Coal is transported by a variety of means. Rail dominates, and other major modes include river barge and truck. Coal-fired power plants may often have multiple supply routes available to them, although one mode will tend to dominate and generally only that mode will have coal-handling capacity sufficient for long-term supply. Coal can be readily stored on site and coal-fired power plants typically have three to eight weeks of fuel supply on hand. For power plants built at coal mines, fuel security is obviously less of an issue, although these plants may require more transmission assets.

2.3.2 Petroleum

Overall, petroleum supplies are considered more vulnerable to deliberate attack than coal supplies, but less than natural gas. The most important vulnerabilities are in refineries and pipeline pumping stations, only a limited number of which typically supply any particular region. Although petroleum production (wells) and shipping (tankers) can and have been attacked (for instance, the destruction and ignition of many of Kuwait's oilfields by retreating Iraqi forces during the 1992 Gulf War), they are numerous and operate through a global market, so substitutes may be relatively readily found. An additional problem is that several chokepoints vulnerable to mines or other types of attack exist on ocean petroleum shipment routes, including the Straits of Malacca, Bosporus Straits, and Strait of Hormuz.

Table II shows the percentage of electricity generation that is fueled by imported oil for the 10 nations with the greatest fraction. (This table and the next two only consider countries with large imports.) The United States accounts for over 24% of world oil imports; however, those oil imports contribute less than 2% to the total electricity generation and so is not included. In contrast, for the next largest oil importer, Japan, electricity generation accounts for

16% of oil imports. Seven countries rely on oil imports for over 10% of their electricity generation.

2.3.3 Natural Gas

The gas supply system is more vulnerable to deliberate attack than coal or petroleum supplies, but it is more robust than the electric system. It is less vulnerable than the electricity system because it is mostly buried underground, it can be used to store gas (line pack), and it can use relatively secure depleted oil and gas wells for storage. Like the electricity industry, companies in the gas business have long recognized and effectively planned for contingencies that mitigate terrorism. Spare parts are generally kept on hand to effect quick repairs. However, the potential vulnerabilities in gas system supply are illustrated by the August 2000 rupture and explosion caused by corrosion in a 30-inch gas pipe near Carlsbad, New Mexico, killing 12 people. This explosion led to significant increases in gas prices in California, exacerbating the electricity crisis there. The U.S. National Transportation Safety Board subsequently determined that decades of inadequate testing and maintenance by the pipeline company caused the mishap.

Table III shows the percentage of electricity generation that is fueled by imported gas for 11 countries with the highest percentages. Due to the regional nature of gas supply, generation is shown for each major gas supply region. Eleven countries rely significantly on imported natural gas for electricity generation. Russia is a key supplier to many of the European countries that rely on natural gas imports for electricity generation. Algeria is a significant supplier for Italy, Belgium, Spain, and Turkey; while the Mideast is the key supply region for Japan and South Korea.

Considering Tables II and III together, two countries rely on imported oil and gas for over half of their electricity generation (Belarus and Italy). For comparison, the United States uses imported oil and gas for about 4.3% of its electricity generation, over half of which is from Canada.

2.3.4 Nuclear

Although nuclear power plants are operating in about 30 countries, uranium fuel is not available in all of them. Although refueling is infrequent (every 18 months or so for most reactors) it does involve risks of deliberate attack associated with production and shipping. The Table IV shows the countries most reliant on nuclear power for their electricity generation and the countries with the greatest known reserves of uranium. The top seven countries, ranked in order of nuclear contribution to electricity generation, have no uranium resources whatsoever (e.g., France, Ukraine, Korea, Germany, Japan, Spain, United Kingdom). However, uranium deposits exist in many countries and are available in significant quantities in several stable democracies.

Considering oil, gas and uranium, six countries import more than half of the energy they use for electricity generation. If coal imports were considered, this number could be larger. Further, given likely policies to limit greenhouse gas emission, gas imports are likely to rise substantially in many nations.

2.3.5 Renewables

Renewable energy sources have little, if any, fuel supply vulnerabilities. However, water impounds behind dams may be a source of concern due to the potential for damage downstream if a large dam is breached. The typically large distances between major renewable energy sources (e.g., rural or offshore locations where wind turbines are both economic and politically acceptable) and major electricity demand centers (i.e., cities) produces an

inherent risk due to the likelihood of producing energy in remote, uninhabited areas and the necessity of long-distance transmission.

3. OTHER ATTACK MODES

Deliberate attacks on some parts of the electric power system could cause damage or terror without necessarily creating a power outage. Nuclear power plants, hydroelectric dams, and cooling towers are the major concerns.

The most obvious threat is a direct attack on nuclear reactors themselves. One possible attack mode is by airplane. Most nuclear reactor containment buildings are massive structures designed to withstand significant impacts (exceptions include plants like the Chernobyl facility in the Ukraine). However, no conclusive analysis shows that all containment buildings and the nuclear systems they house can safely withstand a direct hit by a jumbo jet or by a smaller plane loaded with high explosives. In addition, the spent reactor fuel stored in water-filled pools or aboveground containers at all operating reactor sites may be far more vulnerable, especially if the water that cools and shields hot core elements is lost. These temporary facilities have grown around the world due to the failure of any country to develop a permanent reprocessing or disposal plan for nuclear waste. Attacks on nuclear power plants, even if they have little direct impact, could raise public alarm and lead to the closure of facilities out of fear.

Due to the dread the public has of nuclear radiation (whether scientifically supported or not), it might be possible to create significant public distress (or even terror) even with an unsuccessful attack on a nuclear power plant. The core meltdown of the Three Mile Island plant in Pennsylvania in 1976 had a devastating effect on the nuclear power industry even though no one was hurt and only insignificant amounts of radioactivity were released. Even an unsuccessful attack could lead to nuclear plant closures.

Concerns about direct attack by truck bombs or commando squads have led to physical barriers and armed guards that protect all nuclear power plants. However, it is not clear how effective these steps are; a 1999 review by the U.S. Nuclear Regulatory Commission found "significant weaknesses" in 27 of the 57 plants evaluated.

Nuclear power plants also present a unique threat labeled "proliferation," which is the potential for nuclear power plant fuel (or waste) to be used in creating nuclear weapons. These could be either fission bombs, which would be relatively hard to produce, probably requiring the resources of a nation, or much cruder "dirty bombs," which even small groups could construct from conventional explosives and almost any highly radioactive material. One concern is that reprocessing fuels so that fissile material (plutonium) is separated from highly radioactive fission products could increase the proliferation potential of nuclear waste. New reactor designs that are more resistant to physical assault or require no refueling might be developed, but the cost of doing so is unclear.

Typically, the costs of mitigating the CIP risks of nuclear power plants, and other security risks such as proliferation, are not fully included in the cost of electric power these plants produce. For instance, after the terrorist attacks of September 11, 2001, many state governors put National Guard troops at nuclear plants, so the taxpayer in effect subsidized electricity consumers. As the owners of nuclear power electricity facilities have begun to face competition and the bottom line becomes more important, the costs of security are likely to receive greater scrutiny. This subsidy is similar to the support for private nuclear power plant owners in the United States from the Price-Anderson Act, which limits their liability due to accidents.

The second major threat is to hydroelectric dams, which can store significant amounts of energy in the form of water retained behind them. If they were suddenly breached, both property and lives could be lost. It is not very easy to successfully attack most large dams, however, and physical access to them can

be controlled relatively easily. One complicating factor is that smaller upstream facilities such as locks or small dams may be more vulnerable to attack. Breeching one or more of these could send a pulse of water downstream, possibly causing a larger dam downriver to fail catastrophically.

Third, cooling towers, used in many large power plants, could be used in a deliberate attack as a means of dispersing biological or chemical agents. The magnitude of this threat is not well understood since these facilities have some physical security and the effectiveness of cooling towers to disperse various agents is not well studied.

Finally, large electromagnetic pulses (EMP) can induce instantaneous voltages of hundreds of thousands of volts in conductors, creating large disruptions in electric power systems and destroying electrical equipment components such as motors, backup generators, and microprocessors. Concerns about EMP have traditionally been focused on the impact of high-altitude nuclear detonations, but relatively simple, inexpensive devices that can deliver an EMP have been designed and tested by the United States and other nations. Concerns have emerged that even crude devices could be deployed with significant localized impacts. Such weapons could damage the electric power systems and also use the electric power system as a conduit to attack other infrastructures (e.g., telecommunications) without physically penetrating facility perimeters. It is not clear how vulnerable the system is to such assaults, nor what could be done to defend against them. There is very little information from credible sources on the EMP threat from nonstate actors, so this concern is somewhat speculative.

4. MITIGATION

Mitigation efforts are designed to reduce the probability or magnitude of disruptions to electric power systems or the use of the power system for other attack modes. Mitigation measures can take a variety of forms ranging from improved security procedures to changes in the physical and institutional structure of the system. Before describing specific mitigation strategies, it is necessary to introduce the concept of survivability, which should inform any mitigation strategy.

4.1 Survivability

The traditional reliability planning approach does not lend itself well to responding to unexpected, deliberate, and potentially very high impact attacks. For one thing, it is difficult to imagine all possible attack modes or strategies. Even if this problem could be overcome, practices in reliability analysis allow for essentially only one strategy—provide more reserve capacity—a costly solution that competitive firms are not likely to implement, and one that may divert resources from other important uses in CIP or economic growth. Thus, the advent of restructuring and the possibility of terrorism require the reformulation of the reliability problem. Supply-side solutions are not likely to be sufficient any longer; more attention will need to be paid to the economic and social implications of end-use disruptions. One concept that may serve to link reliability and CIP and also be compatible with a competitive electricity industry is survivability, also known as the self-healing grid or the resilient network.

Survivability is the ability of a system to fulfill its mission in a timely manner, despite attacks, failures, or accidents; survivability can be contrasted with the fortress model of security that tries to prevent or counter all attacks but has disastrous outcomes (e.g., cascading failures) when it does inevitably fail. A fundamental assumption of survivability analysis and design is that no individual component of a system is immune from attacks, accidents, or design errors. Thus, a survivable system must be created out of inherently vulnerable subunits, making survivability an emergent property of the system rather than a design feature for individual components.

Due to the complexity and speed of electricity system operations, it may be difficult to recognize attacks until there is extensive damage. Thus, ways must be found to recognize attack early and to protect the system without taking the time to discover the cause of the attack. Survivable systems must be able to maintain or restore essential services during an attack and to recover full service after the attack. Thus, the system must fail gracefully, shedding low priority tasks and then adding tasks in a priority ordering during recovery.

For example, in most cities, traffic signals are powered by the same circuits that provide service to much less critical loads like billboards. During blackouts, injury and property loss may occur due to blank traffic signals. Worsening the problem, blackouts cause gridlock that prevents police and fire vehicles, as well as emergency response crews from reaching their destinations. This demonstrates the fortress aspect of traditional reliability planning – it creates a system in which frequent or large-scale blackouts are not supposed to occur, but when they

do, the consequences are severe. In contrast, a system designed around survivability concepts might use low-power light-emitting diode traffic lights with battery backup to ensure that a blackout did not interrupt traffic flow.

4.2 Guards, Gates, and Guns

One approach to dealing with these issues is to assess, and if necessary and justified, improve the physical security of installations in the electric power system. This approach also probably requires relying on surveillance technologies to detect attack, ranging from automated systems such as sensors and alarms to detect intrusion to manned surveillance. The primary purpose of such technologies is to detect an attack and mobilize the resources (i.e., private security force, local police, military) to repel the attack and prevent damage. A secondary purpose would be to collect evidence to be used in the investigation of any attack.

While there exist a wide variety of monitoring and surveillance technologies, they are not considered adequate for protecting the electricity infrastructure. In the case of remote facilities, monitoring technologies may not be of use in preventing an attack if the response time of an intervention force is too long.

Unfortunately, any technology used for monitoring or surveillance has the risk of failure. Another problem has to do with nuisance alarms. Surveillance and monitoring systems are not always able to distinguish between an intruder and an animal or between a line being deliberately cut and one that has been struck by a falling tree. Guarding against failures and false positives may require backup systems or complementary technologies that can confirm or deny events, increasing costs.

4.3 Increased Backup

The traditional reliability approach has also led to a localized version of reliability through redundancy at facilities that are particularly concerned about electric power reliability: the use of backup generators. Especially since the recognition of a potential Y2K problem (the probability that older computer programs, especially those embedded in operating systems, would have failed on midnight of January 1, 2000), hospitals, airports, water supply systems, and sometimes office buildings have invested in onsite diesel generators. In some cases, building codes or operating licenses require backup generators. These are typically designed to provide a minimal level of electricity supply for up to a few days before needing refueling. Such approaches may not be satisfactory under attack situations, depending on the level of functionality supported by the backup generator, its own reliability, and the feasibility of long-term refueling. Furthermore, such approaches are typically too expensive for residences and small businesses.

4.4 System Architecture and Control

4.4.1 System Architecture

There may be fundamental limitations to the improvements that can be made in the vulnerability of the electric power system solely through improved physical or cyber security of current systems. One possible method of addressing this limit would be a change in the overall physical architecture of the system. Such changes in the system architecture would be designed to provide the electric power system with more of the properties of survivable systems.

One such approach would be to use significant decentralized (or distributed) generation, often called DG, which places energy supply at the location of its use rather than relying on large, central station plants and long-distance transmission. DG facilities are smaller (though they can range widely in size from the few tens of kW to tens of MW) and more dispersed. Until recently, DG technologies have generally found use in either niche applications (e.g., in certain industrial contexts) or as backup power. However, there are areas (e.g., the Netherlands) in which significant portions of generation is supplied by grid-connected distributed units that both supply local power and feed power into the grid.

However, there has been little analysis presented to indicate either the gain in robustness expected by using DG, nor the impact on system cost. Work has been conducted to quantify some of the costs and benefits of a more distributed system by modeling hypothetical centralized and distributed systems under stress. Generally these efforts find that that distributed systems could prove to be significantly more robust under stress conditions and results in lower reserve requirements, both of which can reduce costs. In addition, in many DG applications it is possible to use waste heat, resulting in higher overall efficiencies and lower costs. The potential effect of DG on cascading failures is unknown.

Advanced renewable energy sources (solar, wind, hydro, and biomass) have the potential for significantly increasing the diversity and flexibility of

electricity generation, but they face limitations due to their cost and their dependency on transmission. (Many renewable resources are located far from demand centers.)

Another approach to improving survivability might be demand response technologies that can reduce and make more flexible demand for electricity. Demand reduction could conceivably come either through energy conservation or through demand response technologies that could adjust demand if necessary.

At its most extreme, demand response could lead to shedding of load, otherwise know as rolling blackouts. Intelligent load shedding under emergency situations could help in preventing cascading grid failures while maintaining service to the most critical loads. Such an approach would provide for inherent deterrence from attack by offering fewer large, obvious targets. It will also emphasize differences in importance among end uses during emergencies (subways and traffic lights might be considered more important than billboards and air conditioners, for instance). Such a system might be able to reconfigure itself to isolate faults (adaptive islanding).

4.4.2 Control

The traditional approach to reliability has led to the automatic control of power system components in response to very small, short-term (seconds to minutes) deviations in demand by adjusting power generated to maintain locally measured frequency and voltage within the acceptable limits. Over longer terms (minutes to hours), human operators start and stop generators to meet forecast demand changes. When major equipment outages occur, decisions are made by human operators intimately familiar with the response of each specific system to the given (previously studied) outage. In spite of these efforts, cascading failures have occurred as a result of events that were not easy to detect by the system operator. An important issue is how system control strategies would perform under attack and how they could be improved.

The primary controllers on power plants are tuned to respond to small deviations in system conditions. It is, however, possible, to make these much "smarter" by equipping them with additional sensing and communications effectively resulting in a more observable system whose dynamics are controlled. In addition, it is possible to design these controllers with adaptive, nonlinear logic. Equipping the existing power plants with such power system stabilizers has been known to greatly enhance transient stability of a power grid under stress.

Problems in protective relaying are frequently at the heart of major blackouts. A typical problem is that a protective relay is not set correctly or it fails and incorrectly senses a fault on line it is protecting. If that happens, the breaker disconnects the line, which, in turn, causes line overflows in other transmission lines creating a sequential blackout situation. The fundamental problem with protective relaying is that it only uses local information, and the settings are tuned for a certain range of operating conditions. If these are exceeded, relay functions may fail.

4.4.3 Institutional Design

The robustness of electric power systems, and the ability to restore power quickly after accidental outages, is no accident. Government regulation and private institutions have been established to promote reliability in the electric power sector. In the United States, voluntary coordination councils were set up by the electric utility industry following the 1965 blackout, partly to avoid government regulation of reliability. State public utility commissions play a role as well. All countries have some form of electricity reliability institution(s). However, industry restructuring is drastically changing institutional arrangements, leading to serious questions about whether such private approaches will be adequate to ensure reliability, let alone provide CIP.

Both reliability and CIP share an important characteristic—they are what economists call public goods, services that if supplied to one person is available to others at no cost (i.e., nonrival consumption and nonexcludable access). Public goods are not provided in socially desired quantities by market forces alone, government action of one sort or another is always needed. Thus, government will probably have to act in some way to ensure sufficient reliability and CIP. Following the 2003 blackout in the United States, pressures to move toward regulation and mandatory reliability rules mounted, although the industry still largely preferred self-regulation.

Institutional issues also play out in apparently purely technical domains. For instance, several studies have shown that barriers are often raised to the interconnection of a distributed source to the grid. These barriers could come from market structure issues, the relative roles of DG owners and utilities, and from standards that are developed

for the interconnection of distributed resources. Similar concerns exist about the incentives for cooperation and investment in new control strategies and technologies.

One of the key challenges for the future is ensuring that institutional solutions to emerging reliability and CIP problems are created for whatever new structure the electricity industry takes. This includes looking at threats that go beyond those considered in traditional contingency planning. However, the potential for creating terror through attacks on the electric power system seem limited (with the exception of an attack on a nuclear facility). Loss of power, even if large-scale and frequent, is costly and annoying, and if caused by malicious attacks can be disconcerting, but it pales in comparison to the effect of the large-scale loss of life that is often the purpose of terrorist acts.

Glossary

coal pyrolysis The process of heating coal in an oxygen-deficient atmosphere.

combined cycle A combination of Brayton (gas turbine) and Rankine(condensing steam turbine) cycles; exhaust heat from gas turbines generates steam for steam turbines, and electric power is produced in both cycles. The efficiency of the combined cycle is high because of the complementary temperature ranges of the Brayton and Rankine cycles.

cycle efficiency The energy output of an energy conversion cycle expressed as the percentage of the energy input.

diffusion flame The flame produced when fuel and oxidant are separately injected through a burner, are only partially mixed prior to ignition, and their mixing continues during combustion. The overall rate of combustion of the fuel is determined by the rate of the fuel/oxidant mixing in the flame.

excess air The air required in addition to the theoretical combustion air to burn the fuel completely (usually expressed as a percentage of the theoretical combustion air).

flue gas desulfurization The postcombustion reduction of SO_x emissions. Most systems involve wet scrubbing of the flue gas with lime to produce calcium sulfate as the waste. Capable of 95% or higher sulfur removal.

fluidized bed combustion The combustion of millimeter-sized size coal particles in a dense bed of limestone (SO_2 sorbent) particles. The particles are suspended in a column of air supplied through a distributor plate at the bottom of the bed. Steam-generating tubes immersed in the fluidized bed extract heat and maintain the bed at a low (<1100 K) combustion temperature. This favors the reduction of SO_2 and NO_x emissions.

premixed flame A combustion system in which fuel and oxidant are mixed prior to ignition. The rate of combustion is determined by the chemical rates of combustion reactions, and hence by the reactant concentrations and the temperature.

Power generation can be fueled by coal or natural gas. Pulverized coal and fluidized bed coal combustion are used for steam generation in the Rankine cycle; natural gas is used in gas turbines for power generation in the Brayton cycle. These techniques, including the problems of combustion-generated pollution and the progress in pollution control technologies, are discussed in this article. The current status of advanced, high-efficiency power-generating cycles, capable of lowering significantly emissions of sulfur oxides, nitrogen oxides, mercury, and CO_2, is highlighted and their potential for deployment and the critical needs of research and development are examined.

1. BACKGROUND

The provision of electric power is one of the prerequisites of prosperity; there is strong correlation between electric power-generating capacity and per capita gross domestic product (GDP) (Fig. 1). Across the world, economic indicators signal that there will be continued growth and increased electricity demand; during the next 15 years, 1200 GW of new capacity is projected to be added to the world's present electric generation capacity of about 3500 GW.

The U.S. Energy Information Administration (EIA) data for 2001 show that 54% of the electricity supply in the United States was generated by coal,

12% by natural gas (increasing to an estimated 32% by 2020), and about 2% by oil, with the rest produced by nuclear power (21%), hydro power (9%), and by renewable solar or wind (2%). Electricity generation (billion kilowatt-hours) by fuel type from 1970 to 2020 in the United States is illustrated in Fig. 2. The increase in the use of coal and, especially, natural gas for power generation projected for the period from 2000 to 2020 is to meet growing demand for electricity and to offset the projected retirement of nuclear power plants.

Because of the large coal reserves in major developing countries such as China, India, and Indonesia, where most of the new power-generating plants are being installed, it can be expected that coal will remain the dominant source of power generation worldwide during the first half of this century. There is also a strongly growing demand for natural gas, a clean fuel capable of being used in power generation with high efficiency.

Coal as an energy source has the attraction of broad availability (there are large reserves in several countries around the world), low cost, and economic utilization by mature technologies. The disadvantages are due mainly to environmental and health impacts at the mining phase and in the course of coal utilization. Both the mining and the utilization of coal are subject to increasingly tightening standards by governmental regulations. Because there is no presently acceptable practical alternative to coal and natural gas, industrial research and development programs are concentrated on methods of reducing pollutant emissions, especially SO_2, NO_x, and fine particulates, from coal-fired plants, and NO_x from natural gas-fired combustion turbines. New environmental technologies developed and demonstrated under the Clean Coal Technology Program of the U.S. Department of Energy (DOE) during the past 15 years have become commercial and are being applied worldwide. Major advances have also been made in stationary gas turbine technology by increasing the inlet gas temperature to the turbine and by significantly reducing nitrogen oxide emissions.

The reduction of CO_2 emission remains a challenge. Research aimed at CO_2 capture and sequestration is receiving governmental and industrial support, but it may take a decade before an economically feasible solution is found. In the mean time, the most practical approach to this problem is the improvement of electric power-generating efficiency. Improved efficiency will reduce the amount of fuel used for the generation of a given electric energy output and hence will reduce the emissions of all of the pollutants.

2. *FOSSIL FUEL UTILIZATION SYSTEMS*

The steam (Rankine) cycle and the gas turbine (Brayton) cycle are the two main thermodynamic cycles in utility power generation. In the Rankine cycle, steam is created in a boiler, and part of the enthalpy of the high-pressure superheated steam is converted to shaft work in a steam turbine that drives an electric generator. In the Brayton cycle, high-pressure and high-temperature gaseous combustion products enter directly a gas turbine, where part of their enthalpy is converted to shaft work. The gas turbine drives a compressor and the electric power generator. Because of the direct entry of the combustion products into the turbine, the gas turbine

cycle is highly sensitive to the quality of fuel and is restricted to the use of natural gas or distillate fuel oil. Boilers in the steam cycle are, by contrast, fairly tolerant to fuel quality and are capable of being fueled even by low-quality coal or waste fuels. Combustion is the prevailing fuel utilization technology in both of these cycles. In future central power plants, there are good prospects for application of gasification, which enables coal use in gas turbines, because of the environmental advantages and the promise of higher cycle efficiency.

During the past decade, there has been a growing trend toward distributed generation. Compared to large, centralized utility plants, power plants of smaller capacity, can be sited close to consumers, thereby reducing electricity transmission losses and improving operational flexibility. Being situated near population centers, these smaller plants have to be highly efficient and use a clean fuel, usually natural gas. Natural gas is free of sulfur and ash, and because of a carbon content lower than that in coal or oil, the CO_2 emission from natural gas combustion is also lower.

High-efficiency utilization is achieved by combined gas turbine–steam cycles. Also, being close to industrial and population centers opens the opportunity for combined heat and power (CHP) generation, which further enhances the plant's energy efficiency. An example of distributed generation and CHP is the Massachusetts Institute of Technology's natural gas-fired gas turbine/steam Cogen plant, which provides the campus with 22 MW of electric power and 80 t/hr of steam for heating or cooling at an energy efficiency above 80% and with very low emissions. This plant replaced a low-efficiency, more polluting, and more costly energy system in which steam was produced on campus in oil-fired boilers and electric power was purchased from a utility.

3. COAL-FIRED POWER GENERATION

3.1 Pulverized Coal Combustion

Pulverized coal (PC) combustion is presently the system of choice for coal-fired power-generating plants. In PC combustion, the coal is dried and is ground to a specified fineness, with a maximum particle size of 250–300 μm, depending on the reactivity of the coal. Coal preparation, which involves feeding, drying, and grinding of the coal, and the pneumatic transport of the pulverized coal to the burners, is fully integrated with the boiler. For lower reactivity coals, the fineness of grind is increased to create a larger specific surface area so as to improve conditions for ignition and combustion. The powdered coal is pneumatically transported to burners and injected via particle-laden jets into the combustion chamber. The transport air that carries the coal from the mill to the burners is a small fraction of the total combustion air. It is kept at low temperature, limited to about 373 K, for reasons of safety against ignition and explosion in the mill and in the powdered coal transport pipeline between the mill and the burners. The rest of the combustion air, which can be preheated to higher temperatures, is injected separately and admixed with the already ignited coal particle-laden jet in the combustion chamber. A schematic illustration of a PC combustion boiler is shown in Fig. 3. The combustion chamber is typically of parallelepiped shape; the dimensions of a 300-MW coal-fired boiler would be approximately be $15 \times 15\,m^2$ of cross-sectional area and 45–50 m in height. The combustion chamber walls are completely

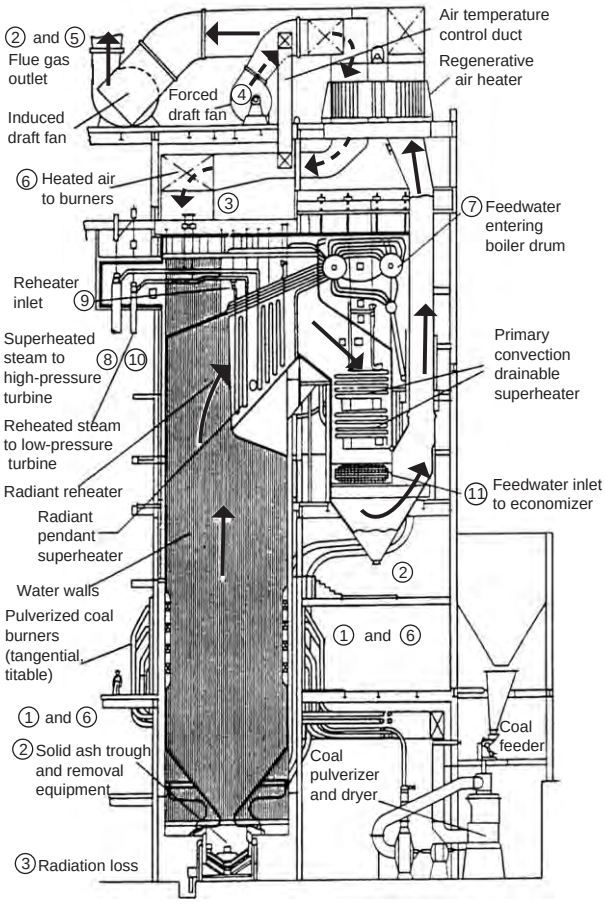

FIGURE 3 Utility boiler fired with pulverized coal.

cooled by steam-generating tubes. As the pulverized coal particles burn, the flame transfers heat, mainly by thermal radiation, to the steam-cooled tube walls of the boiler. The design of the combustion chamber has to provide for sufficient residence time of the burning particle to complete combustion, and for the cooling of the residual fly ash particles to below their "softening temperature" before entry to narrow convective heat exchanger passages, to prevent the build-up of sticky ash deposits. At regular intervals, friable deposits are removed by soot blowing using steam.

Although there are a great variety of burners in PC combustion boilers, the most widespread types are the circular burners and the vertical nozzle arrays. Circular burners are usually positioned perpendicularly to the combustion chamber walls, whereas vertical nozzle arrays are in the corners, firing tangentially onto the circumference of an imaginary cylinder in the middle of the combustion chamber. Designs utilizing circular burners are more concerned with the tailoring of the individual burner flame, whereas vertical nozzle arrays in tangentially fired furnaces are designed to rely more on the furnace volume for the mixing of the fuel and air streams. Complete combustion with a minimum (typically less than 15%) of excess air is a challenging task for a coal combustion system. The excess air, usually expressed as the percentage of the theoretically required combustion air, is the additional air needed for complete burnout of the fuel. The significance of the excess air is that the heat carried by the stack gases into the atmosphere, the largest heat loss (about 10%) of boiler operation, is directly proportional to the volume of the flue gas and, hence, to the excess air.

The fly ash formed in pulverized coal combustion is removed from the flue gas in the form of dry particulate matter; a small proportion ($\sim$10%) of the coal ash that falls off the tube walls as semimolten agglomerated ash is collected from the bottom hopper of the combustion chamber ("bottom ash"). Ash particles are molten in the high-temperature regions of the flame, but cool and solidify as they reach heat exchange surfaces of the boiler, forming friable deposits that are easily removed by soot blowing.

3.2 Fluidized Bed Combustion

In fluidized bed combustion (FBC) (Fig. 4), crushed coal, 5–10 mm in particle size, is burned in a 1000-mm-deep bed of 0.5- to 3.0-mm particles consisting mainly of additive sorbents (limestone or dolomite) and coal ash. The bed is fluidized by a blast of air through a distributor plate at the bottom of the bed.

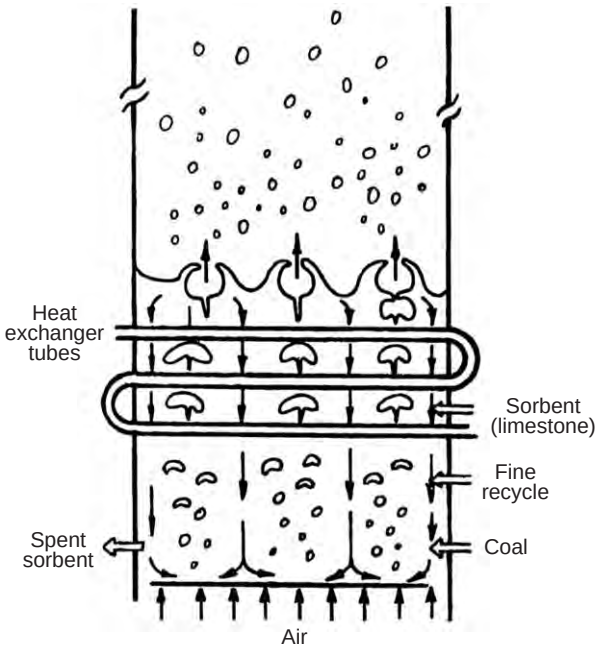

FIGURE 4 Fluidized bed coal combustion with sorbent injection for sulfur capture, and heat extraction by means of steam-generating tubes immersed in the bed. From Sarofim and Beér (1978).

As the airflow through the bed increases, the drag lifts and separates the particles from one another, and the pressure drop across the bed becomes sufficient to support the weight of the bed; the bed is incipiently fluidized. Further increase of the velocity causes the air to form bubbles that rise in the bed like gas in liquid. The bubbles stir the bed by carrying pockets of particles on their tops and in their wake. The particles are released and are returned to the bed as the bubbles burst on the top of the fluidized bed. Less than 2% of the bed material is coal; the rest is coal ash and additive limestone, capable of capturing sulfur after the calcination of the additive limestone and the formation of lime (CaO). Due to the excellent gas–solid contact, the fluidized bed is a favorable reactor for the combustion of millimeter-size coal particles and for sulfur capture in the combustion process. The bed is cooled to a temperature of 1050–1170 K by immersed steam-generating tubes. This relatively low combustion temperature prevents the softening of the coal ash and the chemical decomposition of $CaSO_4$, the product of sulfur capture.

3.2.1 Circulating Fluidized Bed Combustion

In circulating fluidized bed combustion (CFBC) (Fig. 5), the gas velocity is higher than in FBC, and a large part of the solid particles is carried over from

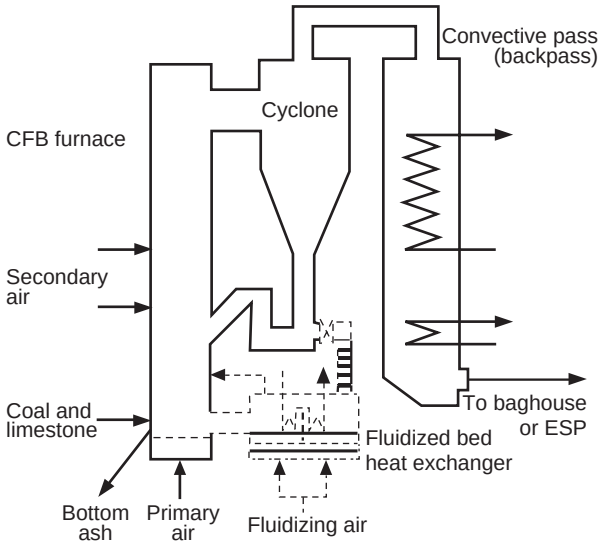

FIGURE 5 Circulating fluidized bed (CFB) furnace. ESP, electrostatic precipitator. From Scott and Nilsson (1999).

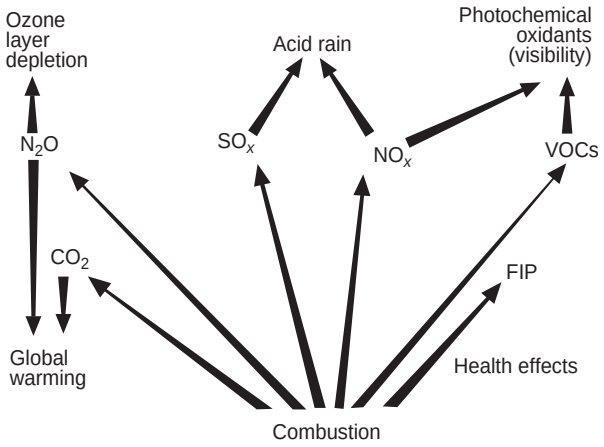

FIGURE 6 Combustion-generated pollutants; environmental and health effects. VOCs, volatile organic compounds; FIP, fine inorganic particles.

the bed into a tall riser, where the particles aggregate into clusters that reflux at the wall. Particles that are carried over from the riser are precipitated by a high-temperature process cyclone and are recirculated into the riser. With the higher gas velocity, the bed cross-sectional area becomes smaller than in FBC, for a given performance. This, in turn, leads to a smaller number of coal feed points required for maintaining uniform coal concentration over the bed cross-sectional area, a significant operational convenience. Also, because of the higher gas velocity and the somewhat smaller sorbent particle size, less additive sorbent is required in CFBC for a given percentage sulfur capture.

FBC and CFBC are commercial, mature technologies; primarily applied to the use of low-grade fuels in smaller unit sizes. The main advantages of CFBC are the capability of capturing sulfur in the combustion process by additive sorbents and the lack of sensitivity to fuel type or fuel quality variation. Due to the refractory lined process cyclone circulating fluidized bed combustors do not lend themselves easily to scale-up to the larger utility boiler sizes ($\geq$660 MW).

4. POLLUTANT EMISSION CONTROL IN COAL-FIRED PLANTS

The combustion-generated pollutants of concern are mercury, fine inorganic particulates, and oxides of sulfur and nitrogen. Figure 6 is an illustration of the pollutants and their effects.

4.1 Sulfur

Sulfur in coal will oxidize to SO_2, a precursor of acid rain. Methods of sulfur capture in the combustion process involve the reactions of sorbents such as calcined limestone (CaO) with SO_2 to produce $CaSO_4$, a stable, disposable solid waste. In the high-temperature, fuel-lean environment of pulverized coal flames ($T_{peak} \sim 2000$ K), however, $CaSO_4$ is unstable; it decomposes, which leaves flue gas desulfurization (FGD) as the viable option for sulfur capture from PC combustion. The development of fluidized bed combustion provided the opportunity to effectively retain sulfur in the combustion process, because $CaSO_4$, is stable at the lower FBC operating temperature of 1050–1170 K. Sulfur capture in fluidized combustion ranges between 70 and 90%, with even higher capture efficiencies obtained for subbituminous coals of high calcium content. FGD technologies are mature and commercially proven; 99% SO_2 reduction has been achieved at some plants, with 90–95% reduction as routine. Sulfur dioxide emissions from utility plants in the United States have been reduced 40% since 1980, even though electricity production increased by 35% during the same period. This was achieved by switching to coals of lower sulfur content and by retrofitting some of the existing coal-fired power plants with scrubbers. This process will have to continue to satisfy the constraints of the Clean Air Act Amendment of 1990, which requires further reductions in SO_2 emissions in the Phase 2 implementation that began in the year 2000.

4.2 Nitrogen Oxides

Nitrogen oxides as pollutants deserve special attention, because of their wide-ranging effect on the environment, including contribution to acid rain, reduction of atmospheric visibility, production of tropospheric (ground level) ozone, and, in the case of N_2O, depletion of stratospheric ozone. It is also noteworthy that NO_x emissions are amenable to reduction by combustion process modifications. The main routes of NO formation in coal flames are the attack of atomic oxygen on molecular nitrogen in high-temperature, fuel-lean flames ("thermal NO"), and the oxidation of the organically bound nitrogen in the coal ("fuel NO"). It is noteworthy that fuel-bound nitrogen and NO can be converted to molecular nitrogen and, hence, rendered innocuous for NO_x emission by coal pyrolysis, a process in which coal is maintained at high temperature in an oxygen-deficient atmosphere. To complete combustion, the rest of the combustion air, called "overfire air" (OFA), ought then to be admixed to the products of the pyrolysis reactions. In this burnout stage of the flame, the temperature needs to be controlled to levels sufficiently high to complete combustion but insufficient for significant thermal NO formation.

NO_x emission control by combustion process modification is accomplished by OFA, low-NO_x burner, and NO reburn technologies. In low-NO_x burners (LNBs) (Fig. 7), air staging is achieved by aerodynamically tailored mixing of the fuel jet with airstreams supplied through each individual burner, rather than through the splitting of the combustion chamber into fuel-rich and fuel-lean combustion zones by the use of OFA. LNBs and OFA represent the most cost-effective methods of achieving reduced NO_x emissions from new plants and also from existing boilers by retrofit.

NO reburning involves a secondary fuel, usually natural gas; the gas, amounting to 10–20% of the total heat input to the boiler, is injected into the combustion chamber and mixed with the NO-bearing coal combustion products. The NO is reduced by reactions with hydrocarbon fragments, CH and CH_2, that are formed in the course of the pyrolysis of the natural gas. Control of NO_x emissions by combustion process modifications and their combinations can yield up to 70% reductions. These technologies are successfully applied in the utility industry; more than 188 GW of electric power-generating capacity currently in operation internationally has been fitted by these combustion measures.

Further reductions in NO_x emissions can be obtained by the injection of additive ammonia into the combustion products. At high temperature (1060–1350 K), no catalyst is needed in the selective noncatalytic reduction (SNCR) process for the removal of up to 40% of the NO formed during coal combustion. In selective catalytic reduction (SCR), the ammonia vapor is injected over a catalyst bed situated at the boiler economizer outlet, where the flue gas temperature ranges from 600 to 650 K. In the presence of the catalyst, the ammonia chemically reacts with NO_x to form water vapor and N_2. The cost of SRC installation is higher than that of SNCR, but much less ammonia has to be injected, and NO_x reductions in excess of 90% can be obtained, depending on the type of coal burned.

4.3 Fine Particulates

Fine particulates are removed by electrostatic precipitators (ESPs) or by baghouse (BH) filters. In the ESP, particles with an electric charge are attracted to collecting electrodes in a high-voltage field. The precipitation efficiency is high, in the 10- to 300-μm size range, but it falls off for smaller particles, especially those in the submicrometer range. These ultrafine particulates have important health effects and their emissions will likely be regulated. Baghouses are fabric collectors in which the dust-laden gas flows

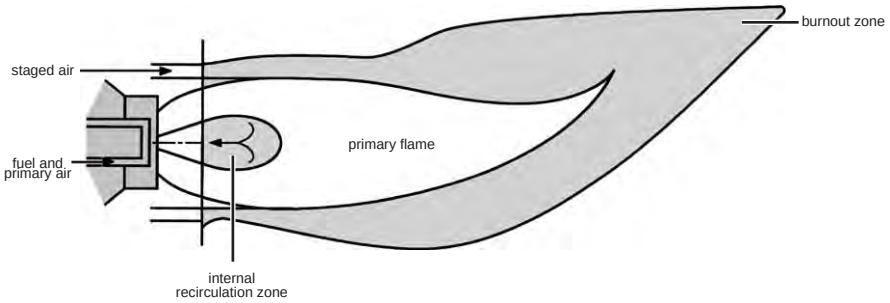

FIGURE 7 Schematic of a low-NO_x burner. From Soud and Fukusawa (1996).

through a cloth tube, where particles are captured by sieving action. As a "filter cake" forms by deposition, particles much smaller than the interstices of the cloth are captured. The particles are then removed by reversed air flow or shaking, and are collected in a bin below the cloth filter tubes. Baghouses are capable of precipitating submicrometer particles and fumes with high efficiency. Their flow resistance is higher than that of the ESP and their operation is, therefore, somewhat more costly.

4.4 Mercury

Mercury has been identified by the U.S. Environmental Protection Agency (EPA) as a toxic substance of great concern, because of its adverse health effects. Regulations for mercury removal from coal-fired utility plants are expected to be issued by the end of 2004. Significant research and development efforts by the U.S. DOE and industry are in progress to find cost-effective ways for the removal of mercury from stack gases. Potential solutions include SO_2 scrubbers that will also capture a high percentage of soluble (oxidized) mercury, SCR catalysts for NO_x removal to oxidize elemental mercury for subsequent capture by electrostatic precipitators or fabric filters, and the absorption of vapor-phase mercury by beds of activated carbon or particles injected into the flue gas and subsequently removed by gas–solid separation devices. The cost of mercury removal is significantly lower in integrated coal gasification combined cycle (IGCC) plants than it is in PC plants because the treated volume of syngas in IGCC plants is much smaller, compared to the flue gas in PC plants. However, this affects mainly the choice of new power plants, because of the small number of IGCC plants presently in operation.

5. NATURAL GAS-FIRED PLANTS

Natural gas is a premium fuel; because of its relatively high price, in the past it was used primarily for "peak-shaving" in gas turbine plants. Reassessment of the long-term availability of natural gas, the development of gas turbine–steam combined cycle (GTCC) plants with high cycle efficiency, environmental pressures for "decarbonization" of the fuel supply, and the rapid growth of distributed power generation have made natural gas the choice fuel for base load power generation. Natural gas has no sulfur, and the carbon:hydrogen ratio of its composition is much lower than that in petroleum fuels or in coals. Because of the lower C:H ratio, CO_2 emissions from the combustion of natural gas are significantly lower compared to the heat equivalent of other fossil fuels.

In the gas turbine cycle, the gaseous combustion product is the direct working medium of power generation. The gas turbine (GT) consists of a compressor, combustor, turbine, and heat exchanger (Fig. 8). Combustion takes place at elevated pressure in the combustor. Large amounts of excess air are used as diluent, to ensure that the combustion product temperature at entry to the gas turbine does not exceed the limit set to protect the structural integrity of the turbine. However, because the cycle efficiency is proportional to GT entry temperature, concerted research and development efforts are in progress to permit higher inlet temperatures by means of improved construction materials and more effective turbine blade cooling technologies. As a result, gas turbine entry temperatures have risen almost steadily over the past two decades to a state-of-the-art value of 1570 K. Further increases can be expected by the introduction of advanced ceramic materials to GT technology.

5.1 Nitrogen Oxides Emission Control in Natural Gas-Fired Gas Turbine Plants

There is no nitrogen organically bound to fuel molecules in natural gas; NO forms primarily by the "thermal NO" process. In the conventional method of combustion, fuel and air are separately injected into the combustor and mix in the course of combustion (diffusion flame). This process is prone to high rates of thermal NO formation because near-stoichiometric (theoretical air:fuel ratio) mixtures prevail on the boundaries of fuel-rich and fuel-lean turbulent eddies in such flames. In contemporary

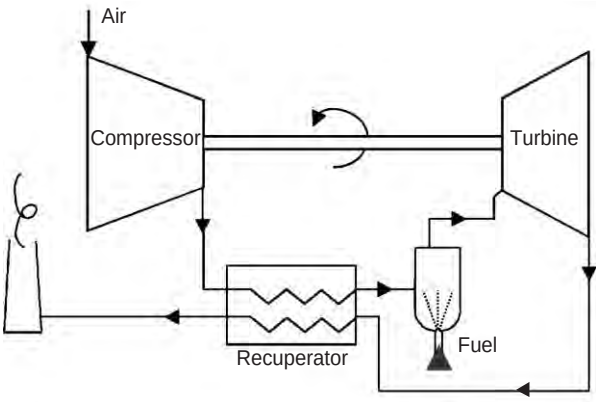

FIGURE 8 Gas turbine cycle with regenerator.

combustion technology's response to this problem, the fuel gas and air are premixed prior to their entry into the combustor, creating a strongly fuel-lean mixture that corresponds to the combustor exit gas temperature. This, so-called ultralean premixed combustion results in very low NO_x emissions, but because the combustor is operated at mixture ratios close to the lean blow-off limit of the fuel gas/air mixture, the flame stability may be impaired. For restoring flame stability, a small amount of non-premixed fuel, say 10%, is injected into the combustor to form a pilot flame and act as a stable source of ignition. Further reduction of NO can be obtained by steam injection into the combustor. Although steam injection will depress the cycle efficiency on account of loss of the latent heat of steam, this effect is somewhat compensated for by the fact that the steam represents additional mass flow through the turbine without the need for expending additional compression work.

6. POWER CYCLES OF INCREASED THERMODYNAMIC EFFICIENCY

Pollutant emissions from electric power-generating plants are inversely proportional to the thermodynamic cycle efficiency of power generation. Some power plants with advanced thermodynamic cycles are in commercial use, others have the potential to be applied in the near and medium term, and there are also long-term research and development programs for very high-efficiency and "zero-emission" cycles in power generation. It has to be borne in mind that in addition to technical feasibility, a novel electric power-generating system needs to be successfully demonstrated at a commercial scale for years, and must be economically viable, before it is accepted for application by the utility industry.

6.1 Pulverized Coal Combustion in Supercritical Steam Cycle

Pulverized coal-fired supercritical steam boilers (e.g. 250 atm, 2×853 K), have been in use since the 1930s, but improvements in materials and increasing demand for higher efficiency are making this system the choice of new coal-fired utility plant worldwide. Their increased efficiency is due to the higher mean temperature of heat addition in the supercritical steam cycle. Because of a strong increase in the moisture content of high-pressure steam as it expands through the last stages of the steam turbine, the steam has to be reheated by taking it back from the turbine to the boiler. Reheating, once or multiple times, will raise also the thermodynamic efficiency of the power cycle because it further increases the mean temperature of heat addition. Advanced supercritical steam power plants with steam parameters of 300 atm pressure, temperatures of 866 K, and cycle efficiencies up to 43% are expected to play a major role in new power generation in the near future. As the steam temperature approaches 973 K, the efficiency may reach 47%, but new advanced designs and materials for the boiler, the steam turbine, and the associated piping will be required; development will likely yield commercial applications after 2010.

6.2 Gas Turbine–Steam Combined Cycles

In gas turbine–steam combined cycle plant, the gas turbine exhaust, typically 750 K and containing 13–15% O_2, raises steam in a heat recovery steam generator for producing power in a steam turbine and/or heat in cogeneration. Because of the complementary temperature ranges of the Brayton (1600–900 K) and Rankine (850–288 K) cycles, their combination can produce significantly improved thermodynamic cycle efficiency, approaching 58% in modern commercial plants. When coal or residual fuel oil is added as a supplementary fuel in the heat recovery steam generator of a GTCC plant (Fig. 9), there is considerable gain in operational flexibility, albeit at the expense of a small reduction in the cycle efficiency. Due to a low first cost ($400–500/kW, less than one-half of the approximate first cost of a PC plant), high efficiency, and low emissions, GTCC plants are the favored choice for new power plants, despite the gas/coal price differential and the uncertainty of future gas prices.

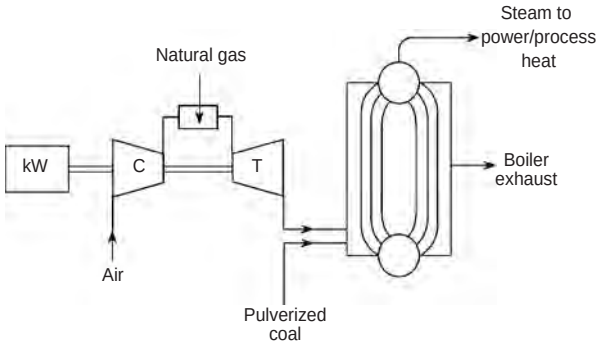

FIGURE 9 Gas turbine–steam combined cycle with fired heat recovery steam generator. C, compressor; T, turbine.

Gas turbines can be used also for retrofitting existing steam plants by injecting the gas turbine (GT) exhaust through the boilers' coal burners ("hot wind box repowering"), or applying it to partial boiler-feed water heating, thereby allowing more of the steam flow in the steam turbine to expand to condenser pressure instead of being bled for regenerative-feed water heating. This will then result in both higher efficiency and increased electric power-generating capacity.

6.3 Pressurized Fluidized Bed Combustion

In pressurized fluidized bed combustion (PFBC), the advantages of sulfur capture by additive sorbents in the bed and an operation insensitive to fuel quality are combined with increased efficiency of the combined steam and gas turbine cycle. Compared to FBC, the heat release rate per unit bed area in PFBC is several times higher, making the "footprint" of the pressurized power plant smaller. The bed height in the PFBC is 3–4 m instead of the typical bed height of 1 m in FBC. Under atmospheric pressure, the acceptable pressure drop of about 100 mbar limits height across the bed. In the PFBC–GT cycle, a 300 mbar pressure drop represents less than 3% of the total pressure ratio. A consequence of the increased bed height is a larger carbon inventory in the bed and lower NO emission due to the reduction of the NO formed by solid carbon. The high carbon load, however, does not reduce the emission of nitrous oxide, N_2O, which is still stable at the relatively low temperature ($\sim$1050 K) in the PFBC. A further disadvantage of this temperature is that it is also low for efficient gas turbine applications. The efficiency of the PFBC combined cycle units in operation is about 41%. Further increases in efficiency can be obtained by raising the turbine inlet temperature using a topping combustor.

6.3.1 The Second Generation of PFBC

The second generation of PFBC is a response to the need for increasing the gas temperature at the inlet to the gas turbine. In this cycle (Fig. 10), coal, usually in the form of a coal–water slurry, is injected into a pressurized fluidized bed carbonizer, where it undergoes mild gasification to produce char and a low-calorific-value gas. The char is burned in a pressurized circulating fluidized bed combustor (PCFBC) with high levels of excess air. Sulfur is captured in the PCFBC by additive dolomite and the flue gas is cleaned of particulates and alkali at high temperature before entry to the GT. Sulfur is also captured in the

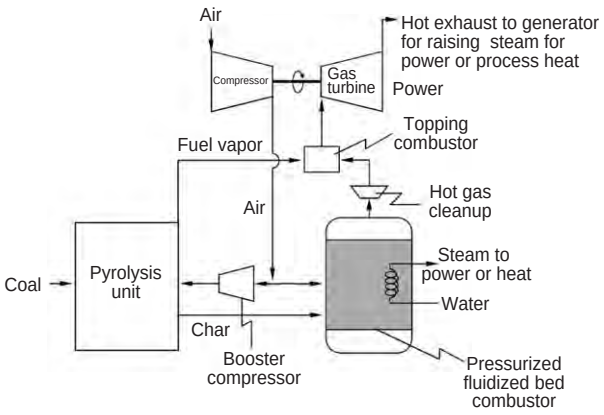

FIGURE 10 Pressurized fluidized bed combined cycle with topping combustion. From Robertson *et al.* (1989).

fluidized bed carbonizer, and the fuel gas, after being cleaned of particulates and alkali, is burned in the topping combustor to increase the temperature at the inlet to the gas turbine to 1470 K. This temperature rise increases the cycle efficiency up to about 45%. Further improvements in efficiency can be obtained by the application of advanced gas turbine technology and, on the steam side, by advanced steam parameters. An additional advantage of this cycle is that the N_2O emission is eliminated because the N_2O formed in the pressurized fluidized combustor decomposes at the elevated temperature in the topping combustor. The successful application of this cycle requires further demonstrations of the hot gas clean up and the topping combustor. The PCFBC with topping combustor is expected to be ready for commercial application after 2010.

6.4 Integrated Gasification Combined Cycle

IGCC involves the total gasification of coal, mostly with oxygen and steam, to produce a medium-calorific-value fuel gas for use in a gas turbine cycle. The fuel gas, after being cleaned of particulates, alkali, and sulfur compounds, is burned in a low-NO_x combustor. The gasifier also produces steam for a steam power cycle. A schematic arrangement of IGCC equipment (gasifier, gas-cleaning tanks, steam-raising tanks, and power-generating apparatus) is illustrated in Fig. 11.

IGCC is the cleanest presently available advanced coal technology. It is working with no major operational problems. The future of IGCC depends on whether it will be possible to reduce its first cost and to increase the cycle efficiency. The cost is

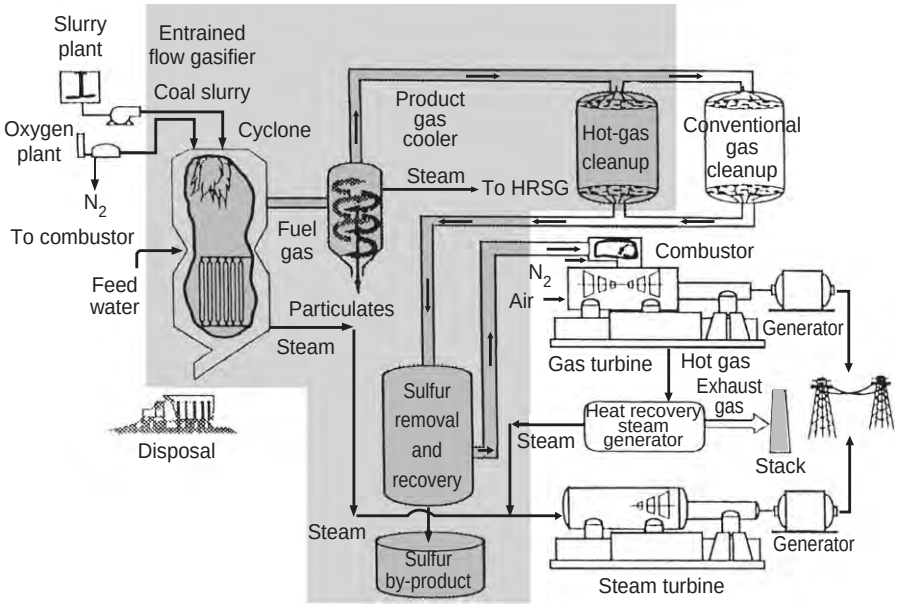

FIGURE 11 Integrated gasification combined cycle. HRSG, heat recovery steam generator. From Ruth (1998).

presently high, mainly because of the oxygen plant needed for the oxygen-blown gasifier and also because of the less than complete integration of the various subsystems, such as the gasifier air separation system, fuel gas cooler and cleanup, and gas turbine and steam plants. Existing IGCC demonstration plants in the United States have efficiencies under 40%, but two newly commissioned European IGCC demonstration plants have higher design efficiencies of 43 and 45%. These higher cycle efficiencies are mainly due to improved gas turbine and steam plant efficiencies and also to better subsystems integration. Further improvements yielding cycle efficiencies up to 50% are possible.

Even with improved cycle efficiencies, however, IGCC plants are presently not competitive with other advanced coal-burning systems, such as PC-fired supercritical steam plants, because of the higher installation costs of IGCC plants. Nevertheless, the following considerations may eventually tilt the balance in favor of IGCC applications:

- The cost of mercury removal in IGCC plants is lower because the treated volume of syngas is much smaller than that of the flue gas in PC-fired plants.
- IGCC lends itself to more efficient removal of CO_2 from high-pressure fuel gas.
- By broadening the fuel supply to the ever-increasing volume of refinery wastes (heavy residual oils and petroleum coke), IGCC could become attractive for clean and efficient central power generation by using fuels of very low or even negative cost (the waste fuel cost is negative if it stands against the cost of disposal).

6.5 Hybrid Gasification/Fuel Cell/Gas Turbine/Steam Combined Cycles

6.5.1 The DOE's Vision 21 Cycle

One of the promising coal-fired advanced cycles expected to be ready for demonstration in the period between 2010 and 2015 is the Vision 21 Cycle of the U.S. DOE. (Fig. 12). The fuel gas produced in an oxygen-blown gasifier at elevated pressure is cleaned at a temperature of 1273 K. The gas, composed mainly of H_2 and CO, enters a solid oxide fuel cell (SOFC) on the anode side, while air from a compressor exhaust, preheated in a recuperator, enters on the side of the cathode. The hydrogen is used to generate electricity in the SOFC, and the CO burns in a combustion turbine that drives the compressor. Electric power is produced in another SOFC and gas turbine, at a lower pressure downstream of the high-pressure turbine, with more power added by a bottoming steam cycle. The efficiency could reach 60% in this "zero-emission" scheme. Concerted research and development efforts by a DOE/industry/university program aim at the development of individual modules of this cycle and the complex control system required for flexible load following.

7. CONCLUSIONS

Coal is the prevailing fuel of power generation worldwide, and it is likely to remain important well into the next century. Natural gas in gas turbine combined cycle plants will, in the short and medium terms, replace some coal-fired capacity, especially in distributed power generation and in heat and power cogeneration. Because of coal's role in pollution, and especially due to the expected future limitations on CO_2 emissions, clean coal utilization technology with high thermodynamic efficiency will have to be applied for new coal-fired central power stations. Pulverized coal combustion in supercritical steam boilers (300 atm, 2×866 K) can play a major role in new power generation because of reduced emissions, improved efficiency (43%), and the long experience with pulverized coal combustion technology. As steam temperatures approach 973 K, efficiency may reach 47%, but new advanced designs and materials for the boiler, the steam turbine, and the associated piping will be required; development will likely yield commercial applications after 2010.

Several small, 70-MWe pressurized fluidized combustion combined cycle plants have been operating satisfactorily since 1991. Efficiencies are around 41% and emissions are low, except for N_2O (50–100 ppm). A larger plant of 360 MWe capacity began operation in 1999 in Japan. Combustion of fuel gas produced by pregasification of coal increases turbine inlet temperature to 1470 K, with efficiency increasing to 45% in the topping cycle (second-generation PFBC). N_2O is eliminated at the elevated temperature in the topping combustor. Enabling technologies, e.g., hot gas cleanup and topping combustors, need to be finalized and are expected to be ready for demonstration by 2010.

IGCC is the cleanest of advanced coal-fired technologies. The demonstration plants in the United States were designed with relatively low cycle efficiency ($\sim$40%), but IGCC is capable of higher efficiencies through the application of advanced gas turbine technology and better subsystem integration. The disadvantage of presently higher installation cost compared to PC-fired plants could be compensated for in the future by lower cost of mercury removal and more favorable conditions for CO_2 capture. Interest in gasification has also continued to increase because of favorable prospects for achieving a zero-emission and near-60% cycle efficiency system by combinations of coal gasification, fuel cell, and gas turbine technology (e.g., Vision 21).

The availability of reliable electric power at low cost is a necessary condition for sustained global economic welfare. However, at the same time, electric power generation is the source of a number of social and environmental problems. Therefore, a wide variety of regulations and economic incentives exist worldwide to promote the introduction of more environmentally benign power generation technologies. When implementing such policy measures, two questions typically arise. First, which technologies are the more relatively environmentally benign? Second, how does one find a proper overall balance between the benefits of electricity production and the costs of environmental degradation?

1. INTRODUCTION

Over recent decades policymakers have shown an increased interest in the market-oriented measures recommended by neoclassical economics. According to this body of analysis, normal market processes are assumed to approximate optimal balances between those private costs and benefits that are reflected in market prices. For those costs and benefits that are "external" to market prices, the neoclassical prescription is to apply nonmarket valuation techniques

to determine the magnitudes of these externalities and, thereby, to enable regulatory or fiscal measures to explicitly include these values in market prices. Under this view, normal processes of market optimization will then be based on total social costs (private costs plus external costs) and, thereby, will reflect a proper balance between the benefits and impacts in their widest sense. Formally, then, an externality (i.e., an external cost or benefit) may be defined as an unpriced and uncompensated side effect of one agent's actions (in our case electric utilities) that directly affects the welfare of another agent. Therefore, the challenge lies in finding techniques by which to derive complete and reliable values for the many different types of external cost associated with electricity production.

In response to increasing demands from policymakers during the 1980s and 1990s, this challenge received intense attention from economists and environmental scientists worldwide. A number of large-scale international studies embarked on the task of quantifying and valuing the externalities associated with electric power production. Examples include the ExternE project in the European Community and the External Costs and Benefits of Fuel Cycles study in the United States. The ultimate goal of these studies has been to guide policymaking by providing a robust basis for new regulations and taxes and, thereby, to aid decision makers in their choices among fuels and technologies.

The results obtained by several of these externality studies have already begun to exert some influence on regulatory decision making and wider policy debates. For instance, certain external cost values have been featured prominently in legislative initiatives for "environmental cost adders" in a few U.S. states, and some other results (e.g., those associated with global warming) have from time to time become the subject of high-profile public policy debates. However, the results obtained in the accumulated extensive body of literature on the external environmental costs of electricity production so far have generally exerted only a limited impact on real policy decisions. Some authors argue that this is because electricity environmental impact studies may have raised more questions than they have answered and because there are important limits to their usefulness in deriving robust recommendations for policymakers.

This article reviews the economic theory behind externality valuation as well as the various methods that can be used to assess external costs in practice. It also surveys some results from the vast externality valuation literature and discusses some important practical issues that bear on efforts to improve the environmental performance of electricity systems by adopting these particular values as a basis for regulatory and policy measures.

2. THE VALUATION OF ELECTRICITY EXTERNALITIES

2.1 The Background to Externality Valuation

The presence of an externality indicates a situation in which the first theorem of welfare economics fails to apply. In other words, externalities cause market failures, which then lead to a failure to accomplish Pareto efficiency. The market failures caused by externalities can arise in both production and consumption activities. Either way, they give rise to resource allocations that are nonoptimal from the point of view of society as a whole. Fig. 1 shows the relationship among a number of key concepts associated with market failure through the existence of externalities. The private costs facing a producer represent the best alternative uses of resources available as reflected by the market prices of the specific resources used by the producer. However, the social costs of production equal private costs plus external costs and represent the best alternative use of resources available to society as a whole. Therefore, a negative externality is equivalent to the difference between the private and social costs of an activity such as electricity production. Because by definition there exists no market for an external impact, a profit-maximizing utility has no incentive to integrate this effect into the decision-making process. Thus, private costs are lower than social costs. However, the existence of a difference between private and external costs is not inevitable. If the external costs can—by means of various fiscal or regulatory instruments—be "internalized" in electricity prices (i.e., be made private), producers and consumers in electricity markets will have an

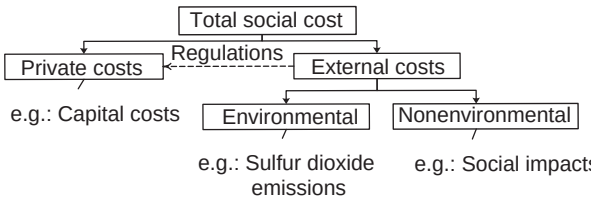

FIGURE 1 Total costs to society of a productive activity.

incentive to undertake actions that help to mitigate the negative environmental impacts of electricity use.

In his seminal work, Coase argued that bargaining between the polluter and the affected agents can, under certain circumstances (e.g., low transaction costs and full information), internalize externalities and achieve an efficient outcome. However, in most cases, because of the large number of parties involved, this calls for some kind of government intervention. One way of correcting the inefficiency of an external cost is the use of so-called Pigovian taxes as originally suggested by Pigou. This implies setting a tax equal to the value of the marginal external cost (at the optimal level of the activity in question) so that the private decision maker is provided with an incentive to economize not only on the traditional input factors but also on unpriced goods and services such as those provided by the natural environment. However, this solution to the externality problem requires that the tax authority is able to identify the external cost function. This returns us to the challenge of how to go about assessing the size of this function and, hence, the value of the damage caused by a negative externality (or the benefits incurred by a positive one).

2.2 Externality Valuation in Theory

The theoretical basis for the economic valuation of externalities (and thus environmental impacts) is outlined in the welfare economics literature. This strand of research recognizes that the economic value of a resource or service is ultimately a function of individual preferences and, therefore, that the tool for analyzing welfare changes is utility theory. For example, consider the welfare of individual i and assume that her utility (u_i) depends on a vector of private consumption possibilities ($\mathbf{x}$) and on a vector of environmental and resource flows ($\mathbf{q}$) given to the individual (i.e., environmental quality). Hence, individual i's utility function,

$$u_i = u_i(\mathbf{x}, \mathbf{q}), \tag{1}$$

shows the various combinations of $\mathbf{x}$ and $\mathbf{q}$ from which the individual derives utility. Furthermore, assume that some of the elements in $\mathbf{q}$ have positive prices, represented by the vector $\mathbf{r}$. The individual maximizes her utility subject to the budget constraint,

$$M_i = \mathbf{px} + \mathbf{rq}, \tag{2}$$

where M_i is individual i's income and $\mathbf{p}$ is a vector of prices for $\mathbf{x}$. The first-order condition for this maximization problem implies that individual i's conditional demand function (i.e., conditioned on the imposed $\mathbf{q}$), x_i, for marketed goods can be written as

$$x_i = x_i(\mathbf{p}, M_i - \mathbf{rq}, \mathbf{q}). \tag{3}$$

Inserting Eq. (3) into Eq. (1) gives the conditional indirect utility function, v, for individual i:

$$v_i = v_i(\mathbf{p}, M_i - \mathbf{rq}, \mathbf{q}). \tag{4}$$

The use of indirect utility functions enables us to express welfare measures in money metric terms. Assuming that $\mathbf{q}$ consists of only one element q, that $\mathbf{x}$ is the numeraire, and that q is an environmental "good" (i.e., *ceteris paribus*, individual i would choose more of q if given the option), consider a project that causes the environmental quality to improve from q^0 to q^1 (i.e., $q^1 > q^0$). The project causes a positive change in individual i's indirect utility (or welfare) so that

$$\Delta v_i = v_i(\mathbf{p}, M_i - rq^1, q^1) - v_i(\mathbf{p}, M_i - rq^0, q^0) > 0. \tag{5}$$

Thus, given the presence of the project, individual i is made better off. However, because utility is not directly observable and because environmental "goods" are not part of market transactions, we need to find alternative ways of assessing the value of this welfare change. Theoretically, two standard monetary measures of quality-based welfare changes are the compensating surplus and the equivalent surplus. The first measure, compensating surplus (CS), is given by the solution to

$$v_i(\mathbf{p}, M_i - rq^0, q^0) = v_i(\mathbf{p}, M_i - rq^1 - CS, q^1). \tag{6}$$

In this case, CS is equal to the maximum willingness to pay (WTP) for the environmental improvement. Second, consider the equivalent surplus (ES) measure, which is given by the solution to

$$v_i(\mathbf{p}, M_i - rq^0 + ES, q^0) = v_i(\mathbf{p}, M_i - rq^1, q^1) \tag{7}$$

Here, ES equals the minimum willingness to accept (WTA) compensation for the environmental improvement not occurring. The interpretation of the CS and ES measures is reversed in the case of an environmental quality deterioration, where CS is equal to the minimum WTA and ES is equal to the maximum WTP.

In empirical studies, it is generally the case that WTA measures tend to be substantially higher than WTP measures for the same change. Thus, the choice of WTP or WTA as a measure of economic value may significantly affect the size of the resulting externality estimate. Even though there is no firm theoretical basis for choosing one approach rather

than another, *WTP* is generally advocated as the most appropriate measure of changes in welfare. This is partly because *WTA* is not constrained by income and, therefore, is seen to introduce an incentive problem. On the other hand, the sensitivity of *WTP* to income introduces certain equity issues.

In sum, the economic valuation of externalities, and thus of many environmental impacts, builds on the assumption that people seek to satisfy their preferences, which are exogenously determined, complete, continuous, and ethically unchallengeable (subjective). The environment is essentially treated as any other private commodity, and people are willing to consider trade-offs in relation to the quantity or quality of environmental "goods." According to the welfare economics literature, the appropriate role of policy in the field of energy externalities is to aggregate the monetary estimates of individual preferences and to weigh them against other (more tangible) economic benefits and costs. Thus, the economics of nonmarket valuation builds on (1) clear but relatively restrictive behavioral assumptions (i.e., utility maximization), (2) a sense of society as the sum of the preferences of its individual members, and (3) a view of the task of public policy involving the internalization of external impacts and with utilitarianism as the ethical principle guiding social choice.

2.3 Externality Valuation in Practice

In practice, there are two basic methodological approaches used for the valuation of external costs in the energy sector: the abatement cost approach and the damage cost approach.

The abatement cost approach uses the costs of controlling or mitigating damage or the costs of meeting legislated regulations as an implicit value of the damage avoided. The rationale behind this approach is that legislatures are assumed to have considered the willingness of the public to pay for alleviation of the damage in setting the standard, thereby providing a revealed preference damage estimate no less reliable than the more direct valuation methods. One of the serious caveats with this approach is that it relies on the rather strong assumption that decision makers always make optimal decisions, that is, that they know the true abatement and damage costs. Also, a necessary condition for social optimality is that the abatement costs used are derived from the pollution control strategy that provides the least cost of control. If not, the estimates cannot reflect damage costs adequately.

Another limitation of the abatement cost approach is that society's preferences change over time as information, analysis, values, and policies change. Hence, past revealed preferences might bear little relation to actual impacts today and their current value to society. For instance, the implicit value of carbon dioxide (CO_2) emissions indicated by a revealed preference analysis would, in many cases, be very low because regulations targeted toward this problem are relatively few in number and low in scale. This built-in "tautology" of the approach means that estimates need to be constantly revised as regulations and policies change. Perhaps more important, given that policy is by definition optimal, the analysis provides no room for relevant policy implications; therefore, one can question why the analysis is needed in the first place.

The damage cost approach is aimed at measuring the net economic damage arising from negative externalities by focusing more or less directly on explicitly expressed preferences. This approach can be subdivided into two main categories: top-down and bottom-up. Top-down approaches make use of highly aggregated data to estimate the external costs of, say, particular pollutants. Top-down studies are typically carried out at the national or regional level, using estimates of total quantities of pollutants and estimates of total damage caused by the pollutants. Specifically some estimate of national damage is divided by total pollutant depositions to obtain a measure of physical damage per unit of pollutant (Fig. 2). These physical damages are then attributed to power plants and converted to damage costs using available monetary estimates of the damages arising from the pollutants under study. The main critique against the top-down approach is that it "generically" cannot take into account the site specificity of many types of impacts or the various stages of the fuel cycle. Another argument that has been raised

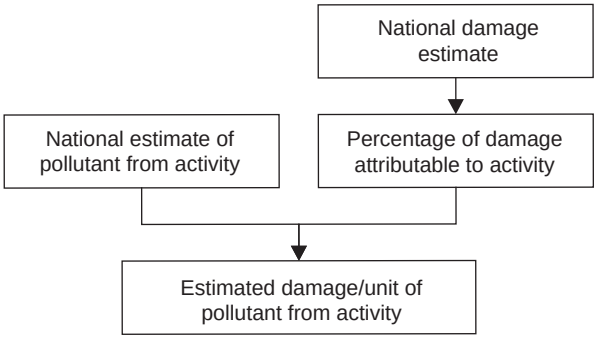

FIGURE 2 The top-down approach.

against the approach is that it is derivative because it depends mostly on previous estimates and approximations.

In the bottom-up approach, damages from a single source are typically traced, quantified, and monetized through damage functions/impact pathways (Fig. 3). This method makes use of technology-specific data combined with dispersion models, information on receptors, and dose–response functions to calculate the impacts of specific externalities. The bottom-up approach has been criticized because applications of the method have unveiled a tendency for only a subset of impacts to be included in assessments, focusing on areas where data are readily available and rendering impact pathways easier to establish. That is, in bottom-up applications important impacts may be left out, especially in cases where data are not readily available. Furthermore, the bottom-up approach relies on models that might not adequately account for complexities in "the real world" given that there may be synergistic effects between pollutants and environmental stresses and

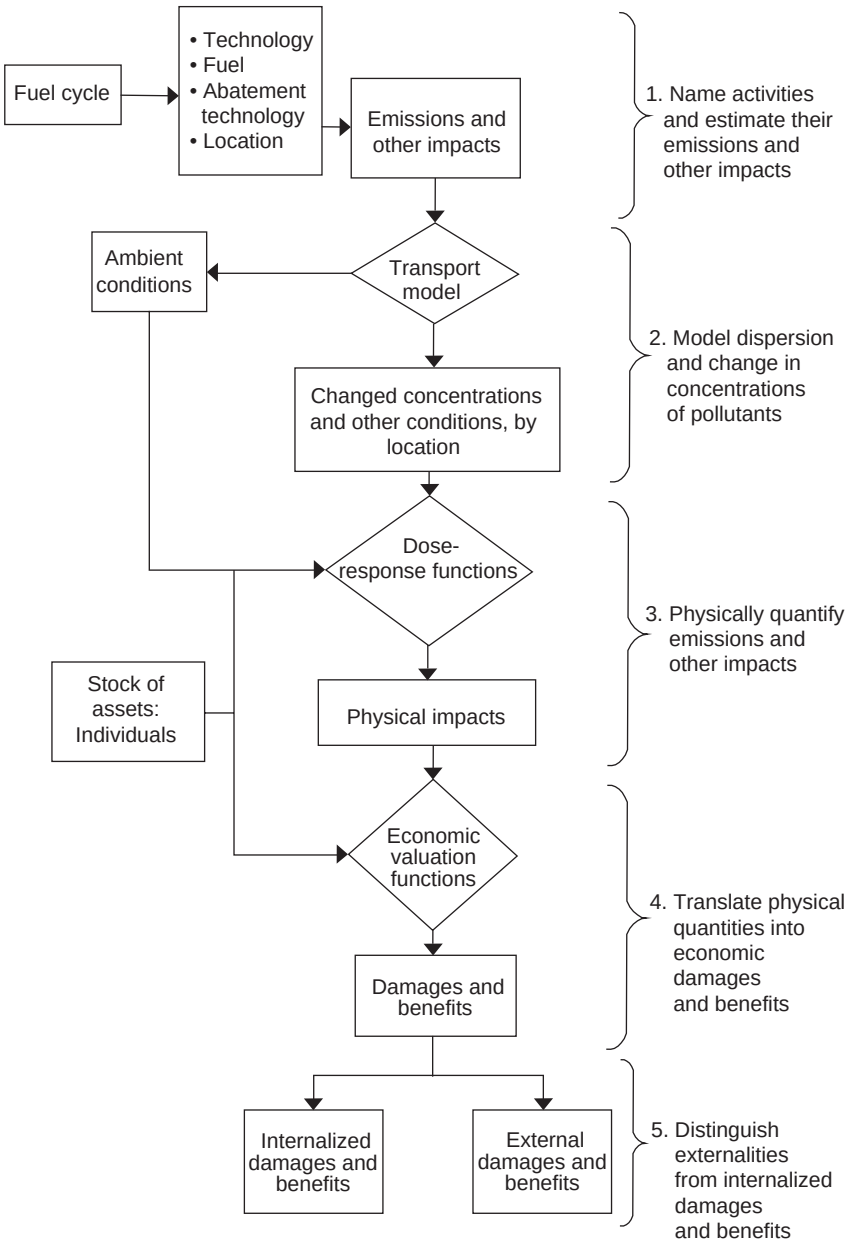

FIGURE 3 The impact pathway (bottom-up approach).

that there may be problems in establishing the timing of effects (e.g., between exposure and impact). Therefore, the argument is that bottom-up approaches might not be sufficiently transparent. Still, this is the approach that, due to its focus on explicit estimates of economic welfare (rather than on implicit ones such as in the abatement cost approach), appears to be most in line with economic theory. As is evident by the methodological choices of recent externality studies, it is also the most preferred approach to the empirical assessment of externalities in the electricity sector (see Section 3.1).

There are several ways of monetizing the identified externalities. The first two approaches discussed previously, abatement cost and top-down damage cost, directly provide a monetary estimate of the damages associated with the externalities. However, in the third approach, bottom-up damage cost, one needs to translate the physically quantified impacts into monetary terms. By definition, externalities are external to the market in question. However, certain costs (e.g., pollution damage to property or agriculture) may be external to electricity markets but subject to pricing in other markets. In such cases, the relevant market prices are used as a direct basis for valuation. Impacts from externalities that are not reflected in prices in any market must then rely on nonmarket valuation methods, which can be subdivided into direct methods and indirect methods.

The direct methods attempt to create a hypothetical market for the environmental good. These methods are direct in the sense that they are based on direct questions to households about willingness to pay. The direct methods possess the advantage that they can assess total economic values, that is, both the use and nonuse values (i.e., existence values) associated with the good. Well-known examples of such techniques include contingent valuation and choice experiments. The indirect methods take their basis in the actual (rather than the hypothetical) behavior of individuals. In terms of willingness to pay, the welfare effects show up as changes in costs or revenues either in observable markets or in markets closely related to the resource that is affected by the externality. Thus, the damage is indirectly valued using an existing relation between the externality and some good that is traded in a market. Examples of indirect methods are hedonic pricing (e.g., looking at property values) and travel costs (e.g., looking at amenity values).

3. ELECTRICITY EXTERNALITY STUDIES

This section gives an overview of the results from the multitude of externality studies carried out during the 1980s and 1990s. This is followed by a brief look at the results from one particularly detailed study, the European ExternE project.

3.1 Overview of Results

A considerable number of externality studies were carried out during the 1980s and 1990s. Figure 4 presents the results from 63 externality studies, with the numbers in square brackets showing the total number of observations for each fuel source (note the use of logarithmic scale). The ranges overlap, rendering ambiguous the ranking of various fuels with respect to externality impacts. Indeed, it is possible, using these overlapping ranges, to argue for virtually any ranking order one likes across the options in question. However, when the preponderance of findings are taken into account, the results do suggest that fossil fuel-fired power (in particular coal and oil) gives rise to the highest external costs, whereas some of the renewable energy sources (solar, wind, and hydropower) tend to have the lowest.

For a specific fuel source, the difference between low and high values is substantial, and this is also true if one looks at single studies. The ranges reported can often vary from a tiny fraction of electricity market prices and the private costs of producing power to a number that is significantly above private cost levels. However, the wider sensitivities are not always fully conveyed or discussed in individual studies, where results are often expressed with a fine degree of precision and are routinely referred to as "real," "full," or "true" values. When attention extends to the literature as a whole, the scale of the discrepancies between the results obtained by various studies for similar fuels does raise concerns about the validity and reliability of an approach to regulatory appraisal based purely on environmental valuation.

This said, it is of course entirely reasonable that there should be some degree of variability among studies. This may be due, for instance, to factors such as (1) a focus on different technologies (e.g., implying separate emission factors); (2) different site-specific characteristics (e.g., population density, income, transport distances); (3) differences in scope (e.g., different selections of externalities may be included, different taxonomies may be used to organize effects,

different stages in fuel cycles or resource chains may be evaluated); (4) different trade-offs may be implicit among the various dimensions of environmental effects (e.g., injuries and disease, immediate or latent effects, concentrated or dispersed effects); (5) different treatments of complexity, uncertainty, or gaps in knowledge (e.g., *ex ante* rather than *ex post* data; likely technological trajectories; indirect, contingent, or synergistic effects). Some of these issues are further discussed in the following section. For the moment, note that it is difficult to determine whether such factors justify such large variability in results, especially given that there is no objective metric against which to compare the "truth" of the contending empirical estimates.

Sundqvist and Söderholm provided an overview of roughly 40 externality studies and showed that, in addition to the apparent disparity of results, several other conceptual issues are of importance. First, most of the fuel sources available for power generation, including coal, oil, natural gas, nuclear, hydro, wind, solar, and biomass as well as (in a few cases) lignite, waste incineration, geothermal, peat, and orimulsion, have been addressed in previous valuation efforts. However, most studies focus on the traditional fuels such as coal and nuclear. Thus, there is a tendency for many studies to focus on existing technologies rather than on those technologies that are generally accepted as being likely to play a significant role in the future (e.g., wind, biomass). In many cases, this is understandable given that empirical data clearly are more available for existing technologies than for emerging ones. Nevertheless, an important goal of externality valuation in the power sector has been to "level the playing field" in the selection between traditional and new generating technologies. This would probably require a stronger focus on promising but as yet uncommercialized technologies.

Second, a majority of the studies have been carried out for the developed world (mostly for Western

Europe and the United States). Thus, only in some rare cases has the focus been on developing countries, where the pressure for additional power capacity is by far the greatest. There are also reasons to believe that externality estimates should differ substantially between developing and developed countries. In developing countries, incomes are lower, sociocultural priorities are likely to differ, and the environmental effects of power production may be fundamentally different. An important example of the latter is the environmental externalities stemming from hydropower. Hydroelectric development in tropical climates may give rise to global warming impacts due to decay of vegetation left in the reservoir, whereas hydroelectric development in cooler climates will not. This raises serious concerns about transferring values from studies conducted in, say, Western Europe for use in a developing country context.

Third, examining the methodologies used over time reveals that the bottom-up damage cost approach has become the dominant paradigm, whereas the abatement cost and top-down approaches were used predominantly during the 1980s and early 1990s (Fig. 5). An important reason for this development is that the national implementation phase of the ExternE project relies solely on damage cost bottom-up models, and these studies together represent a large share of the total number of projects conducted during the latter part of the 1990s. However, this also indicates that the bottom-up model has been accepted as the most appropriate method with which to assess power generation externalities. The ExternE project has largely served as a vehicle in the methodological development of externality valuation. The sophistication and scope of the ExternE work and the detailed attention to methodology have been widely respected at the international level, and many followers rely heavily on the numbers and methods presented. However, this development raises the question of whether the choice of methodological approach (between abatement costs and damage costs) matters for the results. We return to this question in more detail later and suggest that this choice might very well matter. This, in turn, raises important concerns about the reliability of external cost valuation exercises in the power-generating sector.

3.2 An Example: The ExternE Core Project

As noted earlier, one of the most influential externality studies is the European ExternE project. This project aimed at evaluating the external costs of the various power generation fuel cycles in the European Union using the bottom-up approach. Because the ExternE project represents one of the most ambitious and internationally respected attempts to yield a "true" external cost estimate for the various power technologies, it serves well as an example. Tables I and II present the various power generation externalities quantified and priced within the ExternE core project. The ExternE core project was followed up by the so-called national implementation project, whose aim has been to develop a European Union-wide set of external cost data for the various fuel cycles and countries as well as methods for aggregation of results to make them useful for policymakers.

When inspecting Tables I and II, we first observe that most of the fuel cycles involve significant health and mortality impacts on humans (public and occupational). In this project, considerable attention was devoted to the evaluation of public health impacts and much was learned, especially about the importance of fine particle emissions. Overall, the results support the rather unexceptional conclusion that fossil fuels, especially coal, present more serious environmental impacts than do renewables such as hydro and wind. It is notable that the most favorable results are attributed to nuclear power. However, most of the externality damages priced in the ExternE core project are reported to reflect an uncertainty range characterized as "medium to high." This raises a number of salient critical issues bearing on the robustness and meaning of these results and their associated prescriptive rankings.

4. CRITICAL ISSUES IN EXTERNALITY ASSESSMENT

This section discusses a number of critical issues concerning nonmarket valuation of energy externalities and focuses in particular on the role of externality valuation in policymaking.

4.1 Methodological Issues

As already noted, we need not necessarily be concerned about the variability in external cost estimates if we can identify rational reasons for the discrepancies. However, one possible reason for such discrepancies that would itself raise concerns is that the choice of methodology may have a significant impact on the results. By using the results from more than 40 electricity externality studies across eight fuel sources, Sundqvist provided some econometric evidence in support of the conclusion that methodological choice does matter for the results. He reported that the probability of obtaining a "low" externality value is, *ceteris paribus*, generally lower when the abatement cost approach or the top-down damage cost approach is used, whereas the opposite is true when the bottom-up damage cost approach is used. Abatement costs will (theoretically) be representative of damage costs if and only if they are derived from the least cost strategy, but normally most studies employ the most commonly used (or mandated) abatement technology when assessing pollution abatement costs. As a consequence, it can be expected that the results for the abatement cost applications would deviate. The reason why the top-down approach also tends to yield relatively high results is that practical problems may arise in attributing the "exact" damage to each individual source, and this may force researchers to rationalize and use standardized rules for the attribution process. These rules may fail to ascribe the aggregated damage to each and every individual source, especially smaller sources, thereby producing estimates for specific power plants that are positively biased, given that these plants normally are easily identifiable as well as significant sources of pollution.

A fundamental question raised by these results concerns the extent to which the three broad approaches to externality valuation are comparable. So far, we have suggested that the differences reported may be due primarily to a number of technical factors in analysis such as identifying the least cost control strategy and addressing all relevant end points. If these issues can be resolved, it might be hoped (at least in principle) that the methods could begin to generate more similar results. In what follows, we suggest a number of reasons why this is not necessarily the case. However, before turning to this, it may be worth reviewing one final observation that has been made concerning the pattern evident in the picture of environmental valuation results provided in Fig. 4.

Stirling observed that the scope for multiple divergent, but equally legitimate, "framing assumptions" is a feature held in common between environmental valuation and many other forms of regulatory appraisal, including risk assessment and decision analysis. However, one feature that is unique to neoclassical environmental valuation is that what is conveyed to policymaking is not simply the relative performance orderings for different options but also the particular numerical values themselves. These are expressed as particular values for monetary externalities, suitable for adoption as a basis for Pigovian taxes. Stirling argued that this may make environmental valuation peculiarly vulnerable to a phenomenon he referred to as a "price imperative." This describes a situation where, when faced with widely differing but equally valid possible assumptions, the choices made in analysis—implicitly or explicitly—lead results to fall into a domain that is most likely to be practically usable in policymaking. A Pigovian tax set at much less than one-tenth of market prices would have minimal impact on producer or consumer behavior. A Pigovian tax set at 10 times market prices would probably be politically unfeasible. This may be a factor in explaining why, despite ranges of variation spanning more than six orders of magnitude in Fig. 4, the bulk of valuation results lie well within one order of magnitude of existing wholesale electricity prices.

4.2 Externality Classification

The neoclassical welfare economics literature provides a relatively straightforward definition of the concept of externality. However, in practice, the choice of "relevant" externalities tends to differ among various valuation studies. In other words, some studies seem to differ considerably in their definition of what constitutes an externality. As an example, the inclusion of employment benefits (following a power generation investment) as an external benefit strains the definition of what an externality is. For employment effects to be considered external, the local and regional labor markets

must function poorly (i.e., market failures must be present) and workers must be immobile. However, some authors make a strong case for treating employment impacts as external benefits. For instance, to the extent that people obtain disutility (e.g., less self-confidence) from unemployment as such, this notion is valid. However, in such a case, the employment benefits should be compared across all fuel sources and not only for renewable energy projects (as is often the case).

For economists, the existence of externalities motivates regulatory action and the use of taxes and subsidies to improve efficiency. However, lay people and politicians often hold the view that regulations and other policy measures should be used to promote the "good" and discourage the "bad" in a much broader sense. This suggests that economists have to be careful in explaining what the results stemming from externality appraisals show and what they do not show. The preceding also raises the more philosophical question of what should be the ultimate end of policy: economic efficiency based on individual preferences or other value judgments formed in public deliberations (or any mix of these policy principles)? If the latter path is chosen, externality valuation may still provide an important input into the policy decision process, but the notion of some "total" (or "true") cost of electricity production appears less valid. We return to this question later.

4.3 Scope

Even when all of the external costs and benefits of a given power generation source have been identified, there remains the issue of choosing the appropriate level of scope for the valuation effort. At least two choices have to be made. First, which of the externalities are important enough to include in the valuation? Second, should the study address externalities across the entire fuel cycle (including downstream and upstream impacts) or focus only on the generation stage? Studies conducted in the past have made different choices in these respects, and this is likely to explain some of the disparity in the estimates presented. Let us first look at how this question has been dealt with in previous studies.

As a part of the process of deciding what externalities to include, many studies begin with a comprehensive screening of the relevant economic and scientific literature to determine which pathways and end points are likely to be important in the analysis. Thus, some of the externalities are *de facto* assigned a zero value on the basis of their presumed insignificance, whereas others are included in the analysis because the initial screening could not rule out the possibility of significant effects. It should be clear that this approach may lead to total externality values that are significantly downward biased. However, what is perhaps of more importance is those cases where externalities are left out of the analysis because there is insufficient scientific information to establish defensible monetary damage values. The most important example is global warming and CO_2 emissions. During the first phase of the ExternE project, it was noted that the environmental damage cost estimates for greenhouse gas emissions presented in the literature spanned a range of several orders of magnitude, and the main report concluded that "all attempts to value these impacts require important normative judgements, and therefore the potential for synthesis or consensus is remote."

After additional research efforts within the ExternE project, these general conclusions appear to remain valid. However, it is generally agreed that the external costs of CO_2 emissions are substantial and, therefore, may constitute a large share of the total value. Thus, the environmental economist faces a dilemma: is it better to leave out potentially important external damages from the valuation and present biased estimates, or should one make use of rough proxy estimates (e.g., mitigation costs) to provide (or at least approach) some kind of "full-cost" estimate? In the end, the ExternE project chose the latter path and recommended the use of "minimum," "central," and "maximum" estimates.

This raises a number of important issues. The choice of which externalities to include in the assessment cannot be entirely objective but is rather a matter of judgment. The judgment that has to be made is essentially whether the externality under consideration is "mature" enough to "undergo" economic valuation. However, this is not only a question of whether the scientific knowledge is more or less established; it also involves the issue of whether the public is sufficiently informed and, hence, able to form a valid opinion about the issue at hand. Again, economic valuation is ultimately about measuring people's given preferences toward goods, but if no relevant preference structure for a particular good exists (as with global warming), the valuation effort may be seen as arbitrary. We also noted previously that the use of abatement cost estimates (i.e., regulatory-revealed preferences) provides poor substitutes given that such estimates rely on the notion that all relevant preferences

have already been perfectly integrated into policy decisions.

This raises questions about the decision in the ExternE project to present rough estimates of global warming impacts. Moreover, global warming also entails important ethical and justice-related issues such as the question of whether human lives lost in developing countries should count less than corresponding lives in the developed world and to what extent impacts affecting future generations should be discounted (if at all). In such a case, the initial challenge of policy might not lie in "measuring" and aggregating individual preferences but rather might lie in specifying the conditions for public discourse over common ways of understanding the meanings and relative priorities attached to the various pertinent issues.

The preceding also suggests that any notion of "full," "total," or "true" cost of electricity has to be understood as hypothetical at best. The fact that externality studies leave out potentially important externalities might not be a problem per se. On the contrary, nonmarket valuation builds on specific basic assumptions, primarily about the behavior and preferences of the public, and if these are not well articulated, it may be better to refrain from monetary valuation. These concerns are likely to be particularly valid for "goods" with which people have relatively little past experience and that are "complex" and involve far-reaching and unknown consequences. Global warming, like the risk profile for nuclear accidents and radioactive waste, provides examples.

Finally, the choice of what parts of the fuel cycle to focus on also complicates the assessment of the full cost of electricity. Where should one draw the appropriate analytical boundaries and, thus, the limits of the external cost assessment? This choice is perhaps somewhat more technical than that of what externalities to include, but it is no less important. It is also complicated by the fact that the values of many upstream and downstream impacts tend to be highly site specific and depend, for instance, on the mode of transportation and the location of the place where the fuel is extracted. One problem is how one is to define the "entire" fuel supply chain. For instance, if we include in the analysis the externalities incurred by transporting fuels from the mine or well to the power station, should we then not also include the corresponding transport-related externalities involved in bringing building materials and workers to the power plant construction site? The choice of a relevant level of analysis is not easy, and this also suggests that the notion of any "total" or "true" cost of power generation is flawed. Ideally, this choice should be guided by the need for relevant policy information.

4.4 Parameter Input Assumptions

There are essentially two different categories of parameter input assumptions made in electricity externality studies: technical assumptions (e.g., energy efficiency, dose–response functions, emission factors) and economic assumptions (e.g., monetary values, discount rates). Arguably, the assumptions regarding, for example, CO_2 emissions are major drivers of the results. Another striking example concerns the assumptions made about the monetary values used to value mortality impacts due to air pollution. Many studies use the value of a statistical life (VOSL) to assess these types of impacts. For instance, the ExternE core study relies on a VOSL value of U.S. $2.6 million for Europe. In the national implementation part of the ExternE project, the decision was made to introduce an alternative measure on which to base the valuation of mortality impacts due to air pollution. This is the so-called years of life lost (YOLL) approach, which essentially assigns a WTP value to the risk of reducing life expectancy rather than to the risk of death. The YOLL values attributed to the mortality impacts are, as is evident from Fig. 6, reduced by up to two orders of magnitude as compared with the values based on the VOSL method. In addition, the core project that relied on the VOSL approach did not include values for chronic mortality impacts due to air pollution, something that the national implementation studies do.

Thus, it is clear that the assumptions underlying the valuation of human health and mortality impacts, global warming impacts, and dose–response functions are major drivers of external cost estimates. Clearly, this also provides a major explanation as to why the total externality estimates from various studies often differ considerably (even for the same fuel source).

So far in this subsection, we have noted that the input assumptions made in externality assessments play a significant role in affecting the overall external damage estimates and, thus, in guiding policy. To some extent, this is how it should be, of course; different sites and different technologies (depending, e.g., on vintage) incur different emission impacts and, hence, different damages. Still, the large sensitivity in results due to parameter input assumptions also creates problems for policymakers. First, policymakers often wish to gain some notion as to which

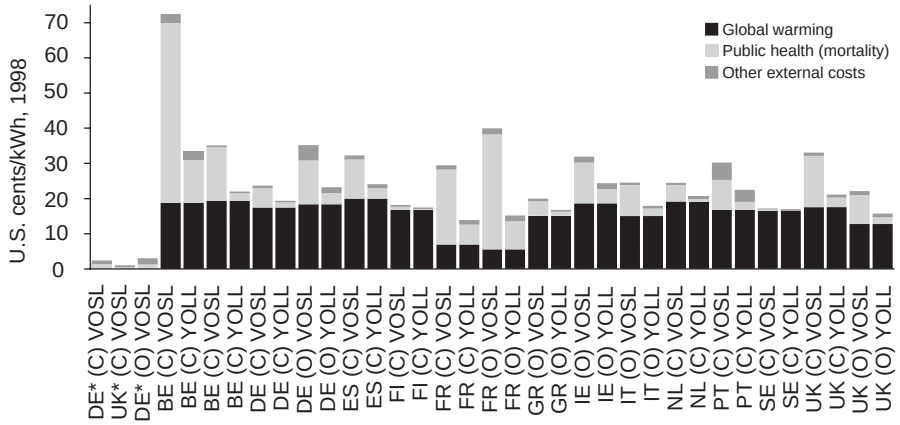

FIGURE 6 External cost estimates in the ExternE core (*) and national implementation projects: coal (C) and oil (O) fuel cycle. From Sundqvist, T., and Söderholm, P. (2002). are the most important external costs (i.e., environmental damages) for each power generation source. This enables them to target policy measures, such as subsidies, research and development (R&D) support, and regulations, toward the most important impacts. However, previous research efforts have provided only limited guidance on this particular point. Also, in many studies, a single category of external damages seems to dominate the total external cost estimates. For example, in the initial ExternE coal study, human health-related impacts dominate the aggregate damage (some 76–95% of the total), whereas global warming impacts constitute an important part of the estimated damages from the coal fuel cycle in the national implementation part of ExternE (Fig. 6). Second, in deregulated electricity markets, one of the most important uses of external cost estimates are as inputs in the development of environmental taxes and tradable permit schemes. However, for this reason, policymakers would need relatively "safe bets" about the general impacts involved, but so far previous studies have provided only wide ranges of estimates. Again, the impact of global warming is a good illustration of this.

This discussion raises a fundamental issue in nonmarket valuation that is rarely touched on in the electricity externality debate. Most environmental economists would agree that environmental valuation requires that a relevant "project" has been defined and that it involves the choice between two or more relevant alternatives. In the case of electricity externalities, these "projects" are normally the investments in various power plants (few companies or governments undertake investments in entire fuel cycles). However, in externality studies, these investment projects are often hypothetical; that is, they do not represent an existing (real) situation, and valuation estimates are transferred from other studies. The problem with this is that according to the literature on nonmarket valuation (and indeed that on market valuation as well), economic values are context dependent and project specific. In other words, it might not make much sense to talk about a universal *WTP* for avoiding 1 ton of SO_2 being emitted, even though that is just what many policymakers would like to know about because they often prefer more or less harmonized standards and taxes across different regions.

4.5 Public versus Private Preferences

Critics of environmental valuation often stress that the methods used rely on overly restrictive assumptions. This implies that such studies often produce poor descriptions of the environmental values that people actually hold as well as underlying processes of preference formation. Specifically, externality valuations rest on an assumption that individuals aim at maximizing personal utility and that they possess well-articulated, ethically unchallengeable, and exogenous preferences for any environmental good. They also effectively assume that these individual preferences may be combined to yield an aggregate preference function for society as a whole. Both types of assumption are quite seriously problematic.

This second assumption is problematic even when approached within the confines of neoclassical welfare economics on which environmental valuation is

built. It glosses over the profound intractabilities involved in seeking definitively to compare the intensities of subjective preference displayed by various social agents. Indeed, even where social choices are addressed simply in ordinal terms as a matter of relative option rankings, economist Kenneth Arrow went a long way toward earning his Nobel Prize by demonstrating formally that it is impossible, under basic axioms of rational choice in neoclassical welfare economics, to guarantee any definitive aggregation of preference orderings in a plural society. In other words, the business of aggregating individual preferences, lying at the heart of neoclassical approaches to environmental valuation, violates its own well-established theoretical principles.

Beyond this, the first assumption raises a number of further concerns arising outside the narrow field of rational choice in neoclassical welfare economics. For instance, rather than being taken simply as an expression of personal utility maximization, environmental values may instead be seen to hold a broad ethical content. Because ethics is a matter for cultural and political discourse, environmental valuation should, it is argued, be endogenous to the political process and rely on social agreements. In other words, the initial challenge of environmental policy might lie not in "discovering" private preferences but rather in specifying the conditions for public discourse over what is worth valuing and for what reason.

Sagoff claimed that individuals essentially have at least two different preference orderings. Their private preferences reflect only their own well-being as consumers of private goods, whereas the public preferences reflect moral values about what persons, as citizens, believe is right and just for society as a whole. In their roles as citizens, people may express a rights-based (or deontological) belief system, which denies the principle of utilitarianism (and trade-offs) and instead recognizes the priority of the right over the good. Such a moral position is likely to be particularly prevalent in the case of environmental goods. The environment is often the subject of ethical concern and involves many cross-cutting dimensions that cannot be causally separated. In this way, the "market analogy" and "commodity fiction" of environmental valuation may break down.

There is empirical evidence that people express public, rather than private, preferences when considering complex environmental issues and when confronted with *WTP* questions in contingent valuation surveys. It is also the case that the consumer–citizen distinction provides one explanation of some puzzling phenomena frequently observed in contingent valuation studies. For example, a large number of studies have found very large discrepancies between *WTP* and *WTA* measures for environmental goods, with the latter often being several times larger than the former. This may be explained by the notion that in the *WTA* case, if the environmental good is morally considerable, the acceptable level of compensation will be extremely high or even undefined.

The distinction between private and public preferences is highly relevant when considering the external costs of power generation. Most important, many power generation externalities are either relatively novel (e.g., the risk profiles of nuclear power) or complex (e.g., ecosystem changes due to hydropower developments). For these types of externalities, most people have yet to find an overall ethical position; consequently, there are no "given" preferences on which economic valuation may rely. In addition, most power generation fuel cycles involve significant impacts on the health and deaths of humans. These impacts raise a moral dilemma: to what extent should we treat humans as means to an end (utility) or as ends in themselves? Such a question should ideally be resolved within the realms of public discourse. Thus, the social choice problem with respect to many energy and environmental issues is first, about advancing common ways of understanding the pertinent issues. This implies that environmental research in the social science field must increasingly address the instruments and content of political and moral debate and not simply the technicalities of established valuation methods. In other words, the process may count every bit as much as the outcome.

The preceding discussion also adds a new perspective to the observed differences in reported externality estimates between the abatement cost approach and the damage cost approach. The two methods involve different ethical bases. For example, the damage estimates developed within the ExternE project are considered *ex ante* (i.e., the damages themselves determine whether one power source is "better" than another), whereas the estimates derived using the abatement cost approach are *ex post* (i.e., the price is an outcome of a political process and does not play a direct role in the decision). Therefore, the damages developed in "advance" (as in the ExternE project) might not be directly comparable to "implicit" estimates that are based on the cost of abating as revealed by decision makers given that

they reflect different reasoning processes. Policymakers, in their formulation of regulations, may very well rely on ethical foundations other than economic welfare theory.

5. CONCLUSIONS

This discussion has considered the theoretical framework, reviewed the principal methodologies, and surveyed the detailed results associated with the valuation of external environmental costs of electricity production. Given the magnitude and pressing nature of the environmental imperatives in this area, it is clear that serious careful study of the kind that is well represented in this field has a crucial role to play in informing policy. However, it supports neither the cause of rigorous analysis nor that of environmental protection to neglect the series of profound difficulties and intractable challenges that attend neoclassical environmental valuation. In particular, it is important to note that the theoretical foundations are contestable, the methods are problematic, and the practical results are highly variable and sensitive to divergent "framing assumptions".

Overall, the externality studies carried out have provided a welcome contribution to increasing the knowledge about the economic effects associated with the environmental problems in the electricity sector. However, more research is likely needed before these and future studies will be of practical use in shaping policymaking. Thus, perhaps the main positive conclusion that may be drawn from this critical survey is that the real value of environmental externality studies lies not so much in the particular numerical results they yield but more in the opportunity they provide to focus on the key sources of variability and sensitivity. In this regard, there may be considerable potential to combine these methods with techniques such as sensitivity and scenario analysis to systematically explore the implications of various possible frameworks and assumptions. By embedding such broader based approaches in inclusive deliberative procedures involving different industry and public stakeholders, the emphasis might usefully shift away from the numbers themselves and toward the contending perspectives and assumptions that "frame" these numbers. In this way, environmental valuation might contribute toward establishing a truly well-informed and robust basis for future environmental decision making in the electricity sector.

active power The part of the instantaneous power that can do real work. Real work is done when the resistive component of a load consumes electrical energy. Active power is measured in watts (W).

apparent power The total power (the complex vector sum of active and reactive power), measured in volt-amperes (VA).

bundling Transmission lines are bundled when there is more than one conductor per phase in extra high-voltage lines.

distribution The process of delivering electricity from substations to customers. The distribution system "steps down" power from higher voltage transmission lines to a level that can be used in homes and businesses.

grid The transmission network through which electricity moves from suppliers to customers.

load A device that uses the power supplied from the source for doing work.

reactive power The part of the instantaneous power that does no real work. It is absorbed by the inductive and/or capacitive components of the power system. It is measured in volt-amperes reactive (VAR).

short circuit A fault that occurs in an electric circuit or apparatus usually due to imperfect insulation causing a large current to flow through the system to ground. A short circuit has the potential of inflicting significant damage to the system.

substation The set of apparatus in a power system network that is used to change some characteristic, such as frequency or voltage, of power supplies.

transformer A device that is used to convert high alternating voltage to low alternating voltage and vice versa.

transmission The process that transports electric energy in bulk form, usually at high voltages, from a source of supply to a distribution system.

The modern electric power system is comprised of three primary entities: the generating system, which produces the electricity; the transmission system, which transfers the electricity over high-voltage transmission lines to regional substations; and the distribution system, which distributes the electricity to local customers. The transmission system consists of transmission lines and structures, substations, and transformers to convert the electricity and one voltage level to another. The substations also house a variety of equipment to protect against lightening, short circuits, and other faults that may occur in the system that adversely affect the distribution of the electricity to the customers. Electric power system customers range from residential home and small business owners to commercial customers and large industrial customers. Each type of customer impacts the transmission and distribution of electricity in different ways during daily and seasonal electric power variations.

1. A BRIEF HISTORY OF ELECTRIFICATION

The electrical utility industry is arguably the largest and most complex man-made system in the world and has been hailed as one of the greatest engineering achievements of the 20th century. The invention of the electric incandescent lamp by Thomas A. Edison

in 1878 marked the first step toward electrification. Edison is also credited with first proposing the idea of a centrally located power station for distributed lighting and developed the first electric network in the United States providing direct current (DC) power for lighting the lower Manhattan area of New York City. After the invention of the transformer, alternating current (AC) power became more popular than DC, with the first single-phase AC line being constructed in Oregon in 1889. The first three-phase system was installed by Southern California Edison at 2300 V in 1893. The development of electric power generation, transmission, and distribution has been increasing steadily ever since. From the construction of the first 220-V DC grids by Thomas Edison to the recent construction of AC grids with transmission voltages of 765,000 V, the drive to provide more reliable and efficient power has led to many significant developments in the field.

2. ELECTRIC POWER

The sinusoidal waveforms that comprise the voltages in most three-phase power transmission system typically have the form $v(t) = V\cos(\omega t)$ and the current has the form $i(t) = I\cos(\omega t + \phi)$, where ω is the system frequency (typically either 50 or 60 Hertz) and ϕ is the power factor angle. The angle ϕ is introduced due to the inherent inductive or capacitive nature of the transmission system and the system load, and it is the angle difference between the current and voltage waveforms. In an inductive circuit, the current lags the voltage, whereas in a capacitive circuit the current leads the voltage. In a purely inductive system, the current will lag the voltage by exactly 90°, whereas in a purely capacitive system the current will lead the voltage by exactly 90°. A purely resistive system will have the current and voltage in phase with each other. Most power systems are inductive due to the large reactance of the transmission lines. Figure 1 shows the phasor diagram and voltage and current waveforms of an inductive circuit in which the current lags the voltage by 30°.

For a circuit that has a combination of resistances and inductances, the product of the voltage (V) and the component of the current I that is in phase with the voltage ($I\cos\phi$) is the actual power that is used by the load. This quantity is known as the active power, P. The out-of-phase component ($VI\sin\phi$) is not used by the load directly but rather is responsible for the energization and deenergization of the reactive components in the circuit. This component is called

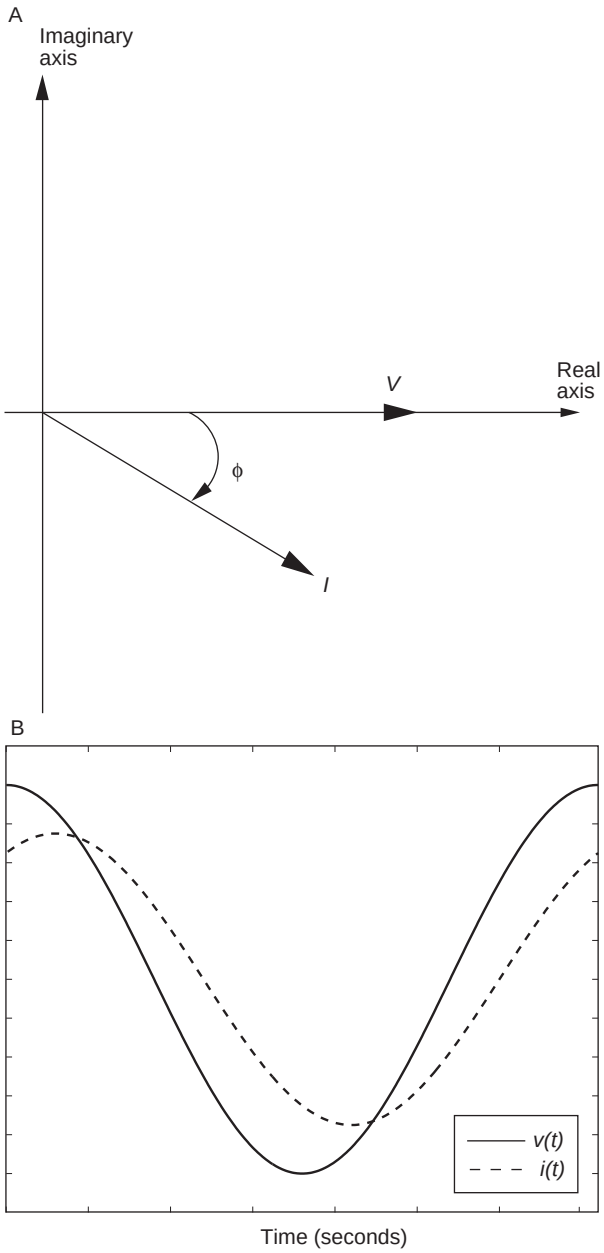

FIGURE 1 Inductive circuit (A) phasor diagram and (B) waveforms.

the reactive power, Q. Given the unique relationship between P and Q, the power in the AC circuit can be represented by $S = P + jQ$, where this complex sum S is called the apparent power with units of volt-amperes (VA). These relationships exist only in AC circuits. In a DC circuit there is no phase difference between the voltage and current; therefore, there is no reactive power and all the power generated is useful active power P. An inductive circuit will absorb both active and reactive power, whereas a

capacitive circuit will absorb active power but will inject reactive power.

2.1 Three-Phase Power

With the invention of the power transformer, AC systems became more popular than DC systems since the electric power could be transmitted across the transmission lines at higher voltage levels. Since power is the product of voltage and current, higher voltage levels require less current flow to transmit power. The reduced current subsequently reduces the active power losses in the line since the losses are given as I^2R, where R is the transmission line resistance.

Most electric power is transmitted in three phases, a–c. The three sets of sinusoidal voltages (and currents) are equal in magnitude but differ in phase angle of $\pm 120^\circ$ from each other. The voltages shown in Fig. 2 have three phases. By convention, the a phase is usually taken as the reference voltage. From these waveforms, it can be seen that the combination of three waveforms at any instant in time is identically zero. The same is true for the a–c phase currents. However, the product of these voltage and current waveforms yields the instantaneous electric power. If the three phases of electric power are combined, the resulting power is always constant at every instant under steady-state conditions even though the voltages and current are varying sinusoidally. This property of constant power is the primary reason that three-phase power is used. The same constant power result cannot be achieved by two-phase or four-phase power; thus, three-phase power is unique.

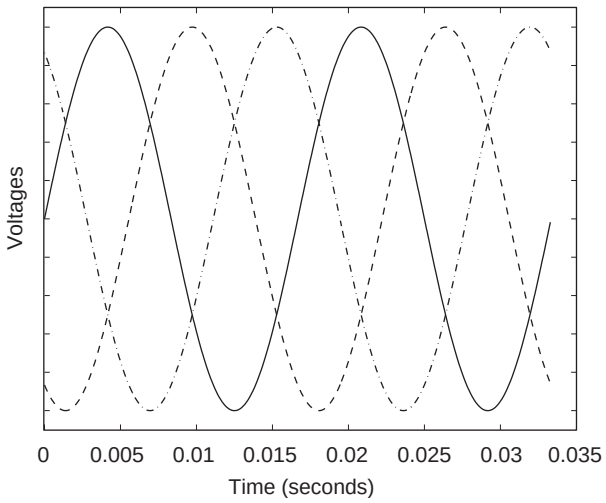

FIGURE 2 Power system voltages. Solid line, a phase; dashed line, b phase; and dashed–dotted line, c phase.

The second reason for using three-phase power is the ease of generation. A single-phase generator always experiences pulsating torque because the generated magnetic field does not rotate. The magnetic field simply changes direction at synchronous speed (i.e., it changes direction every 1/60 of a second). Conversely, the magnetic field generated by three-phase windings smoothly rotates at synchronous speed and does not produce pulsating torque. Similarly, motor loads require three-phase power for smooth and efficient operation. The three-phase system is also capable of eliminating the third harmonic currents that are often present in the distribution system by the use of delta-wye transformers, which are unique to the three-phase system. This idea can be extended to a six-phase system; however, such a system would not be economical because of the cost of additional cables and insulation. Hence, the three-phase system is considered to be optimal for electric power transmission.

2.2 Power System Voltage Levels

The three-phase power is typically generated at a particular voltage and is then "stepped up" to a higher voltage using a three-phase transformer. The higher voltage is used for transmission (to reduce currents and thereby losses) and is then "stepped down" to lower values at the distribution substation. The voltage ratings of large generators employed at generating stations range from 13.8 to 24 kV. This is stepped up to transmission-level voltages of 69–765 kV using transformers. The evolution of voltages from 138 to 765 kV in the United States was a result of the developing transmission technology. These voltage increases met the needs of the larger and more economical generators begin developed. This evolution is shown in Fig. 3. Electricity is delivered from the transmission system to the customer's home through a primary distribution system. This system is composed of a network of power lines delivering electricity at lower voltage. The voltage is stepped down again to the distribution system by a transformer. The voltages on a distribution level range from 220 V to 5 kV depending on the load connected. A typical power system configuration is shown in Fig. 4.

3. POWER TRANSFORMERS

A power transformer is used in a substation to step up or step down the incoming and outgoing voltages.

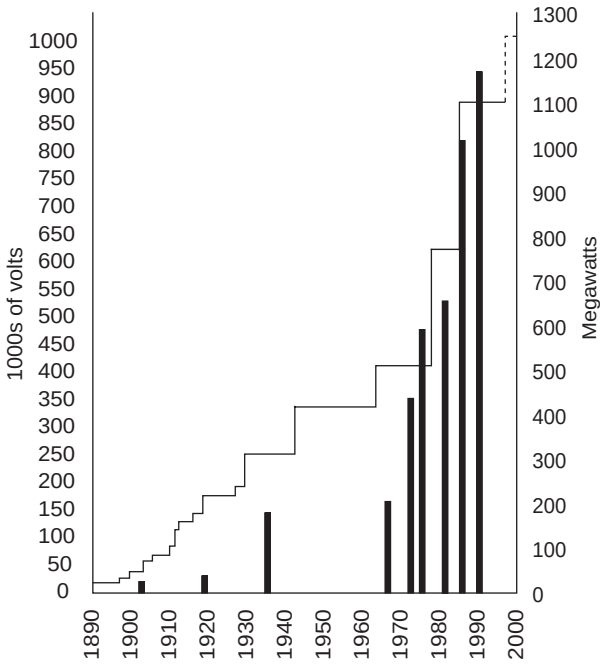

FIGURE 3 Evolution of maximum generating units and maximum transmission voltages.

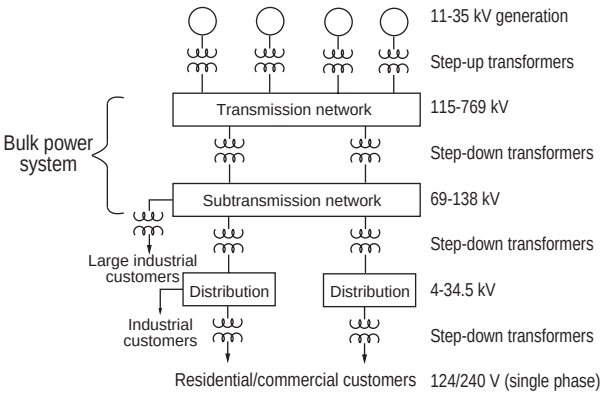

FIGURE 4 Power system configuration.

The transformers at distribution substations always step down the incoming transmission voltages to lower voltages used at the distribution level. Distribution lines emanate from substations at voltages of 4–25 kV. The power is then transmitted to a distribution transformer, where the voltage is further stepped down to the utilization voltage that ranges from 110 to 480 V for direct consumer usage.

When the transformer was invented by William Stanley in 1886, the early restrictions on the range and power levels of power systems were eliminated. In the DC system designed by Thomas Edison, the transmitted power required exceptionally high current levels because the voltage was low. These large current levels caused large voltage drops and power losses in the transmission lines. The use of transformers greatly reduced voltage drops and power losses. The basic premise of an ideal transformer is that if the system voltage is increased, the current levels decrease proportionally to maintain a constant power output.

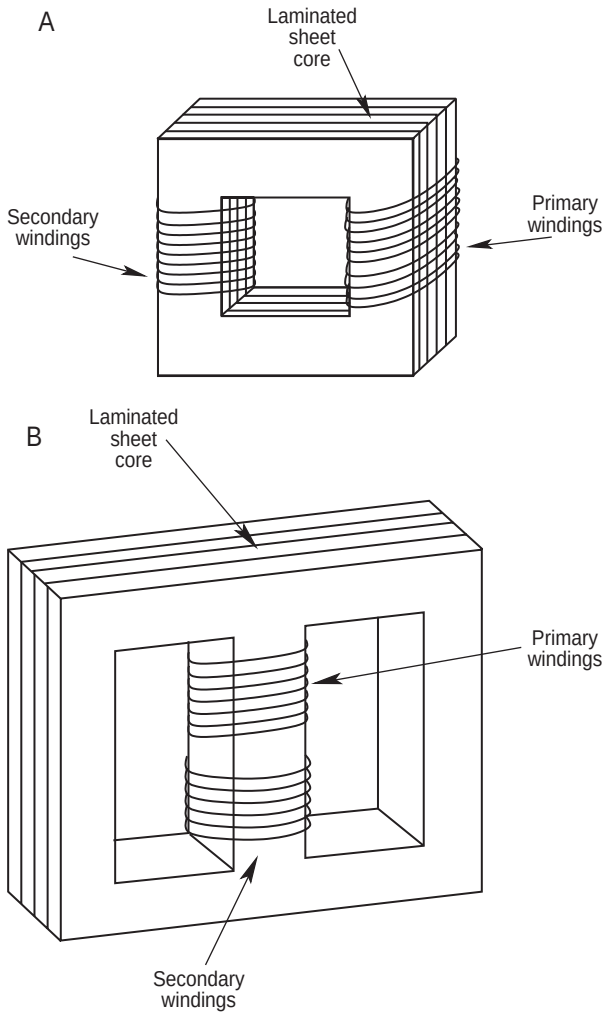

FIGURE 5 Single phase transformers: (A) core type and (B) shell type.

A transformer is typically constructed in one of two ways. The following basic configurations are shown in Fig. 5:

- Core type: This consists of a simple rectangular laminated piece of steel with the transformer winding wrapped on both sides. The winding connected to the source is called the primary winding, and that which is connected to the impedance or load is known as secondary winding.

• Shell type: This type of construction consists of a three-legged core with the windings wrapped around the center leg.

In both types of transformers, the core is constructed of thin laminations electrically isolated from each other in order to minimize eddy currents or those currents that circulate within the core material and cause heating losses.

The transformer works on the principle of magnetic induction. The time-varying voltage, V_p, that is applied to the input (primary) side produces a time-varying flux in the core. This changing flux couples with the secondary winding and induces a secondary voltage, V_s, in proportion to the ratio of the windings. The relationship between the voltages at both the sides of an ideal transformer is given by

$$V_p/V_s = N_p/N_s,$$

where N_p and N_s are the number of turns of the primary and secondary windings, respectively. The relationship between the current flowing in both sides of the ideal transformer is given by

$$N_p I_p = N_s I_s,$$

where I_p and I_s are the primary and secondary currents, respectively. If the transformer is lossless, then the input power is equal to the output power and the voltages and currents are related by $V_p/V_s = I_s/I_p$. Thus, as the voltage increases from secondary to primary, the current decreases; therefore, the current is lower at higher voltages.

In modern power systems, transformers can be found everywhere. Transformers have a variety of names, depending on the purpose for which they are used in a power system. A transformer connected to the output of the generator and used to step up its voltage to transmission levels is called a unit transformer. The transformers that bring down the transmission voltage levels to distribution levels are known as substation transformers. Lastly, the transformers that bring down the distribution-level voltage to the voltage level made available to the customers are known as distribution transformers.

Transformers are typically placed in a variety of locations. Many transformers are overhead transformers hung on poles with direct access to the wires. Underground transformers are typically placed in underground vaults to protect them from public access and environmental disturbances. The most common type of transformer is the pad-mounted transformer, which typically sits on a concrete pad at ground level. Pad mounts are designed for contact with the general public and therefore must adhere to strict American National Standards Institute (ANSI) standards. The last type of transformer is the interior transformer, which is designed to be placed in a building, usually at ground level. Due to concerns about the oil used for coolant, most interior transformers are cooled with a less flammable coolant such as gas and are frequently referred to as dry-type transformers.

A unique set of transformers are the under-load-tap-changing (ULTC) transformers. Since the voltage along a distribution line typically decreases with an increase in load being drawn by customers, it is desirable to regulate the voltage magnitude at the substation. The most economical method of voltage regulation is with an ULTC transformer. The ULTC transformer is built with several tap settings that allow the number of secondary windings to be adjusted based on the desired voltage level. As the ratio of primary to secondary windings varies, the voltage ratio on the primary and secondary side also changes. This changing of the tap setting enables the secondary voltage to be changed in response to changes in load. These taps are fully automatic and operate in response to voltage on the secondary side of the transformer.

4. TRANSMISSION SYSTEM COMPONENTS

An overhead transmission line consists of conductors, insulators, support structures, and, in most cases, shielding wires.

4.1 Power Cables

Copper has been replaced by aluminum for construction of overhead lines due to the availability and cost factor. The most commonly used conductor is aluminum conductor-steel reinforced (ACSR), which has a central core of galvanized steel wire. Surrounding this central core are strands of aluminum, which have good conductivity. The steel strands provide strength and the aluminum conducts the current. This type of conductor is shown in Fig. 6. The other conductors in common use are all-aluminum conductor, all-aluminum alloy, aluminum-clad steel conductor, aluminum-clad steel conductor (Alumoweld), and extra high-strength steel conductor. Fillers such as fiber or paper can be added between the aluminum and steel strands to increase the conductor spacing to reduce the electric field at the conductor surface.

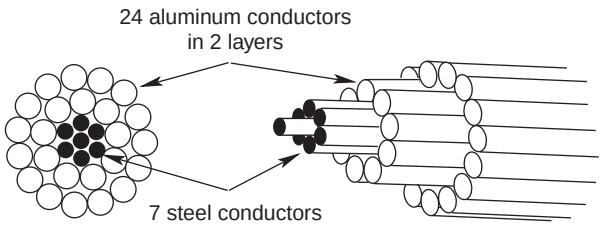

FIGURE 6 ACSR 24/7 conductor.

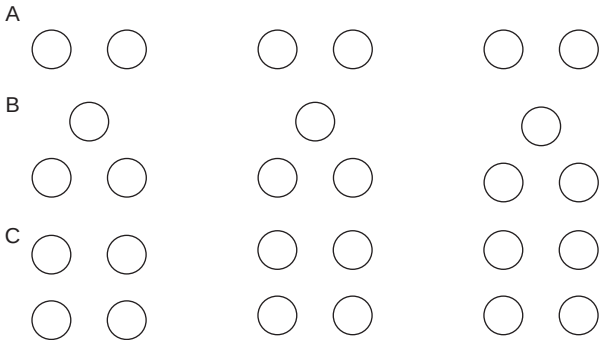

FIGURE 7 Typical bundle configurations.

Extra high-voltage lines often have more than one conductor per phase. This configuration is commonly referred as conductor bundling. Line bundling allows transmission of large amounts of power over long distances. A bundle consists of two–four conductors. Bundling increases the effective radius of the conductor and reduces the electric field strength near the conductors, which reduces corona power loss, audible noise, and radio interference. Line bundling also reduces line reactance, allowing greater current carrying capacity. Figure 7 shows typical bundle configurations.

4.2 Shielding Wires

Shielding wires are located over the load-carrying conductors on transmission lines to prevent a direct lightning strike. Almost all lines above 34.5 kV employ shielding wires. The shield wire provides a 30° protection on either side of the wires. The number and location of the shielding wires are selected such that a lightning strike will terminate on the shielding wires and not on the phase wires. Shielding wires are essentially grounded neutral wires located above the phase wires. They bypass a lightning strike harmlessly to the ground, provided that the tower impedance and tower footing resistance are small.

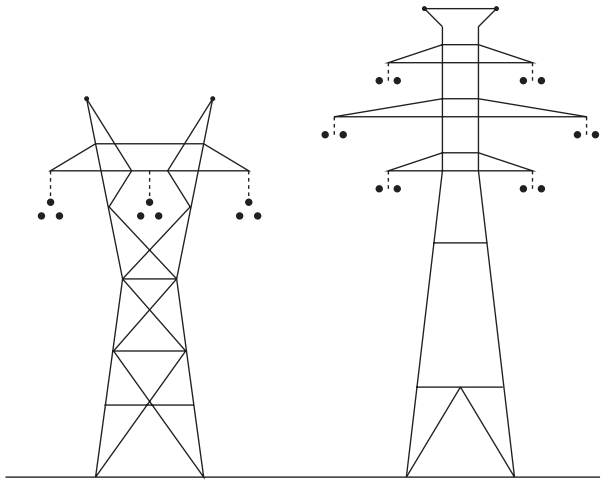

FIGURE 8 Typical lattice structures for 345-kV transmission lines.

4.3 Transmission Line Structures

The primary function of a transmission line structure is to support the transmission lines. The design of the transmission line structure must consider environmental conditions, area requirements, voltage levels, and right-of-way (ROW) requirements. The ROW is the amount of clearance required on either side of the transmission line for safety purposes. Double-circuit 345-kV lines usually have self-supporting steel towers with the phases arranged in a triangular configuration to reduce tower height or in a vertical configuration to reduce tower width. For transmission of voltages of 345 kV and less, wood-frame configurations are commonly used. Typical lattice-type structures for a 345-kV transmission line are shown in Fig. 8. Single-pole, tubular-steel structures are also popular for 345-kV transmission lines. These structures are preferred over the less expensive lattice-type structures when the ROW is restricted. Tubular-steel structures are typically more expensive than lattice-type structures, but lower maintenance requirements may make them competitive in situations in which access is difficult.

4.4 Insulators

Overhead line conductors must be supported on poles or towers such that currents from the conductors do not flow to the ground through the supports. This requires proper insulation of the lines from the supports, which is achieved by securing the line conductors to the supports by insulators. Insulators for transmission lines higher than 69 kV are suspension-type insulators that consist of a string

of discs, typically constructed of porcelain. All the discs are connected in series by metal links in the form of a string. The conductor is suspended to the bottom end of this string. The other end of the string is secured to the cross-arm of the tower. Each disc can only withstand a voltage of approximately 16 kV; therefore, the number of discs per insulator is proportional to the voltage rating of the line. A 120-kV insulator has 6–8 units, whereas a 500-kV insulator is constructed of 26–32 units.

Another type of insulator in operation is the post-type insulator, which is housed in substations to support conductors, busbars, and other equipment. This type of insulator is used for medium- and high-voltage transmission lines in which the insulator replaces the cross-arms of the transmission tower.

Composite insulators are becoming more common as an alternative to porcelain. Composite insulators are constructed around a fiberglass rod, which gives it high mechanical strength. A forged-steel or iron fitting is then compressed to the rod to provide a slippage-free end fitting.

5. SUBSTATIONS

Electrical power is produced at power-generating stations, which are located at favorable but typically geographically remote locations. The power is delivered to the customers at homes or offices through a large network of interconnecting transmission and distribution lines. At many places in the power system, it is necessary to alter some of the electric power characteristics, such as voltage or current. For example, the transmission-level voltages are reduced to distribution-level voltages for the purpose of supplying it to the customers. The place where this conversion of transmission to distribution takes place is known as a substation. Similarly, the generating voltages are also stepped up to transmission levels at substations near the generating unit. A typical distribution substation contains equipment discussed in the following sections.

5.1 Busbar

The busbar, or bus, is used to distribute the power in different directions. Many feeders come out of the substation because they have to cater to different customers in various geographical locations. The bus is a node in the power system circuit. In a power system, when two or more lines are attached to a common point, that point is called a bus. Physically, busbars are copper rods or thin-walled tubes at a common voltage in a substation to which two or more lines (feeders) are connected. If a number of generators or feeders at the same voltage are directly connected at a point, busbars are used as the common electrical component.

5.2 Isolating Switches and Circuit Breakers

In substations, it is often desired to disconnect a part of the system for general maintenance and repairs. This is accomplished with the help of isolators or isolating switches. A circuit breaker is a device that can open or close a circuit under normal as well as fault conditions. It is designed so that it can be operated manually under normal conditions and automatically under fault conditions.

5.3 Converter Stations

Converter stations are present only in high-voltage DC substations. The components are power electronic-based inverters or rectifiers, which are needed to convert the incoming AC components to DC and vice versa. If a DC link exists between two substations, then the voltage has to be converted at the first substation and back to DC by inverters at the second substation.

6. DISTRIBUTION SYSTEMS

The distribution system is the primary means of distributing the electric power from the substation to the system customers. A typical distribution substation serves 1–10 feeder circuits. Each feeder circuit may serve a variety of load types.

6.1 Power System Loads

A load is any device that draws electrical energy from a power system. A load can be resistive, inductive, capacitive, or a combination of these characteristics. Loads in a typical power system are classified as residential, commercial, and industrial. Of these, residential loads are mostly single-phase loads, whereas the other two types are generally three-phase loads. Residential loads have lower voltage levels and include lighting, air-conditioning, heating, and other household appliances. They are usually rated below 2 kW. On the other hand, industrial

loads have the highest voltage levels. Industrial loads include high-power motors used for drilling, pumping, grinding, or other manufacturing purposes and furnaces. Industrial loads are generally rated from 25 kW for small-scale industry to 500 kW or higher for large-scale industry. Lighting, heating, or cooling of large commercial areas such as shopping malls are commercial loads. Figure 9 shows the utility sales by sector for the United States from 1990 to 2001.

The magnitude of a load may vary continuously throughout the day, week, season, and year. Therefore, loads may also be differentiated in terms of time as opposed to end-use sector:

- Base load: The minimum load that has to be served throughout the day. This load is typically served by the largest and/or most inexpensive generators.
- Peak load: The maximum load that has to be served by the utility during the time period of interest. For example, industrial loads usually peak once during each day, but the summer peak load occurs just one day per year.
- Off-peak load: Any load other than peak or base loads is referred to as an off-peak load.

7. POWER SYSTEM PROTECTION

A fail-free power system is not technically feasible since faults occur in a power system at regular intervals for various reasons. Short circuits occur in power systems when equipment insulation fails due to system overvoltages caused by lightning or switching surges. Faults can occur in any power system component, including generators, transformers, buses, or lines. The most prone to faults are the transmission lines since they are the component most exposed to the environment. Typical transmission line faults that can occur are insulation degradation and short circuits caused by contact with tree branches, lightning, and grounding failures. These faults can cause sustained or momentary interruption of power to the customer and may cause considerable economic losses. Approximately 80% of the faults that occur in the power system are temporary in nature. Proper protection schemes can ensure that reliable power can still be supplied to the customer.

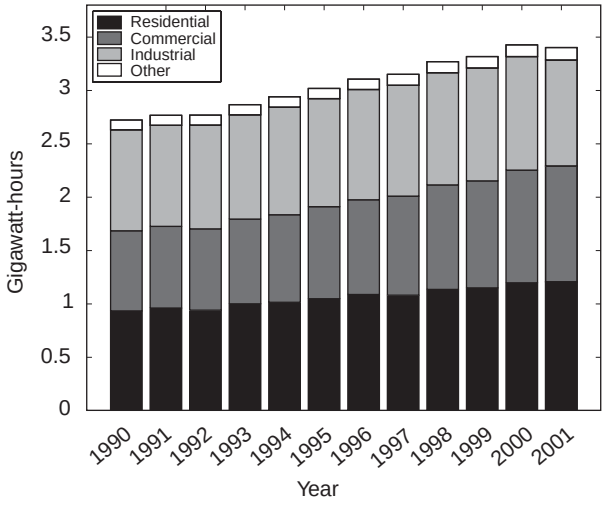

FIGURE 9 U.S. electric utility retail sales of electricity by sector, 1990–2001.

ANSI standards require that faults should be cleared within 3 cycles in extra high-voltage lines and in 5–20 cycles in lower voltage equipment. Faults that occur on a power system are cleared by placing protection equipment throughout the line.

7.1 Circuit Breakers

Circuit breakers are a self-controlled device for automatically interrupting and reclosing an AC circuit with a preset sequence of opening and reclosures. Circuit breakers do not have built-in controls, and they open or reclose based on relay operation. Relays sense the current or voltage and energize the trip coil of the circuit breaker, which in turn causes the poles to separate. As the poles separate, an electric arc is induced across the intervening gap. Different quenching mediums are used to interrupt the arc, thereby opening the circuit:

- Air-break circuit breaker: This type of circuit breaker is generally the indoor type and is installed on vertical panels. They are used for DC circuits up to 12 kV and for medium- and low-voltage AC circuits, usually up to 6.6 kV. In this case, the arc is lengthened in the breaker by a magnetic field and is extinguished by arc splitters.
- Oil circuit breaker: Oil is employed as the quenching medium in this family of breakers. Early bulk-oil breakers used a large oil tank for quenching the arc. However, modern practice is to use minimum-oil circuit breakers in which the arc is extinguished in a small arc control device filled with oil. The voltage rating for this type of breaker is 3.6–245 kV. The disadvantage of this type of breaker is that since oil is hygroscopic, it must be sealed in an air-tight chamber.
- Vacuum circuit breaker: The principle for this type of circuit breaker is that a vacuum is a dielectric

medium and an arc cannot persist in an ideal vacuum. The arc is generally extinguished in half a cycle. Vacuum circuit breakers are generally employed up to 72.5 kV and are smaller than oil circuit breakers.

- Air-blast circuit breaker: To extinguish the arc in an air-blast circuit breaker, a blast of air is blown at the current zero-crossing. These circuit breakers can be employed up to a voltage of 275 kV.
- SF-6 circuit breaker: SF-6 is a heavy, chemically inert, nontoxic, nonflammable gas. Breakers using SF-6 are popular and are used for voltages of 6.6–765 kV.

7.2 Relays

Relays are devices whose primary function is to detect faults and take proper control action to clear the faults. Whenever the relay senses a faulty condition in the power system, it energizes the trip coil of the circuit breaker to clear the fault. Relays and circuit breakers comprise the protection system of the power system. The following are the different types of relays:

- Overcurrent relays: This type of relay operates when the current through it exceeds the pickup value of the relay. For currents lower than this pickup value, the circuit breaker is not tripped. For system-wide coordination of overcurrent relays, it is essential that the relays conform to an inverse-time characteristic in which the operating time (time to trip for a given current) decreases as the relay current increases. Such relays are known as inverse definite minimum time lag relays.
- Directional relays: Directional relays are designed to operate for fault currents flowing in only one direction. When two or more sources are present at different locations, it is frequently difficult to coordinate overcurrent relays. In such cases, directional relays can be used.
- Impedance relays: Impedance relays operate on the basis of the voltage-to-current, or impedance, ratio. The impedance relay is also called a distance relay since the line impedance is proportional to distance. The relay trips when the measured impedance $|Z|$ falls below $|Z_r|$, where $|Z_r|$ is an adjustable relay setting and $|Z|$ is the voltage-to-current ratio at the relay location.
- Differential relays: A differential relay is a suitably connected overcurrent relay operating on the difference between the currents at the two ends of the protected element. It does not operate for faults outside of the equipment. Only for an internal fault will a difference of currents occur, causing the trip coil to be energized. Differential relays are commonly used to protect generators and transformers.

Relays were introduced in the early 1900s and were electromechanical in nature. They are relatively maintenance free and are still found in operation today. Solid-state relays using analog circuits and logic gates provided the same reliability as electromechanical relays but at a more competitive price. The latest technological devices are digital relays that allow the relay characteristics to be changed from a remote location in real time. The principles of digital relays are the same as those of previous electromechanical relay, but these relays have the advantage that a central computer can coordinate between the different local digital relays.

7.3 Fuses

The simplest overcurrent protective element in a power system network is a fuse. Fuses are generally used in large numbers by utility companies because they are inexpensive and maintenance free. The fuse consists of a metal "fusible" link or links encapsulated in a tube, packed in a filler material such as sand. The metal link is generally silver, and it is connected to the contact terminals. If the current flowing through the fuse is normal, the fuse acts as a conductor. However, when abnormal current levels are reached, the link melts. Most of the fuses are current limiting in nature (i.e., the fuse will melt in less than half a cycle for high fault current). In the event of a fault, only the fuse closest to the fault should interrupt and open the circuit immediately downstream. The fuse with the highest continuous current rating is placed closest to the source in the case of a radial feeder. The primary disadvantage of fuses is that they operate only once and cannot operate again without manually replacing the fuse link.

7.4 Circuit Recloser

An automatic circuit recloser is an overcurrent protective device that automatically trips and recloses a preset number of times to clear temporary faults or to isolate permanent faults. It also has provisions for manual opening and reclosing. A recloser unit has a built-in relay and a circuit breaker. Most temporary faults are cleared in one or two recloser operations. Since 80% of the faults that

occur on the power system are temporary in nature, the presence of a recloser helps eliminate the unnecessary tripping of loads for temporary faults. The recloser and the fuses must be coordinated so that only the faulted section is affected.

7.5 Sectionalizer

A sectionalizer is a self-opening device that is used in conjunction with the source-side recloser or circuit breaker to automatically isolate faults. When the source-side protective device operates to deenergize the circuit, the sectionalizer will count the number of operations. After a set number of operations, the sectionalizer permanently opens, thus limiting the outage to the faulted section only. Sectionalizers isolate permanent faults to smaller sections of the line, which in turn improves the reliability of the system. Another advantage is that the sectionalizer does not have a time–current curve and therefore does not have to be coordinated. It can be placed between existing reclosers and fuses without changing its setting.

7.6 Lightning Arrestors

A lightning arrestor, or surge arrestor, is a protective device that conducts the high-voltage surges on the power system to the ground. One end of the arrestor is attached to the terminal of the equipment and the other end is effectively grounded. It consists of a spark gap in series with a nonlinear resistor. The length of the gap is set such that normal line voltage is not enough to cause an arc across the gap, but a dangerously high voltage will break down the air insulation and form an arc. The property of the nonlinear resistance is such that its resistance decreases as the voltage or current increases and vice versa.

Glossary

cross-subsidy A subsidy to one set of consumers of a service to reduce the cost of providing access or the cost of consumption, paid for by charging other consumers more.

electricity service concession A contract to a private sector firm to provide electricity in a defined area under a set of rules and incentives established by the government.

end-use energy efficiency programs Efforts at increasing the efficiency of the energy system by focusing on changing use patterns of and technologies deployed by the final consumer.

environmental dispatch The dispatch of electricity from electricity generators based on a pollution index that allows adjustment of both the order of dispatch and the price to internalize pollution costs.

integrated resource planning A planning framework that allows for comparison of the costs and benefits of alternative electricity supply mechanisms—including demand-side savings and nontraditional electricity sources such as renewable sources—across an electricity system. This framework should include consideration of environmental and social externalities.

lifeline rates Reduced rates, often financed by cross-subsidies, which allow poor households that use minimal amounts of a service to pay less than wealthier households that use more of those services.

universal service obligation A commitment by service providers to provide electricity services to those who request it within their service area, often accompanied by a commitment to provide this service at an affordable price.

The issue of equity and environment in electric power reform is rooted in a larger debate over the nature of the electricity sector. Is electricity a commodity like any other? Should the production, transmission, and distribution of electricity be managed largely by the private sector? Or is electricity an instrument of policy aimed at sustainable development, over which governments should retain policy control, if not ownership? In furthering the debate, a position that has found resonance is that although provision of electricity services may indeed be benefited by some commercial role, electricity provision also has strong positive and negative externalities that call for proactive government involvement.

1. INTRODUCTION

Electric power reform commonly refers to changes in ownership and structure of an electricity system, with the purpose of introducing private ownership and competition. Discussions over how to implement these reforms have focused on improving the technological and financial performance of the sector. Scholars and policy makers have also recognized that power sector reform can have implications for social and environmental outcomes, and that these concerns are not captured by a focus on technical and economic concerns alone. Prominent among relevant social outcomes are the extent to which members of a society have access to electricity, the affordability of electricity, the impact on labor employed in the sector, and the reliability of electricity supply. Relevant among environmental outcomes are the impacts of sector reforms on global, regional, and local pollution caused by production of electricity. Important factors shaping environmental outcomes include the impact of

reforms on consumption levels, technology change, efficiency of supply and demand, and regulatory practice. Finally, an important factor in determining equity and environmental outcomes of electric power reform is the quality of governance in the sector.

2. REASONS FOR REFORM OF THE ELECTRIC POWER SECTOR

2.1 Electric Power Reform Defined

As described in a widely used formulation by authors Sally Hunt and Graham Shuttleworth, electric power reform captures changes in the electricity sector along two dimensions: ownership/control and market structure. Changes in control and ownership can be further broken into three categories:

1. Commercialization. A government surrenders control over a state-owned enterprise in order to promote operation along commercial lines. However, ownership remains in government hands, with no change in organizational form.
2. Corporatization. A government formally and legally relinquishes control and management over a public enterprise to create a corporation. Management is independent of the government, although ownership remains in government hands, and the corporation may be subject to regulatory oversight.
3. Privatization. A government sells a corporation to private owners. The new owners' primary accountability is to investors, although the corporation may be subject to regulatory oversight.

Changes in market structure to promote competition can be subdivided into four steps:

1. Monopoly. No competition at any level. A single entity, usually government owned and operated, handles generation and transmission of electricity. This company provides electricity to distribution companies, which have a monopoly relationship with the final consumer.
3. Single buyer. Competition in generation. Public or private power generators sell power to a single purchasing agency. The purchasing agency transmits power to distribution companies, which have a monopoly relationship with the final consumer.
3. Wholesale competition. Competing generating companies sell directly to distribution companies, and also to very large consumers. Generators have open access to the transmission grid in order to deliver power to their consumers. With the exception of large consumers, distribution companies have a monopoly over final consumers.
4. Retail competition. Generating companies sell directly to distributing companies and final consumers. Generators have open access to both transmission and distribution grids. Final consumers can choose their supplier.

This simple framework conceals considerable discussion and debate over the details of creating markets, and the appropriate sequencing of these various stages.

2.2 Drivers of Electric Power Reform

Historically, electric power systems have been publicly owned and operated because of their natural monopoly characteristics. Governments were better able to exploit the economies of scale in power generation, raise the large amounts of capital required, bear the long time periods for returns on investment, and address the networked nature of the system. Over time, electric power became part of a set of essential services, provision of which was associated with governments. In much of the industrialized world, this approach succeeded in providing reliable and affordable power to citizens, although in the developing world success was far more modest. However, it was in industrialized countries that this approach to power provision was first questioned. At least three factors spurred the questioning, albeit with different emphases in different countries. First, demand for electricity began to slow, undermining the predictable sources of growing income on which utility financing had been based. Second, new generation technologies, particularly gas turbines, reversed the scale economies in the sector. Third, costs and risks increased in the sector due to a rising environmental consciousness, a corresponding increase in regulations, and burdensome investments in high-capital-cost nuclear power plants.

Countries began to act on these changed realities. In the 1970s, the United States allowed independent power producers to sell electricity to utilities, undermining the idea that electricity was best run as a natural monopoly. In the 1980s, the United Kingdom and Chile remade their electricity sectors around the objective of promoting competition. In particular, they unbundled the component parts of the electricity system—generation, transmission, and distribution—and offered components for sale to the private sector. Around the same time, Norway also introduced competition, but without an

accompanying process of privatization. The rapid growth and declining costs of information technology facilitated these changes by enabling the development of new control techniques consistent with greater decentralization of the grid.

Advocates of market-based reforms suggest that reforms bring greater incentives for cost-saving and productivity enhancement. Specifically, it is argued that market reforms provide appropriate price signals to consumers (which spurs more efficient economy-wide resources allocation), reward the efficient use of inputs with profit, and force cost cutting through competitive pressures. Critics point to several difficulties with creating a well-functioning market in electricity. These include the difficulties of defending against market power, the higher cost of capital faced by the private sector, which can translate to higher average costs in a capital-intensive sector such as electricity, and the difficulty of planning, particularly for transmission, in a decentralized system when information is hidden and incomplete. In addition, critics challenge the emphasis on reforms aimed at facilitating private participation, and question whether a change in ownership is a critical element in solving the sector's problems.

It is beyond the scope here to settle these debates conclusively, but the empirical record provides a few lessons of relevance to this discussion. Designing and implementing a market for electricity is a complicated affair, and it is certainly possible to make an electricity system worse off through reforms, as the disastrous California experience showed only too well. Where electricity reforms have resulted in some efficiency gains, competition is at least as important as privatization in achieving these gains. Where efficiency gains have led to lower electricity prices, such as in the United Kingdom and Europe, benefits have gone disproportionately to industrial users. Finally, controlling price volatility has been a considerable challenge, in some cases even threatening the reliability of the system. Despite these continued uncertainties, electricity reform has proceeded apace worldwide, including in developing countries. Reforms in developing countries have been driven by financial and economic concerns such as the poor performance of public utilities, a shortage of capital for investment, a broader fiscal crisis due in part to electricity subsidies, and a short-term need to raise capital through the sale of electricity assets. In many cases, countries have embarked on a reform trajectory at the urging of international financial institutions, and as part of a larger package of economic reforms.

The application of a uniform reform approach as just described to countries in the developing world has led to criticism. One prominent critic, A. K. N. Reddy, points out that the approach followed in the developing world was developed for quite a different purpose—to exploit opportunities for efficiency gains in mature electricity systems in industrialized countries. Existing problems—technological and financial performance crises, the failure to provide access to electricity to large portions of the population, and the lack of attention to the environmental trajectory of the sector—find little explicit attention in the reform approach that has been carried out to date. This observation is an important reason for seeking a broader and more context-specific set of design parameters for electric power reform in the developing world.

3. SOCIAL CONCERNS IN ELECTRIC POWER REFORM

Electricity services enable many positive economic and social benefits. Electricity is a key infrastructural element for industrialized growth and for irrigation. At a household level, electricity can have positive impacts on education, due to better lighting; on time and effort savings, by substituting for traditional fuels used for cooking and heating; on health, by reducing indoor air pollution and through use of refrigeration for foods; and on entrepreneurial activity, through better information and digital connectivity. To achieve these gains, citizens must have access to electricity, and this access must be affordable and reliable. In addition, the electricity sector is also a large employer in many countries, which has provoked concerns among labor groups about the impacts of reforms. The discussion here focuses on access, affordability, and labor concerns. Although reliability is also an important concern, it is already an important and explicit goal of the reform agenda, and so is not treated further here.

3.1 Access to Electricity

Worldwide, rates of access to electricity remain low. Two billion people around the world are commonly estimated to lack electricity. The World Energy Assessment states that in rural areas the situation is particularly bad; 56% of the world's rural population has to manage without electricity. The situation is particularly dire in Sub-Saharan Africa, where the World Bank found that in 1990, 62% of the urban

population and 92% of the rural population rely entirely on energy sources other than electricity.

Historically, many public utilities have undertaken grid extension by setting targets, and financing investment through levies or cross-subsidies. For example, South Africa's public utility, Eskom, exceeded its target of 350,000 new connections a year through much of the 1990s, financed by a cross-subsidy from existing users. South Africa, however, is an exception, and the experience with target setting for public utilities has been disappointing in much of the world. There are several reasons for this failure to provide access to electricity. The rural poor are particularly costly to serve because of remote locations, low population density, high transmission line losses, low consumption levels (which raise average costs), poor credit and minimal collateral, and a lack of purchasing and political power. Many of these factors, other than geographically determined factors, also apply to poor urban and periurban populations. These problematic conditions have been compounded by institutional failure at public utilities. Uncollected levies, the failure to apply least-cost electrification approaches, and the use of electricity as an instrument of political patronage have further stymied efforts at electrification.

The proposed new model of private participation in a market-oriented sector may be no better placed to solve this problem than the public utility approach. In a market model driven by profitability, interest in serving the rural or urban poor is likely to be muted in the absence of specific incentives provided by public policy. Research conducted at the World Resources Institute suggests that through the 1990s, access to electricity was rarely a priority in developing country reform efforts. Early indications suggest that the outcome is indeed minimal progress toward increased access to electricity. For example, a review of reforms in Bolivia concluded that expansion of the grid will not take place as a consequence of privatization and restructuring. In addition, the private sector may choose to disconnect nonpaying customers that the public utility had continued to supply as an implicit form of social welfare. For example, in Argentina, reforms led to a measure of deelectrification of the poor as the privatized utility clamped down on nonpayment and informal connections.

As it has become clear that additional policy incentives are necessary if increasing access to electricity is to remain a priority, more attention has been paid to ways of integrating access into reform approaches. In a market-based electricity sector, two possible entry points for access concerns are (1) the conditions of privatization and (2) concession agreements with the private sector for provision of electricity.

3.1.1 Institutional Mechanisms for Promoting Enhanced Electricity Access

Governments may place obligations on private providers of electricity, as a condition of participation in the market. Such an obligation can take various forms. One approach is to specify an "obligatory service" commitment, which requires a company to provide access to its services to all who wish to avail themselves of services at the prevailing tariff. However, many consumers may not be able to afford consumption at the prevailing tariff. A "universal service obligation" addresses this issue by requiring a company to provide a specified level of service to all customers at an affordable tariff. Because this tariff is necessarily below the price the company would otherwise seek to charge, establishment of a universal service obligation also entails finding financing to support this obligation. This can be arranged through three approaches: a fund collected through a special charge on consumers, which is then paid to the service-providing company; by allowing cross-subsidies; or by defining the service area in such a way that profitable and unprofitable areas are bundled together.

For populations beyond the scope of the existing grid, however, more explicit and targeted programs of access are necessary. Electricity concessions provide one such approach that is potentially compatible with a postreform electricity sector. The central idea is that the private sector is awarded a contract to provide electricity in a defined area under a set of rules and incentives, including financial incentives, established by the government. The desired end is access to electricity, and not necessarily grid extension. Because generation closer to the point of consumption will obviate the need for investment in transmission lines, the concession approach provides an incentive to seek out the lowest cost technology for providing access. Consequently, distributed electricity using technologies such as small hydropower, wind, solar, and biomass may prove to be cheaper and more practical options for providing electricity, and may be adopted by concessionaires.

There are several variants on this approach, which vary in their method of subsidy allocation and degree of private participation. For example, in Argentina, the government has sought to maximize cost-effectiveness by awarding concessions to the company

that requires the lowest subsidy to provide service to a concession area. In Chile, private distribution companies, acting in partnership with municipalities or rural communities, submit project proposals to receive subsidies to cover investment, but not operating, costs. Only projects that have a negative private return but a positive social return are eligible. The state agency evaluates these projects on the basis of cost–benefit analysis, financial contribution by communities and the company, and the degree of social impact. In another example, electrification in Morocco is promoted by a combination of a public and private approach. In some cases, the national electric utility maintains full control over installation, maintenance, and collection of fees; in other cases, it contracts private retailers to install distributed power systems in return for a share of fees. In addition, the utility requires municipalities and households to cofinance 45% of the investment costs of electrification.

The discussion here so far has focused on institutional mechanisms for involving the private sector in electricity provision. However, the same mechanisms can work effectively for nonprofit entities, such as community groups or cooperatives. There are precedents for electrification organized around cooperatives, most notably in the United States. Starting in 1935, electrification in the United States was built around rural electricity cooperatives financed by low-interest public funding. These cooperatives applied a principle of universal coverage and drew on standardized engineering across the country to reduce costs. Cooperatives and smaller scale entities also benefit from greater knowledge of local circumstances, which can enable them to better adapt technologies and more effectively fulfill difficult tasks such as bill collection.

3.1.2 Financing Access

It is significant that the approaches described in the preceding sections do not lift from the state the burden of raising funds, but rather provide a new way of channeling those funds, and potentially leveraging additional funds. Historically, electrification has been financed through cross-subsidies—charging some consumers more to subsidize investment in access for others. In the drive to introduce market reforms, cross-subsidies are increasingly frowned on as introducing distorted price signals leading to suboptimal patterns of use. More transparent, but also distorting, are explicit levies on some consumers to be used for electrification. The use of levies requires sufficient state capacity to effectively administer such a fund. A third approach, and one most favored by market-oriented reform advocates, is an explicit allocation from the central budget for electricity access. However, aspirations to transparent and explicit subsidy allocation ignore the political reality in many countries where access is a concern. Where budget allocation is determined by a complex of national and subnational political interests, it is far from clear that forcing subsidy allocation to pass through a national governmental process will yield a satisfactory allocation of funds for promoting electricity access. In general, the choice of financing mechanism should be determined not only by considerations of economic efficiency, but also by considerations of government fiscal and administrative capacity and the likely impact of local politics.

3.1.3 Local-Level Competition for Electricity Provision

The approaches described so far are all built around monopoly provision of electricity at some local scale, even if the selection of the monopoly provider is on a competitive basis. An alternative approach would allow free entry to the market for electricity services. Advocates of competition at the local level suggest that the result will be increased efficiency of service provision and incentives for innovation, with the result that the need for subsidies may be reduced. To realize this vision, arrangement for exclusive provision will have to be opened to all providers, and regulations will have to be designed minimally in order to reduce entry costs. However, open entry and competition for provision of services bring potential problems. First, there is a strong link between market structure and financing of electrification. Where there is an existing service provider, competition could allow an entrant to "cherry pick" rich customers or rich areas, leaving only the poorer customers. This problem is particularly pernicious where services to poor customers are financed through cross-subsidies, or where the incumbent provider has a universal service obligation. In areas where there are no existing providers and where subsidies are necessary to lure entrants, the burden of administering subsidies increases considerably with multiple players. This is particularly true if provision of subsidies is dependent on performance criteria, such as number of customers served. Second, in the absence of adequate regulation, there is scope for formation of cartels and price gouging of customers. Finally, there are basic issues of safety in electricity provision that are left unaddressed in an unregulated or lightly regulated market for electricity services.

3.2 Price

In both industrialized and developing countries, electricity reform leads to price changes, although for different reasons and sometimes in opposite directions. In industrialized countries, reforms are expected to lead to efficiency gains and lower prices for consumers. In practice, where these gains have been realized, they have benefited shareholders and rich consumers more than they have benefited poor consumers. The results can be highly regressive. In Argentina, for example, prices went down postreform for all consumer classes, but the price for high-consumption (and likely wealthy) users dropped by 70% whereas that for low-consumption (and poor) users fell only marginally. The net effect was that, in absolute terms, the rich paid 40% less than the poor paid per unit of electricity. In the United Kingdom, electricity companies reaped the greatest share of benefits, government gained from increased sales revenue and higher taxes on profits, but power purchasers paid higher prices than they would have under public ownership.

In many developing countries, prices for consumers are likely to rise, at least in the short to medium term, as cross-subsidies and price restrictions are removed. In some instances, these price increases have been considerable. In Ghana, the tariff increased by about 300% in the course of implementing reforms. Higher prices disproportionately affect the poor, who tend to spend a larger proportion of their income on energy services than do wealthy consumers. Although the higher prices may be necessary to put the sector on a sound commercial footing, they also bring social costs. Consequently, to ensure that social policy goals of providing effective access to electricity are met may require a measure of public support in the form of subsidies.

The question of subsidizing the price of electricity is closely tied to the discussion on access to electricity (Section 3.1), because a given subsidy allocation can be used either for the cost of facilitating access to electricity or for reducing the per-unit cost for the consumer. Both benefit the consumer, but in different ways. There are good arguments for subsidizing access rather than consumption. Populations without access to electricity are likely to be among the poorest in a country. By focusing on access, subsidies are automatically targeted toward the neediest. In addition, subsidizing use can skew consumption patterns in detrimental ways. For example, electricity subsidies for farmers in India have encouraged heavy use of groundwater, including the introduction of water-intensive crops in areas of water shortage. One means of avoiding this problem is to subsidize the fixed costs associated with consumption, such as connection fees. The result can be substantial savings for low-income groups, even while eliminating the potential for price distortions.

Although subsidizing access is preferable to subsidizing consumption, subsidizing a minimal level of consumption can afford low-income groups access to basic electricity services, with considerable social gains. Such subsidies are normally structured as "lifeline rates," which are cross-subsidies that allow poor households that use basic services to pay less, compared to wealthier households that use more electricity services. Although challenged under a reform approach that seeks to remove market distortions, these lifeline rates continue to be an effective way to balance social objectives with efficiency gains.

Several factors bear consideration in the design of price subsidies. First, subsidies should be well targeted to a population. In many cases, subsidies have become mechanisms for appeasing politically important constituencies rather than an effective way of supporting a social objective. Second, the amount of subsidy should be consistent with the goal of the subsidy program. For example, a lifeline rate should be limited to basic electricity services, and should not be set at a consumption level that encompasses groups beyond the target group. Third, the subsidy should be designed so as to minimize distorting consumer decisions.

Another means of minimizing social pain due to price increases is to increase the efficiency of electricity use. Doing so would enable consumers to extract greater services out of each unit of electricity consumed. In this sense, programs to promote end-use energy efficiency, typically conceived of as environmental programs, also have social benefits.

3.3 Employment

In many countries, the electricity sector is a significant employer. Reform of the sector is often accompanied by job cuts, as privatized utilities seek to cut costs and improve efficiency. In the European Union, for example, the research unit of Public Services International, a labor union, found that between 1990 and 1995, 212,000 jobs were lost in the energy sector, equivalent to a 17% reduction. The United Kingdom, where 42% of jobs in the sector were cut, accounted for more than half of these losses.

In some countries, reform of the sector to restore efficient functioning and financial viability may indeed require some measure of employee reduction. For example, in many African countries, the number of customers per employee hovers in the range of 20–80, as against a nominal international target of around 125. However, these numbers must be read with caution, because they do not account for differences across companies that only generate power and those that also distribute power. Moreover, the relative costs of labor and capital vary across countries, which suggests that the appropriate ratio of customers to employees need not be the same across the world. Nonetheless, it is safe to assume that there are many cases in which effective reform requires a measure of labor retrenchment. In these cases, a socially progressive approach to reform would ensure safeguards for laid-off workers, such as retraining programs and assistance with reemployment. Even more wide-reaching are plans to include workers at large in the capitalization of electric utilities. In Bolivia, for example, labor unions, political parties, business groups, and others forged a "capitalization plan" whereby a portion of the shares of state-owned enterprises, including electricity, were distributed among the broader working-age population. Specifically, half the shares were sold to strategic investors and the other half were credited to workers' individual retirement accounts, with a portion distributed as annuities. The general point is that although employee reductions may be necessary in some cases, the associated social pain can be reduced by appropriate mitigation, and by undertaking privatization in a manner that distributes benefits across the population.

4. ENVIRONMENTAL CONCERNS IN ELECTRIC POWER REFORM

The electricity sector has a considerable environmental footprint. Many of the environmental impacts associated with electricity are related to the heavy reliance on fossil fuels for electricity generation in much of the world. As the World Energy Assessment summarizes, combustion of fossil fuels releases local pollutants such as particulates and lead, regional pollutants such as sulfur dioxide, and global pollutants such as carbon dioxide. These pollutants have consequences for human health and the well-being of ecosystems. In addition, there are upstream environmental impacts such as those caused by mining and fuel transport, storage, and processing, and downstream impacts such as ash disposal. Nonfossil sources of electricity also cause environmental disturbance. For example, hydropower (in particular, large hydropower) causes several land-use-related impacts, such as submergence, displacement of populations, greenhouse gas emissions caused by decaying biomass, and disruption of fisheries. The discussion in this section, however, focuses largely on air pollution impacts.

What will be the net effect of electric power reform on the environment? There is no single answer to this question. Instead, the net effect of the several changes that collectively constitute reform will depend at minimum on the time frame (short versus long term), the specifics of how policies are implemented, and the initial conditions in the reforming country. However, systematic tendencies can be associated with particular reform steps. And, in addition, countries may choose to take proactive measures to address some of these tendencies. The discussions that follow outline these environmental tendencies and spell out possible proactive steps to increase the likelihood of environmentally positive outcomes.

4.1 Environmental Implications of Institutional Change for Electricity Reform

There are several overlapping ways to analyze the environmental implications of institutional change in the electric power sector. One approach is to examine the various components of electricity reform (as described in Section 2.1), with an eye to assessing the environmental implications of each component. This is the approach followed in this discussion. Another would focus on pathways through which reforms would have an environmental impact, such as on choice of generation technologies. These are not exclusive approaches, and there is necessarily some overlap in the categories under each approach. To complement an analysis based on the reform component, Table I, which is intended to be illustrative rather than comprehensive, summarizes a pathway approach.

The remainder of this section follows a framework laid out by Keith Kozloff in studies for the U.S. Agency for International Development and for the Renewable Energy Policy Project. The discussion is organized around five dimensions of reform: commercialization, privatization, unbundling, wholesale competition, and retail competition. The first two dimensions are related to ownership, and

the last three, to structure. These categories often blur at the edges, and links listed under one could often feasibly be listed under several other categories.

4.1.1 Commercialization

Commercialization in the power sector is likely to have a range of positive impacts on the environment. First, the principle of cost recovery introduced through commercialization could increase incentives for better management and operation of existing capacity and more efficient transmission and distribution. Cost recovery will also provide an incentive to utilities to implement end-use efficiency programs, especially to reduce losses in rural areas, where the revenue generated often does not meet the marginal cost of supplying electricity.

Second, commercialization is often accompanied by tariff reform that releases controls on electricity rates. Although in industrialized countries reform has led to greater efficiency and often to lower prices, in developing countries reforms are likely to lead to higher prices as government-mandated price caps are removed. Higher prices will provide consumers greater incentive to implement end-use efficiency programs, and may provide market opportunities for firms that provide energy efficiency products and services. However, price effects may be muted because the price elasticity of electricity is considerably lower—perhaps as much as 50% lower—in developing countries as compared to industrialized countries. On the negative side, they will also partially undermine the benefits utilities gain from loss-reducing efficiency programs in rural areas.

Third, the combination of cost recovery and more accurate price signals suggests that a commercialized utility has a strong incentive to identify least-cost ways of extending services to rural areas. This will likely provide an incentive to distributed renewable energy technologies.

4.1.2 Privatization

Privatized utilities have little or no commitment to achieving social or environmental goals, unless they are explicitly required to or are given incentives to do so through regulatory structures. However, on the positive side of the environmental ledger, because a private utility not only seeks to recover costs but also to turn a profit, the incentives for greater efficiency in supply-side efficiency improvements in operation and maintenance also introduced through

commercialization are strengthened. Similarly, a private utility may have an incentive to invest in low-cost technologies, which will promote a switch to cleaner burning natural gas.

On the negative side, the private sector typically has a higher cost of capital and a higher discount rate than does the public sector, both of which provide disincentives to environmentally sensible investments that yield benefits over time. For example, because demand-side management (DSM) measures yield benefits over a number of years, they will yield a lower return under private ownership and will be less attractive. Similarly, higher capital costs and discount rates are unfavorable to renewable energy sources that require large up-front capital investments, and are more friendly to technologies such as gas turbines, which have low capital costs but high fuel costs. In addition, privatization could attract greater investment to the sector, which would increase generation capacity and result in a larger environmental footprint. However, to the extent that new capacity replaces small-scale diesel self-generation by industry, this effect would be mitigated.

If requirements are placed on the private sector to reverse some of the negative incentives just discussed, then it is important that these be put in place prior to privatization. Once existing assets are sold off, it will be politically difficult to change the rules, and sends future investors a signal of inconsistent policy.

4.1.3 Unbundling

As a result of unbundling, the costs of providing generation, transmission, distribution, and retailing services are accounted for separately. As a result, unbundling can provide disincentives to activities that promote energy efficiency. In an unbundled sector, generation and transmission companies do not have direct contact with the consumer in order to undertake end-use efficiency programs. Distribution companies, which are in a position to undertake these programs, are unable to capture the full benefits of greater efficiency because the benefits of reduced generation and transmission requirements are shared with other distribution companies. This separation also limits access to useful information—those on the supply side are cut off from information on consumption patterns, and distribution companies may not have access to billing data from retailing companies. In addition, unbundling makes it more difficult for a single entity to identify and capture the full upstream savings in generation and transmission costs provided by distributed renewable sources. Consequently, there is diminished incentive to invest in distributed renewable power.

Beyond these general observations, the environmental impact of the unbundling process depends on the details of implementation. First, in an unbundled structure, the terms and conditions of access to transmission have environmental implications. Open transmission access could stimulate investments in grid-connected renewable sources. However, this advantage will be negated if renewable power developers are charged higher prices, as is possible under some pricing schemes. In addition, transmission access opens opportunities for interregional electricity exchange that may affect the overall fuel mix. If access to broader markets increases use of low-cost coal plants, which operate under their operating potential, then the result will be negative environmental outcomes. This may be less of a problem in developing countries, where such excess idle capacity typically does not exist. Finally, transmission access could also promote cogeneration. However, in order for this to work, access prices must be low enough for cogeneration to compete with other supply sources.

Second, in the single-buyer model (many generators but one monopoly buyer), the environmental consequences are influenced by the details of power purchase agreements (PPAs). Existing PPAs are structured around low-capital-cost technologies such as fossil fuel plants, which may be unfavorable to renewable energy technologies with equivalent life-cycle costs but higher up-front costs. Important considerations are payment schedules and the treatment of risk in fuel price. In addition, because renewable power projects tend to be smaller but transactions costs tend to be fixed, the transactions costs per unit tend to be higher for renewables. In order to overcome these problems, PPAs need to be tailored to renewable sources and standardized. Moreover, the long-term nature of PPAs is potentially damaging because it locks in technologies that might rapidly become obsolete. A spot market is more likely to take advantage of new technological options as they develop.

4.1.4 Wholesale Competition

Wholesale competition may promote more efficient operation of thermal power plants, but has disincentive effects on energy efficiency. First, when wholesale competition is organized around spot markets in electricity, plant operators have an incentive to run their plants as much as possible in order to maximize returns. Second, price signals in

spot markets are based on short-term costs rather than on life-cycle costs. Because the benefits of energy efficiency are spread over a long period, these benefits tend not to be factored into spot markets. Third, spot markets potentially increase the expected variability in prices, which leads to more uncertain savings from energy efficiency, which are then discounted compared to more certain savings derived from life-cycle costs.

Wholesale competition will likely also negatively affect adoption of renewable energy technologies, because these technologies are more difficult to finance in short-term electricity markets. Spot markets imply a more uncertain revenue stream than do long-term PPAs, thus lenders are less willing to finance the high capital costs of renewable power projects in a short-term market. Moreover, the high debt burden of renewable power projects leaves the projects susceptible to a slump in spot market prices. In addition, some "intermittent" renewable energy sources, such as wind and solar, are at a disadvantage in spot markets because they are unable to provide power on demand in peak periods. This disadvantage needs to be addressed explicitly in the formulation of rules governing the spot market.

4.1.5 Retail Competition

Retail competition, if appropriately structured, may introduce some features that mitigate the negative environmental effects of wholesale competition, whereas others worsen the problem. There are three possible positive effects. First, retail competition requires access to distribution lines. The costs of access require that area-specific marginal costs are assessed. If these costs are charged to customers, their incentive to manage their load is enhanced. Second, a generator who is also a retailer could invest in conservation measures within its customer base, and use the saved energy to compete in other markets. This mechanism is enhanced where generators face an "obligation to serve" in rural areas at an unprofitable tariff. Efficiency measures allow the utility to reduce losses in these unprofitable areas and sell the saved power in profit-making areas. Third, retail competition allows renewable energy suppliers to distinguish themselves by the source of their energy, by, for example, promoting themselves as "green" power suppliers. However, this strategy may be less successful in developing countries, in which electricity prices account for a larger share of budgets, as compared to industrialized countries.

On the other side of the ledger, retail competition will likely lead to an electricity price decline, further diminishing the incentives to undertake efficiency-improving measures. Second, because retail competition allows a customer to switch between suppliers at any time, a retailer is not guaranteed of capturing the full stream of benefits of end-use energy efficiency investments, providing a strong disincentive to make those investments.

4.2 Measures to Improve Environmental Outcomes Following Reform

As the preceding discussion suggests, the environmental impact of electricity reform in a particular place will depend on the details of implementation. In this section, three important elements of implementation are summarized, each with examples of environmentally positive policy steps.

4.2.1 System Planning and Portfolio Management

Effective system planning and portfolio management require that the costs and benefits of alternative electricity supply mechanisms are comparable across a system. This comparison should include consideration of demand-side savings and non-traditional sources such as renewable energy, should internalize environmental and social considerations, and should provide a mechanism for public input. Integrated resource planning (IRP) was the tool devised to meet these requirements under an integrated system. IRP provides a means to minimize the "total resources cost" involved in meeting electricity service needs, which includes not only the costs to the utility and its customers, but also the indirect social and environmental costs.

Centralized IRP at the system level is incompatible with a market structure. However, the essential planning and portfolio management functions remain important, and should be performed through other institutional mechanisms. For example, under wholesale competition, distribution utilities can still conduct, or can be required by law to conduct, an integrated analysis of alternative portfolios, and can draw up a plan based on that analysis. Instead of directly acting on the plan, however, the distribution utility must then solicit bids from the marketplace to meet the plan. Over time, the demand pattern would force a more balanced portfolio of resource investment.

Another approach to internalizing environmental externalities would shift the focus from procurement to dispatch. An "environmental dispatch" approach would use a pollution index to adjust both the order in which electricity is dispatched from generators and the price the generators are paid. Environmentally

clean generators are dispatched preferentially and receive a higher price.

4.2.2 *Environmental Implications of Regulatory Decisions: Transactions Costs and Prices*

Many decisions routinely made by electricity regulators for economic reasons often have environmental implications. Regulatory decisions can unintentionally increase the transactions costs for more environmentally sound forms of electricity. In other cases, opportunities to reduce these transactions costs may be missed. In addition, rules on pricing decisions may systematically underplay the economic benefits that energy efficiency and renewable energy can bring. For example, a regulatory decision that links utility profits to the amount of electricity sold works as an obstacle to energy efficiency. Specifically, a price cap does just this, whereas a revenue cap decouples sales from revenues. In addition, unbundling raises the transactions costs to investing in efficiency—price signals are less clear, distribution utilities have an incentive to "free ride," and generators have inadequate access to consumers. Regulators can play a role in fixing these problems. If retail bills reflect actual service costs, customers receive signals that allow them to tailor demands to reduce costs. On the other hand, if these costs are represented as fixed charges, then effective demand management becomes harder.

With respect to renewable energy, a simple approach to minimizing transaction cost is to offer a standardized contract for power purchase to small-scale renewable energy suppliers. Without such a standard contract, the fixed cost of negotiating a power purchase agreement may be prohibitive for small suppliers. This approach has worked with some success for small hydropower developers in Sri Lanka. In addition, open access to the transmission grid is a prerequisite for renewable energy suppliers to compete in a market. These policies are credited with stimulating a renewable energy industry in India.

The absence of facilities for net metering (a bidirectional meter that registers flow in both directions) introduces a transactions cost that discourages investment in very small-scale renewable energy. The existence of net metering would allow embedded small-scale generation to realize its full potential by allowing the sale of extra power generated on site to the grid. Finally, the bidding rules that govern power pools may be written based on the characteristics of large generation plants, and may systematically disadvantage renewable energy, small generating units, and energy efficiency.

Similarly, there is a set of regulatory decisions that operate through the mechanism by which prices are set. For example, because distribution costs can vary widely across a service area, an average cost-based price conceals the true gains from distributed energy generation and from energy efficiency. By contrast, a deaveraged distribution price would send consumers the appropriate price signals. In another example, subsidies for line extensions also artificially lower the cost of on-grid generation technologies, undermining the competitiveness of off-grid technologies. Finally, transmission prices and terms of access will need to reflect the special circumstances of renewable energy and small generating units if they are to be competitive. For example, distance-based pricing, pricing based on maximum rated capacity rather than actual generation, and a penalty for intermittent transmission could all work against renewable power developers.

4.2.3 *Proactive Policy Measures to Promote Energy Efficiency and Renewable Energy*

In addition to ensuring that economic regulation does not disadvantage energy efficiency and renewable energy, there are a number of proactive measures consistent with competition available to promote these approaches. A number of countries have adopted price-driven, or supply-push, renewable energy incentives programs. In the United States, utilities were required to purchase all the renewable energy offered to them at a price equivalent to the "avoided cost" of generating that power. The United Kingdom has imposed a tax on fossil fuel generation; under the Non Fossil Fuel Obligation program, the tax is used to support nonfossil energy sources. Germany and Denmark have implemented a "feed-in" law, which sets a guaranteed price for the purchase of renewable energy. India has allowed generous depreciation allowances to promote wind energy.

Quantity-driven incentives such as a renewable portfolio standard (RPS) offer another approach. An RPS requires all retail electricity service providers to purchase a specific proportion of their electricity from renewable energy sources. This approach has been adopted in several European countries and in several states in the United States.

A systems benefits charge provides a more general way to support environmentally (and socially) desirable investment requirements by means of a general surcharge across the system. For example, Brazil has adopted a modified version of a system benefits charge, requiring distribution utilities to spend 1% of revenues on energy conservation, of which 0.25%

must be spent on end-use efficiency. More generally, the funds gathered through a systems benefits charge may be spent on increasing access to electricity for disadvantaged populations, on energy efficiency, or on research and development of sustainable energy technologies.

5. GOVERNANCE OF ELECTRIC POWER REFORM

It is increasingly clear that although provision of electricity services would benefit from the application of commercial principles, application of these principles should not exclude a strong government role to maintain essential public benefits (social and environmental) in the electricity sector. As the preceding discussion suggests, there are various mechanisms through which to promote social and environmental interests.

A technical understanding of the links between social and environmental concerns and electric power reform is a necessary, but not sufficient, condition for these interests to be addressed. If decisions about electricity reform are made without advocates for concerns such as access to electricity, price, and environmental outcomes, present and past experience suggests that these issues are likely to be crowded out by more narrow economic considerations. Equitable and environmentally sound reform will require that decision-making processes be open to concerns from rural populations, civil society, environmentalists, and others who typically articulate a public benefits agenda. Hence, equity and environment in electricity reform are equally about an effective system of sectoral governance and a technical or policy understanding of social and environmental concerns in the sector.

Glossary

forced outage or blackout Loss of electrical power due to the shutdown of a major component, such as a power plant, transformer, or transmission line.
gains Increase in signal power, voltage, or current by amplification.
governor A control device on a machine or engine that is used to maintain a steady speed, pressure, or temperature automatically (as by controlling the fuel supply).
load A device or destination to which electrical power is delivered; also, output of a generator or power plant.
primary controller An electrical instrument or set of instruments that serves as the main regulating or guiding device for a mechanical or electrical system.
transformer An electrical device used to transfer electric energy from one circuit to another, especially equipment that produces such a transfer with a change in voltage.
utility A company that performs a public service (such as sewage disposal or supply of gas for heating) subject to government regulation; in this context, an electricity generation/supply company.

It first describes basic objectives of electric power systems engineering. The primary emphasis of the article is on IT tools and the key challenges that must be overcome to further benefit from using electric power systems engineering (EPSE) tools in support of the electric power industry under restructuring. The material in this article is of direct relevance for managing the electric power systems in a reliable and efficient way without major widespread loss of service to customers.

1. INTRODUCTION

Electric power systems engineering (EPSE) is a subfield of electric power engineering, with the prime concern being performance of an interconnected electric power system. The EPSE subfield has evolved over the past 40 years in response to the industry needs to manage the system (1) securely under unexpected equipment outages and unusually wide variations in load demand patterns and (2) as economically as possible in response to normal load-demand variations. Its growth has been made possible through tremendous progress in the general fields of computers, communications, and control engineering for complex, large-scale systems. Nevertheless, the general tools had to be formulated and made useful in the context of the specific applications to the electric power systems.

by surprise in a widespread industry failure to provide electricity to over 60 million customers for over 24 h. Questions about why such an event spread over very large geographical areas are being asked. A typical belief that an electric power grid has automated protection against cascading failures despite an unexpected failure of a major piece of equipment, such as a transmission line or a power plant, has once more been proven wrong. A related category of questions concerns prevention of massive power failures by isolating only parts of the grid that had to be disconnected. Still other questions focus on what should be done to modernize the electric power grid in order to prevent future cascading failures.

This unplanned coincidence between the blackout and the completion of this article has forced the authors to revisit its earlier version. To the authors, the 2003 blackout represents yet another example of challenges to the operating practices and the information technology (IT)-based methods for facilitating reliable and efficient operation of complex electric power grids. It is, unfortunately, one of many in the long list of hard-to-predict, high-impact, cascading events of this type that have taken place since the early 1960s worldwide. It is hoped that the reader will see several connections between the material in this article and the recent events.

The following quotation from *Dynamics and Control of Large Electric Power Systems*, by Ilic and Zaborszky, briefly summarizes the gradual evolution of the U.S. interconnection and points out the rationale for its present complexity:

> *The U.S. structure of power-system operation was developing generally during the twentieth century without much awareness or attention to the implications of the evolution of power-system structure. With the gradual infiltration of the computer into on-line operation in the 1950s, a surge of interconnections developed for utilizing the potential for improved efficiency and economy. As is typically the case in human activities, the development took the form of designs for individual cases of construction based only on the local situation of the case and only during normal, stationary system operation. The vital questions of the effects of off-nominal conditions were essentially ignored. A striking example is the omission in new construction of self-starting house units and the total dependence for starting large power plants on power drawn from transmission lines to neighboring stations. This general attitude was the root cause of the famous Northeast Blackout, a cascading system collapse that disabled ten states for approximately 1 week in 1964 followed by a few other large events, such as that occurring in Manhattan in 1967.*
>
> *After this rude awakening, consciousness of the importance of the structure of the complete system (the interconnected U.S. electric power system) started to gradually creep into the awareness within the field.*
>
> —*Ilic and Zaborszky, 2000, p. 642*

Also, recent electric power restructuring has created very new challenges to the existing EPSE methods. One of the qualitative changes related to the organizational changes in this industry involves the shift from a top-down coordinated monitoring and decision-making to more distributed information managing and decision-making. This change is opening doors to new technical and pricing paradigms for operating complex power grids in a self-healing manner by the system end users adjusting to the changing conditions in a bottom-up manner.

The most recent blackout, the above quote summarizing the beginnings of EPSE, and the recent industry reorganization all concern on-line information essential for determining the system-wide status beyond single components and single utilities. Since the specifics of particular physical and policy/regulatory phenomena vary with the nature of triggering events and system designs, the complexity of data and difficulty of extracting critical information quickly are issues at the heart of any blackout. The critical physical information may concern frequency-, voltage-, or transmission-related physical phenomena; the importance of these factors is well documented in several post mortem analyses of major blackouts. The critical policy/regulatory information may affect capacity available for managing the system as a whole under forced outage and its valuation or it may concern state versus federal responsibility for building stronger transmission lines for exchanging power under outages.

This article is devoted to the electric power systems engineering subfield of electric power engineering, focusing on systems aspects of modeling, analysis, and decision-making tools for operating and planning complex electric power grids. It first describes basic objectives of electric power systems engineering. The primary emphasis of the article is on IT tools and the key challenges that must be overcome to further benefit from using EPSE for operating and planning electric power systems of the future. The final section describes fundamental challenges to developing EPSE tools in support of the electric power industry under restructuring.

Electric power systems engineering must evolve as the industry needs evolve, both as the industry reorganization takes place and as the new hardware technologies become more available and cost-effective. Much could be improved by supporting the

power grid's on-line operations via carefully designed minimal coordination at its various layers. Doing this correctly remains a tremendous challenge in pursuit of increased system-wide efficiency and ability to prevent huge failures.

2. BASIC OBJECTIVES OF EPSE

The main objectives of EPSE are monitoring, analysis, and decision-making tools for facilitating operations and planning of an electric power system as a whole. The EPSE methods are available for monitoring, analyzing, and controlling electric power grids in a semiautomated manner under normal operating conditions, i.e., when the status of the equipment is as planned. The EPSE approaches to managing the system under forced outages are not as mature in comparison with the tools available for normal operation; instead, these methods are generally utility-specific and based on human expert knowledge about the system. The events on August 14, 2003 confirmed once more that industry practices are not fully capable of preventing widespread power failures under forced equipment outages. Moreover, as the electric power industry restructures and new technologies become more cost-effective, the objectives of electric power systems engineering evolve, requiring novel problem formulations and computer-aided tools for relating often conflicting engineering and economic objectives.

The early stages of electric power engineering were primarily concerned with the design and operation of individual pieces of equipment, power plants, transformers, transmission lines, and the like. However, as the electric power grid has expanded over time, it has become essential to understand the interactions among various system components and the effect of these interactions on the overall quality of electricity service. The quality and cost of power service to customers have greatly improved as a result of optimizing utilization of system-wide resources under normal conditions. IT-based power systems engineering tools for scheduling the electric power generation required to meet the time-varying load demand have been basic to efficient use of the least operating cost power generation. In particular, under normal conditions, the cheapest generation is scheduled and delivered across the power system to supply both forecasted demand and demand fluctuations that are hard to predict. Ideally, under unexpected forced outages of major components (power plants, transformers, or transmission lines), power should be delivered from other parts of the system so that the load in the affected area remains served. To achieve this, power systems engineering tools have been developed for scheduling short-term generation reserve to supply customers in case major components of power equipment fail as a result of hard-to-predict forced outages.

The software tools for balancing supply and demand under normal conditions are based on implicit assumptions about the electric power system structure. Naturally this structure allows simplification of very complex electric power system dynamics by the separation of operations into subprocesses that evolve at different temporal rates and at various system levels. It is important to use the IT-based tools to assess the validity of the assumptions and underlying algorithms used, as system conditions vary over time. In particular, the useful structure and unique features of complex power system dynamics are typically violated under forced outages. Moreover, industry restructuring may inadvertently lead to qualitatively new power system architectures, which, in turn, will require careful assessment of the software tools used for operating them.

Some of the fundamental policy- and technology-related changes are discussed in Sections 5 and 6 below. A typical power systems architecture characteristic of normal operation and regulated industry is described in Section 2 in preparation for reviewing the IT tools for operating regulated utilities under normal conditions. The most difficult challenges concern trade-offs between efficient operation under normal conditions and the stand-by reserve to be used in case of forced outages. Since the critical events are unknown and are very hard to predict in a timely manner, conventional probabilistic tools are difficult to use for efficient on-line decision-making.

2.1 Basic Structure of Electric Power Systems

A typical organization of today's electric power systems is shown in Fig. 1. The generation and distribution of electric power geographically are accomplished over one single electric network in the United States. Traditionally in the regulated industry, generation is provided in very large quantities at power plants. Under restructuring, small-quantity distributed generation also enters with a naturally limited scope of providing power locally. Electricity consumption ranges from very large levels (factories) to very small levels (residential).

This immense interconnected network inescapably has an internal structure. Generation in very large

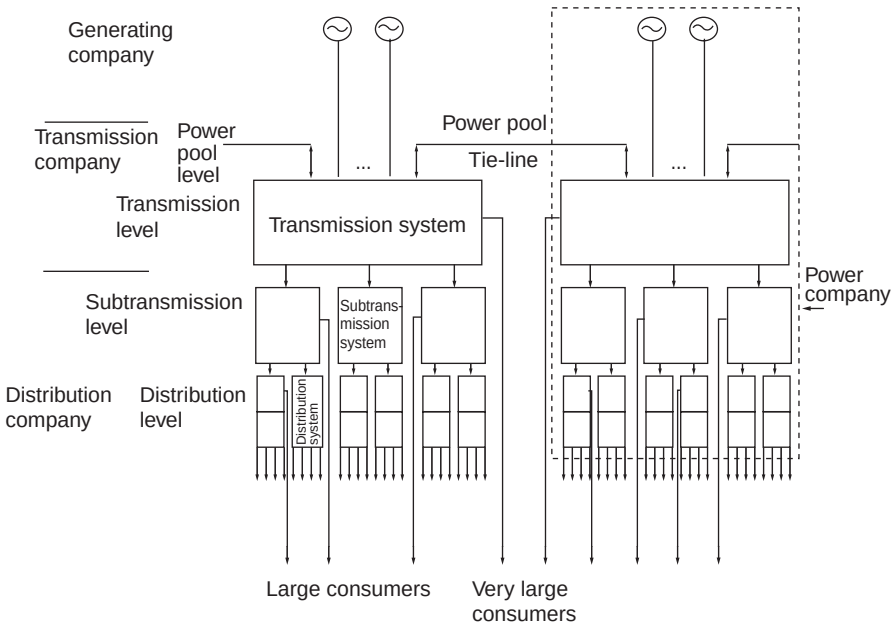

FIGURE 1 Typical organization of existing electric power systems.

quantities in power plants demands high- to very-high-voltage (ranging from 20,000 to 1 million V) transmission line networks. Such networks make up the pool or bulk transmission level network that covers the United States but is also geographically subdivided into large blocks according to ownership, as indicated in Fig. 1. The power distribution process within each geographic bulk transmission block is typically subdivided into geographic subtransmission areas, which historically do not connect to individual generating facilities; instead, only large loads are supplied from the subtransmission networks along with the various distribution sections within each subtransmission area. Finally, the lowest voltage distribution level also splits into two voltage sublevels, ending at the residential households.

The network consists of transmission lines that interconnect nodes, known as buses, at high voltage levels. Different levels of voltage within this structure are interconnected via transformers. Buses are the sole connection points to the transmission system of all equipment:

(1) the sources, that is, generators;
(2) the loads, either large and concentrated like an aluminum plant or distributed like the feeding point of subtransmission networks supplying a composition of smaller loads and eventually leading to distribution lines on residential streets;
(3) reactive-power storage devices, such as capacitor banks or reactors;
(4) increasingly numerous electronically switched power devices (thyristors), such as static Var compensators, the coupling equipment between the high-voltage (HV) alternating current (AC) bus and the high-voltage direct current (HV-DC) transmission lines, and flexible AC transmission systems (FACTS) devices that are in development;
(5) series capacitor compensation; and
(6) lightning arrestors and other equipment connected to a bus by links other than transmission lines.

Buses form large islands of complex equipment connected to the outside world exclusively through the high-voltage lines (AC or DC) of the transmission network.

The business organization of this gigantic system in the traditional regulated sense was single ownership of each vertical column; see Fig. 1. This division preserves the coast-to-coast nature of the total network, but the sale and purchase of power are carried out between companies owning the individual vertical blocks within Fig. 1 under very strict government regulations. In the new industry environment, individual blocks in Fig. 1 are separately owned, and free market trading proceeds for a fee between individually owned transmission blocks under relatively mild government regulation. The above-described strict separation by size is also fading; any amount of power can be bought and sold at any power flow level.

The above-described organizational structure in the regulated industry maps into various power flow levels. The bulk power is transmitted from a very few large power plants to the load centers within a region or from a power pool composed of several subsystems; these subsystems most often are defined as the boundaries of the individual electric power utilities, loosely coupled with the neighboring utilities. The delivery of power between utilities within an electric power pool or within similar horizontal structures occurs by means of an extra-high-voltage (EHV) sparse electric transmission grid, at typical voltages of 500 kV and higher; the pool (or region) level is referred to as a tertiary level. Within each subsystem, the transmission grid is less sparse and at high voltage, typically above 200 kV, known as the secondary level. Finally, major pieces of equipment, such as power plants, transmission lines, transformers, and substations (load centers), are connected to an even lower level voltage network, known as subtransmission; they are referred to as the primary (component) level. The substations are further connected through a low-voltage distribution system to different loads; larger industrial loads are connected at voltage levels similar to the substation voltage level and the smaller loads are progressively connected to lower and lower voltage levels within a distribution system, terminating at the lowest level residential end users.

2.2 Primary Control of an Electric Power System

An electric power system characterized by the above structure serves the basic purpose of producing and distributing electric power to the customers. The system as a whole is operated in anticipation of and in response to the temporal variations in load demand. Electric power is produced by the turbine–generator–governor sets at the power plant locations. The mechanical power is produced by the prime movers. The key control of how much power goes to the network is the governor, which is a local (primary) controller of each modern power plant. Like any other automated controller, a governor has a setpoint and reacts to the deviations from this setpoint automatically. This controller reacts to the frequency deviations from the frequency setpoint value. The faster the turbine turns, the more power is decreased by controlling fuel income to the prime mover by means of a governor (Watt regulator). Standard operating practice has been to adjust the setpoints on governors of generators in each area so that the anticipated area load is fully supplied and the system frequency is nominal. The mechanical power is then converted to the electric power in generators and distributed via the electric power transmission network to the load centers and further distributed to the individual end users via the local electric distribution networks. It is generally hard to predict load exactly. This results in an imbalance between mechanical power produced and power consumed. In this case, according to Kirchhoff laws, the electric power into each node of the electric power network still equals electric power out of the node instantaneously. If there is not enough mechanical power to supply electric power consumed, the generators slow down, resulting in reduced system frequency.

Most of the electric power transmission today is AC, requiring all power generators to operate at the same nominal frequency. In order to maintain frequency very close to its nominal value, each system has several power plants that participate in so-called automatic generation control (AGC). These plants automatically adjust their electric power output by resetting the setpoints on their governors in response to frequency deviations in each control area. Similarly, power plants have so-called automatic voltage regulators (AVRs), which automatically control reactive power produced by the power plant in order to maintain voltage magnitudes at the location of power plants within acceptable voltage deviations. The voltage regulators are also local (primary) controllers. The setpoints of these controllers are adjusted in anticipation of reactive power consumption on the system to ensure that voltage magnitudes at the consumers' side stay within the acceptable limits. Given a setpoint, the primary AVR regulates the reactive power output of a generator so that the voltage magnitude remains within the threshold of the setpoint. This is very similar to the way the governor responds to frequency deviations by producing real power in order to maintain frequency close to the nominal frequency. Some power plants also have power system stabilizers, which represent more advanced local controllers that respond simultaneously to the deviations in frequency and voltage and/or acceleration and have a faster response to the error than the governors and AVRs. If the power system stabilizers are tuned correctly and are implemented on the key power plants, the electric power system as a whole responds in a much more robust way to major disturbances than if the power plants do not have these controllers.

The response of all primary controllers is tuned for the assumed range of operating conditions. The

tuning is achieved by modeling the rest of the complex system as a simple equivalent circuit. However, it is critical to observe that system operating conditions could deviate significantly from the assumed conditions if either (1) load deviates significantly from the assumed or (2) a piece of major equipment is out of operation. In either case, the primary controllers may not perform their function most effectively because their gains are not adjusted to respond effectively to the new conditions. Readjusting these gains in anticipation of or in response to the unusual conditions forms the basis for some form of adaptive control to enable the most effective use of system resources over the wide range of changes in its conditions.

Advanced logic using local measurements in typical primary controllers (e.g., using acceleration measurement in addition to frequency) could contribute significantly to the power plant's ability to adjust better and faster to the changing conditions—such measurements might, for example, result in the development of a controller that would return the system back to its normal frequency and voltage by adapting its power output faster and more effectively. Also, much could be gained from at least partial communication among the primary controllers. This is particularly critical for detecting qualitative changes in system conditions, in order to trigger the change in the logic of the primary controllers determining more adequate settings for the new system conditions. There exist representative examples of the potential gains from wide area measurement systems for stabilizing system conditions under forced outages that would be otherwise uncontrollable without coordination among several controllers; on-load tap changing transformers for regulating voltage at the receiving end of the line have been known to be critical in several voltage problem-related blackouts in France and Belgium; however, the change in their logic when the operating conditions are qualitatively different could potentially prevent these blackouts from occurring.

These seemingly small improvements in primary control of power system equipment could be shown to enhance the ability of the system as a whole to withstand unpredictable difficult conditions without collapsing. The major challenge here is the design of control logic and supporting communications to implement advanced primary control in a robust way—that is, if the controller and/or its communication fail, the system as a whole will still not be affected in a detrimental way. Since this is hard to do with provable robustness, the more common way is to enhance system performance by adding major redundant hardware for stand-by reserves. Establishing a balance between flexibility and over-design has always been the challenge in EPSE.

2.3 System Protection

Under some major forced outages, the system may not be able to return to the nominal frequency after a fault is cleared. In particular, if a fault is not cleared within the so-called critical clearing time, the basic integrity of the operation is endangered. Computing critical clearing time for complex electric power systems still presents an enormous technical challenge.

At each time-step, the proper commands are generated for correcting the abnormality or protecting the system from its consequences. If no abnormality is observed, then the normal operation proceeds for the next sample interval. If the frequency deviations are large and sustained, the under- and over-frequency protective relays automatically disconnect power plants at which the unacceptable deviations occur. Similarly, if a large transmission line goes out of operation, this could lead to current overload in the neighboring transmission lines. A typical scenario here is that a line becomes shorted as a tree touches it, resulting in an unacceptably large current passing through it, and the over-current protective relay of that line disconnects the line to prevent it from further damage. This further activates the over-current protective relays of other lines and they in turn become disconnected.

Protective relaying plays a tremendous role in preventing particular pieces of equipment from becoming damaged under unusual operating conditions. Recall that protective relaying has evolved around the objective of ensuring the safety of individual pieces of equipment under abnormal conditions. For example, transmission lines are allowed to carry only a certain maximum current, blades on turbines can turn only at the speeds specified by the design specifications, and appliances in households operate without being damaged if the voltage applied to them is within the prespecified thresholds of deviations from the nominal voltage at which they are intended to operate. The principles of setting thresholds on relays have evolved over many years and are often system-specific. The relay settings are not changed dynamically to adapt to the changing operating conditions.

For these reasons, relays are key to the cascading events causing major blackouts. The relay settings and their coordination are critical to the efficient use

of the system as a whole. While it is often difficult to differentiate the role of relays in protecting individual pieces of equipment from their role in the system as a whole, it is known that the malfunctioning of protective relaying has played a critical role in several major blackouts. A typical scenario of a blackout of this type starts by a major piece of equipment undergoing forced outage, which, in turn, causes unacceptable over-currents, over- or under-voltages, or unacceptable frequency deviations somewhere else in the system. This situation then triggers the disconnection of the protective relays in the pieces of the affected equipment for safety reasons, which creates further imbalances in the remaining portion of the system, where the protection disconnects the remaining pieces of the equipment. This ultimately results in the disconnection of all pieces of equipment, known as the system blackout or collapse. An even more difficult scenario is related to the false tripping of a relay, which disconnects a piece of equipment without a forced outage actually causing it. Once this piece of equipment is disconnected, the same cascading process of disconnecting the affected pieces of equipment throughout the systems begins. This scenario is known as a "hidden failure." The need to rethink the overall concept of protective relaying in light of system needs and progress in fast computer/communications technologies was recognized some time ago; it has been only recently that this direction is being revived.

Because of this critical role that protective relays play in affecting the interactions among various pieces of the system, it is important to improve their logic and make them both error-free and more adaptive to the changing conditions. Similarly as for primary controllers, this is possible either through a redundant design or through more communications among relays associated with the individual pieces of equipment as these interact to perform system-wide objectives. With the major breakthroughs in the communications technologies, significant progress is being made toward adaptive relaying. Whereas protective relaying could be viewed as the extreme case of primary control, the two problems have not been viewed this way in the past.

2.4 Structure-Based Hierarchical Operation under Normal Conditions

A typical electric power system of the structure described above has millions of nonuniform components and local primary controllers and relays. One of the major goals of EPSE is to design power system control for achieving a desired prespecified performance. Despite many years of research and development, it has remained difficult to provide a reliable, flexible methodology for automated tuning and switching of a variety of control equipment spread throughout the system. In addition to the problem of high dimensionality, the development of such general tools is particularly challenging for this class of systems because of the nonuniformity of control components, reflected in their uneven spatial distribution throughout the system as well as in a large spread of response times.

Instead of developing the most general computer tools for any possible condition, current operating practice is much simpler and different under normal conditions than under the forced outages. Under normal conditions, the power systems are operated hierarchically by various control centers and their on-line interactions. Typically, decisions are made by individual control centers about the status of the area (utility, control area) under often strongly implied or explicitly understood assumptions about the status of the rest of the interconnection and their interactions with the neighboring areas. As explained later in more detail, the entire hierarchical control of today's electric power systems is based on the assumption that any system change would primarily affect the system only locally and that the effects on the rest of the system are secondary. This underlies the decentralized logic of the primary controllers and relays; it further underlies decentralized decision-making by individual control areas within the overall system interconnection. These simplifying assumptions, generally valid under normal operation, lead to the hierarchical control with spatially and temporally separable sub-objectives within an otherwise very complex system.

The critical assumptions under which the interconnection is planned and operated are generally violated under some abnormal conditions associated with forced outages and/or large deviations in load demand from its forecast. When the system enters such conditions, many of the software tools routinely used under normal operation are disabled by the system operators and the main decision maker becomes a system operator. In addition to adequacy problems, i.e., the failure of power plants to supply power, the other major aspect of abnormalities concerns unusual power flow patterns through the delivery system that are very different from the conditions assumed when primary controllers and protective relays are set. It is, therefore, at least in concept, clear why these "malfunction" under

emergency conditions. Under forced outages, system survivability is the prime objective and the cost is secondary. This means that in regulated industry different control areas cooperate by sharing stand-by reserves needed for emergency conditions. The system interconnection as a whole is considered to be viable under contingencies when there are no widespread failures affecting service to a large number of customers and the system grid remains intact; i.e., conditions that may trigger disconnecting pieces of equipment automatically for safety are avoided. The entire concept assumes no active participation by the end users in emergencies.

Because an electric power system is operated very differently in these two modes, one of the largest challenges to effective power systems engineering tools has been to classify the system status according to how close it may be to either its normal condition or the abnormal states. This challenge was conceptualized for the first time by DyLiacco, who introduced the classification of power system operation shown in Fig. 2. There are many degrees and many timescales of abnormal operation that are shown in Fig. 2. Conditions are generally assessed as normal when they are stationary and as expected. All equipment is working that is supposed to work; loads, fuel supplies, water, and weather conditions are within the expected ranges. This classification was later enhanced, but its overall philosophy has remained as initially proposed. Using this classification of system status, a system operator is in a position to schedule power for the forecasted demand and leave the rest to automation at the secondary and primary levels or override the automation and rely on an expert system knowledge about the specifics of the area of interest and act in real time to prevent major system-wide failures. It is worth observing, however, that the boundaries between normal and abnormal conditions are not straightforward to establish, making it necessary to use this classification always with caution. Requiring much margin between normal and abnormal conditions generally results in subefficient use of the existing resources; also, pushing the system to the boundaries of its secure operation for efficiency reasons could result in less robust and less reliable operation. Balancing these two conflicting objectives is generally very difficult.

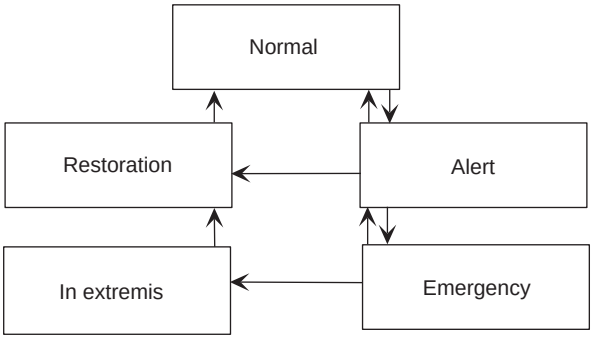

FIGURE 2 Classification of power system operation.

2.5 Operating the System by Decision and Control

To actually operate the system within any of the basic conditions defined in Fig. 2 and during intentional or spontaneous transition between them inherently needs to be done in time-steps where the system state is identified at each time and a decision is made regarding control action to be made at each time-step. After these control decisions are set up at each bus system-wide, then the system responds during the interstate intervals, monitored appropriately to provide the basis for decision at the next sampling time.

The system-wide flow of information and action for this process is of immense size and complexity. Its basic structure is summed up in Fig. 3. Note the two columns for decision and for control at each sampling time. The information base—the system-wide measurement data—is indicated as entering at the bottom of the decision column, where the first task is the classification of the system state into basic operating modes of Fig. 2 or the transition between them. Identifying the position of the current system condition within this column represents the decision regarding the phase of the operation. This information is then passed over to the appropriate block into the control column of Fig. 3 for appropriate control action, which then is passed to the appropriate equipment within the system as indicated in Fig. 3. The equipment then carries out the action called for in system-wide control.

Figures 1 through 3 give a summary of the structure and functioning of a nationwide electric power system. The details and their complexity and volume of the contents of this gross frame of the national power system and economics are immense.

3. EPSE TOOLS FOR SYSTEM OPERATION UNDER NORMAL CONDITIONS

EPSE tools have been developed to accommodate the hierarchical structure of typical electric power

interconnection shown in Fig. 1, horizontally structured into utilities with their own sub-objectives and loosely coupled with the neighboring utilities for sharing generation reserves in case of major equipment outages within the entire interconnection. System monitoring, control, and protection methods are based on these hierarchical structures.

Principal computer-based algorithms for this condition in a decision phase are as follows:

- monitoring and estimation of load and generation;
- static state estimation;
- monitoring of the system loading conditions and security.

Some principal algorithms used for controlling systems under normal operation include the following:

- unit commitment (UC);
- economic dispatch (ED) or optimal power flow (OPF);
- automatic generation control (AGC) to match area real power supply and demand automatically as real power load varies slowly;

- automatic voltage control (AVC) to match area reactive power supply and load and voltage profiles (in some parts of the world only);
- load management.

3.1 System Monitoring

Modern electric power systems are monitored in normal operation to estimate load variations, the status of generators (functional, out for maintenance, or under forced outage), and the status of transmission lines (connected to the rest of the system or shorted out). This information is used as an input to the decision and control phase to balance supply and demand as the system status and levels of load demand vary. In a specific utility area, load variations have typical periodic patterns: annual, seasonal, monthly, weekly, daily, and hourly. Different computer-based methods are used to forecast these system load variations; the long-term forecast (annual and longer) is the hardest and least accurate and the shorter term forecasts are more accurate.

Much progress has been made since the time static state estimation was first introduced to the area of electric power systems. However, this type of estimation is still in use. The basic principle is to use on-line redundant transmission line flow measurements, which estimate false data on the system. The most challenging false data are caused by the incorrectly assumed status of equipment. After many years of researching and developing state estimators, many control centers have them in on-line operations.

The system is also monitored for its proximity to its safe operating limits. The system is generally considered to be in a secure state if none of the operating conditions are violated and the status of the equipment is as expected. The System Control and Data Acquisition System (SCADA) is the basic system in support of area monitoring and decision-making in each control center.

3.2 System Decision and Control

As the loading conditions, power plants' availability status, and the status of transmission lines vary over time, system operators rely heavily on computer-aided software for adjusting overall system resources as needed to supply customers, while maintaining currents/voltage/frequency within the prespecified acceptable threshold of variations. The basic objective of system decision and control in normal operation is to cover the consumers' demand for power using generating sources available throughout the system.

3.2.1 Objectives under Regulated Industry

- The total operating cost of the full system including transmission losses is minimized.
- The price the consumers pay for power is subject to government regulation and control in such a way that the total cost of estimated power production and delivery is covered with adequate profit margins.
- There is enough power available in the system to cover current load estimated statistically using the past year's records plus adequate reserves to cover deviations of the current load from the estimated values and for emergencies of a first-contingency class.
- The power quality is adequate for consumer satisfaction; that is, voltage and frequency are kept within an adequate viability band and kept sufficiently steady. Note that synchronous time frequency is a courtesy to customers. Much less precision would be enough for engineering purposes.
- The system has security that minimizes outages.

3.2.2 Hierarchies in Regulated Generation Control

The only major changes considered in normal operation are the result of load dynamics. Therefore, power systems dynamics under normal conditions are driven primarily by changes in demand. Typical demand curves exhibit several rates of response, ranging from very fast random variations (order of seconds), through hourly, daily, weekly, and seasonal patterns of larger deviations. In today's hierarchical organization, generation-based scheduling is open-loop for balancing anticipated load on weekly, daily, and hourly bases; the secondary level of control (AGC and/or AVC) is closed-loop, automated, and responsive to the voltage and frequency deviations on a minute-by-minute basis, as the unexpected slow and small load deviations in real and reactive power occur. This power balancing on a minute-by-minute basis is performed by each control area within an electric interconnection for the assumed transmission line flows to the other neighboring areas.

There is very little or no coordination of control areas to adjust their line flow exchanges in near real time; instead, control areas agree how much to exchange for the following day and jointly adjust

their internal resources to implement these agreements. However, since the transmission line flows are not directly controllable in typical AC systems, variations from pre-agreed upon schedules take place in real time. This has not been considered to be a big problem, and utilities have established ways to pay back this inadvertent energy exchange approximately once a month, without any major disturbances to the overall system operations, since the system is operated according to the preventive security criteria for the given regional design. As the line flow patterns between control areas deviate for economic transfers—creating considerably different patterns than originally anticipated when the regional system was planned—mainly for implementing energy trades across control areas, the need for on-line minimal coordination of exchanges between control areas at the regional (tertiary) level and even among the regions may become necessary. Several blackouts, including the August 2003 blackout in the Northeast, clearly indicate the need for such monitoring.

Variations of the hierarchies and their automation can be found throughout the world; for example, the system in the United Kingdom does not have automated frequency control, and, moreover, since the entire system is effectively a single control area, tertiary and secondary levels merge into a single level. On the other hand, the European Interconnection is similar in structure to the U.S. horizontal structure, with the control areas corresponding to the countries, instead of particular utilities, respectively. As the electrically interconnected systems open increasingly to the free energy trades across the traditional control area boundaries, the need for advanced EPSE coordinating tools is becoming more pronounced. The blackout of the Italian electric power grid in September 2003, much in the same way as the U.S. August 2003 blackout, was also related to the failure of pieces of equipment outside the affected network; in this case, it was triggered by the failure of an EHV transmission line interconnecting Italian, French, and Swiss subsystems.

3.2.3 Temporal Separation of Basic Control Functions under Normal Operation

The normal-state standard system control functions are summarized as follows:

- Time frame function;
- 2–3 s Inertia, loads, excitation systems;
- 7–10 s Governors;
- 5–10 min AGC;
- 5–10 min AVC;
- 5-30 min ED/OPF;
- 1–10 h UC, restarting and shutting off units.

3.3 System Control

During normal operation, real power and voltage control functions are separable within a certain decoupling error. The operating practices described here are developed assuming this separation.

3.3.1 Real Power Unit Commitment and Economic Dispatch

The unit commitment and economic dispatch are basic computer-aided tools for optimizing total variable operating costs in industry. This is accomplished by using the least expensive units to supply base load and more expensive units for load following and (load) frequency control. At a control center, the most cost-effective units are scheduled on and off to optimize generation use over daily or weekly time intervals in accordance with coordinated unit commitment. The function is open-loop, performed only for anticipated, not actual, system conditions. The longer term economic efficiency is determined by how power plants are turned on and off and cost optimization is achieved by performing economic dispatch as the information about system loads becomes available through a SCADA system.

3.3.2 Automatic Real Power Generation Control

Of course, the actual current load will virtually never match its statistically estimated value for which generation dispatch is done, and the system frequency is also subject to small fluctuations. Consequently, some form of on-line control will be needed to keep the system frequency close to nominal. The specific control generally depends on the horizontal structure of the given electric power system and it could range from a manual frequency control of an isolated system, as in the United Kingdom, through a hierarchical generation control in a multi-control-area setup, as in the United States.

An important observation concerning frequency control is that even the most advanced hierarchical frequency control is strikingly simple with respect to its on-line information and coordination requirements. The area control error (ACE) is the basic measurement to which AGC reacts to balance supply and demand in each control area in near real time. It is defined as the sum of the weighted deviation of the

control area frequency at each particular sampling instant from the nominal system frequency and the deviation of the net power flow exchange with the neighboring areas measured at the same time from the pre-agreed upon net tie-line flow exchange. This entirely decentralized balancing of supply and demand in the entire electric interconnection comprising several control areas is based on the fact that when the ACE is zero for each area, the system is running exactly on schedule. Therefore, if each area independently controls its generation economically to drive its own ACE to zero, then:

- The actual load for the system is covered;
- The system frequency is as scheduled;
- All net tie-line exchanges are at their scheduled values area by area, thus satisfying the scheduled trades;
- If an area is unable to supply its scheduled net tie-line exchange and drive its own ACE to zero, then system frequency will drop and net tie-line exchanges at other areas will rise to cover the deficiency in the load of the deficient area.

3.3.3 Basic Hierarchical System for Real Power Control

• The top (tertiary, regional, interconnection) level simply adjusts the setpoint frequency to drive the actual system frequency and synchronous time back to normal. This one piece of information, the setpoint frequency, needs to be communicated to all areas. This minimal central action will rearrange the area net tie-line exchanges to balance the entire load. This is known as time–error correction in the regulated industry structure.

• Each area individually acts on the change of frequency setpoint by keeping its ACE to zero. No communication is needed between the areas.

• The system is fully decoupled; the areas do not need to communicate with one another or the center. The center needs only to watch the synchronous time to generate its single control command.

• Primary controllers (governors and power system stabilizers) stabilize very fast transients as the power supply/demand balancing at each control area level is performed through AGC.

It is important to recognize the role of accurate short-term load forecasting: the more accurately and more frequently the load is projected, the more efficient the use of available generation will be. The ED and UC are an integral part of a single complex function whose economic performance and technical performance are the result of the actual interdependencies of UC and ED, on one side, and the AGC, on the other. For example, it was estimated that the main inefficiency when performing UC comes from leaving unused generation on some regulating units for frequency control. One could envision, with sufficient computing power, that generation control based solely on dynamic economic dispatch and stochastic unit commitment would be sufficient to balance supply and demand in real time without violating frequency quality specifications.

3.3.4 Reactive Power Economic Dispatch

For an interconnected power system to remain viable, the reactive power must balance at each bus. The problem of reactive power dispatch in the regulated industry is generally bundled with the problem of maintaining (load) voltages within the prespecified limits. The (generator) voltage setpoint values are optimized with respect to certain performance criteria subject to the reactive power balance constraints, the load-voltage acceptable limits, and the limits on generator voltages. Although the voltage control of an interconnected large-scale power system is widely recognized as a very important problem, its basic formulations and solutions are often utility-specific. In the U.S. interconnection, voltage control at the secondary (control area) and tertiary (regional) levels is viewed strictly as a static optimization problem. The most common tool for solving this optimization problem is an algorithm based on OPF.

Compared with generation-based frequency control, generation-based reactive power or voltage control is less standardized and less automated. Only a handful of countries in the world have semiautomated reactive power dispatch of generators.

The generation-based reactive power dispatch falls under the category of the OPF. Depending on the actual choice of the optimization criterion, two formulations are of interest:

1. The cost function is the total fuel cost required to supply a given demand.
2. The cost function is the total transmission loss that occurs as power is delivered from the power plants to customers.

An increased severity of voltage-related operating problems has resulted in an effort to make OPF-based formulations more directly related to these problems than the general OPF methods. Among many developments, the most notable are as follows: (1) an improved formulation of the decoupled OPF;

(2) OPF-based optimization of reactive power margins; and (3) an OPF targeted on improving energy transfer over far electrical distances.

3.3.5 A Hierarchical System for Reactive Power/Voltage Control

A qualitatively different approach to the voltage-control design is hierarchical and is based on temporal separation of reactive power fluctuations and corresponding control levels. Similar to the hierarchical real power-frequency control schemes, the approach is based on decomposing a large system into control areas equipped with decentralized closed-loop secondary-level voltage controllers. A close look into this approach indicates that the objectives of a hierarchical voltage control scheme are analogous to the objectives of frequency control; the main objective at the secondary (control area) level of voltage control is, for example, to update setpoints of generator exciters to maintain voltages at critical ("pilot") points within the prespecified deviations as the reactive power demand and generation deviate from their scheduled (anticipated) values. The hierarchical control for the regulated industry, based on the systematic implementations in several European countries, is often referred to as AVC.

3.3.6 Load Management

It has been well understood for quite some time that having an active response to the changing system conditions seen in frequency and voltage deviations from their nominal values by the end users could significantly contribute to a more robust performance of the system as a whole. In basically the same way that the control area supply/demand imbalance (seen in its ACE) becomes reduced by increasing generation, one could decrease control area load and drive ACE back to zero. Responsive load management is particularly important at times of unexpected shortage in generation and transmission capacity, as well as for using less costly generation reserves instead of peaking units under normal operation.

Except for some early experiments known as demand-side management programs, customers have largely remained passive power consumers. As the industry restructures, the need for more system conditions and price-responsive load will increase. The early vision of homeostatic control, in which all end users react to local deviations in frequency and demand in an automated way, could go a very long way toward more efficient use of resources under normal conditions and reduced reserves for emergency conditions. Sections 5 and 6 state that price-responsive load is the key to the well-functioning electricity markets; the difficult question is providing on-line incentives to the end users to respond at the value as seen by themselves.

4. EPSE FOR EMERGENCY OPERATION

The ultimate challenge to electric power systems engineering at its present stage is reflected in the lack of model-based analytic tools and algorithms for detecting abnormalities in system operation and for deciding what actions to take as the abnormal situation evolves. The classification of potential abnormal modes of operation according to the famous DyLiacco diagram shown in Fig. 2 and its later enhancements suggests that the following operating modes could occur: alert mode and emergency mode.

This section briefly summarizes the tools for monitoring and responding under these abnormal conditions.

4.1 System Monitoring

4.1.1 Alert Operating Mode

SCADA-based monitoring could detect a situation in which conditions are normal; the system is viable and within the acceptable operating constraints. However, the structure has been altered from what was expected by an earlier event—a transmission line is missing, for example. If this is detected, the operating mode is recognized to be under an alert condition.

4.1.2 Emergency Operating Mode

The emergency conditions could be reflected in several different system-wide problems, ranging from stability and viability crisis through system failure. This division, however, is not clear-cut. The conditions overlap, but normally one dominates. Take in sequence:

4.1.2.1 Stability Crisis The system is in a momentary dynamic state, typically caused by a fault, which is sufficiently violent to endanger the integrity of the system.

4.1.2.2 Viability Crisis The system in its present condition is incapable of operating within voltage,

current, frequency, etc., operating constraints, given the available generation and transmission capability for the existing load demand. This condition could result from a fault and is then often preceded by a stability crisis. Nonviable conditions can, however, come on quietly, for instance, if major generation or other equipment does not become available when it is scheduled to come on-line for peak demand.

4.1.2.3 Integrity Crisis The integrity of the system is violated—for instance, load was dropped or the portion of the system is dropped off. Principally, this is a severe and extensive accumulation of stability and viability crises or the damage left by them with islanding and blackout patches in the system. During the crisis phase, events are still occurring and a struggle is still going on to avoid as much disintegration as possible.

4.1.2.4 Restoration This is an extensive and collective control (generally interpreted) effort to remedy the damage left by any combination of the three crises.

4.2 System Decision and Control

4.2.1 Alert Operating Mode

The principal operating algorithms are as for the normal operating mode, but, in addition, future consequences of the structural change must be evaluated and, if necessary, remedied. For example, the structural change may violate security constraints while approaching peak load. Industry practice is preventive in this operating mode, in the sense that the system is operated so that it meets normal operating constraints when any one of the most likely and most severe unexpected structural changes (contingencies) takes place. It is often cost-inefficient because it does not allow for least-cost use of resources without considering future events. To circumvent this problem, the operating limits under structural changes are allowed to be less restrictive in the alert mode than in the normal mode. For example, typically accepted voltage variations under normal operation are within 2% or 0.002 per unit, and in the alert mode they are relaxed to 5%. When a more severe structural change occurs, it may bring the system very close to the limits of acceptable operating constraints. For such conditions, economic criteria are overruled by the security criteria. Different ancillary algorithms for readjusting network flows, bringing on new, more expensive generation, modifying load dispatch, etc., are used to assist the operator under these conditions.

Moreover, since the system operation is still normal under the alert state, the control tools and actions of the normal state are used. The special alert-state control actions consist primarily of equipment switching and changes in control setpoints and schedules to improve security.

4.2.2 Emergency Operating Mode

The decision and control actions in emergency mode are often left to the human operator and are often dependent on the specifics of a particular control area or region. At best, off-line computer-based analysis is performed for scenarios of interest and particular procedures are in place in case the particular scenario occurs. Model-based simulations of such scenarios are generally very time-consuming and are therefore not feasible as on-line means of facilitating decision-making and control in emergency situations, when time is critical. One of the typical decisions concerns the so-called critical clearing time, i.e., the longest time of fault duration, so that when the fault is removed, the system can still return to its normal operation. The following are representative decision and control actions characteristic of an emergency operating mode.

4.2.2.1 Stability Crisis Some of the principal control tools can be:

- Local structural control or protective relaying to eliminate faulty components and local control actions to preserve system stability.
- Stability augmentation utilizing FACTS, technologies, breaking resistors, load skipping, etc.
- Load dropping or major structural changes to separate the system in the least objectionable manner when integrity cannot be maintained. Note that this action pushes the system into the integrity crisis or an *in extremis* condition.

4.2.2.2 Viability Crisis Principal algorithms in an approximate order of increasing undesirability include:

- Frequency reduction of the AGC type;
- Use of spinning reserves or cold reserves;
- Special measures, such as fast turbine run-back;
- Help from neighboring areas;
- Exploiting time-limited overload capability of the equipment;
- Special measures, such as voltage reduction;

- First-stage structural control, such as starting a new generation, returning equipment from maintenance, or load dropping (for minutes or hours);
- Second-stage structural control-islanding involving separation of a power network into parts, some of which are not supplied with power.

4.2.2.3 Integrity Crisis The tools are mostly the same as for the stability and viability crisis.

4.2.2.4 Restoration The main processes taking place during restoration are reconnection of the islands and restoration of loads. This is, of course, an operation by itself and it has been researched extensively over time.

5. CHALLENGES TO EPSE IN THE CHANGING INDUSTRY

Over the past decades, the electric power industry has been undergoing major organizational changes. It is critical to recognize that an electric power structure, along with the objectives and performance metrics used in various EPSE methods for monitoring, decision-making, and on-line operations of a complex electric power system, must be posed in the context of each specific industry structure. The interplay between technical, economic, and policy signals over various time horizons and among various industry layers is fundamental to the overall system performance as a whole. One of the more difficult tasks of EPSE even for fully regulated industry has been how to establish the right balance between system robustness to unexpected events, such as forced outages, and the efficient use of the existing equipment under normal conditions. In other words, the tradeoffs between system security/reliability and the economics of providing power to the end users have been generally difficult to mediate. The performance metrics of the system as a whole have been affected by the utility-dependent performance metrics within the system. Basic security criteria adopted by the regulated industry are discussed above; all software tools for monitoring and decision-making in control centers are based on these well-established objectives.

Electric power restructuring has brought about many fundamental changes to the way EPSE might be performed in the future. To start with, a once vertically integrated utility with a single objective of supplying its native customers has become unbundled into power supply, transmission, and distribution businesses and/or functions. Delivery and consumption are becoming businesses with their own objectives, typically not aligned with the objectives of the power suppliers. In addition, the service is provided through some forms of markets, with marketers managing both the physical, forced outage-related risks and the financial risks with the objectives of making their own profits. Design of markets for various services (delivery, voltage, frequency control) in addition to the basic power market is at rudimentary stages. Providing electric power service competitively asks for complex new economic and policy designs, with a full understanding of their overall effects on the system and the unbundled market participants themselves.

The EPSE tools in support of electric power provision in these evolving industry structures are still rudimentary. One thing is certain, although not widely recognized: it is going to be impossible to continue using the same EPSE models, analysis, and decision-making tools developed for the regulated industry to manage effectively the power system under restructuring. This lack of understanding of the gaps between the engineering tools and market objectives has already caused unexpected outcomes. The remainder of this section briefly summarizes evolving EPSE concepts. The last part of this section provides a possible systems view for bridging this gap between regulated and restructured industry models. The section explains how potentially new paradigms for the electric power system may be based on distributed decision-making by all market participants actively pursuing their subobjectives under incomplete information. Minimal coordination at various industry layers in order to ensure well-understood performance metrics is the ultimate goal. This challenge is briefly elaborated at the end.

6. OBJECTIVES OF EPSE AS A FUNCTION OF CHANGING INDUSTRY STRUCTURES

6.1 EPSE Tools for Vertically Unbundling Industry

6.1.1 Objectives in Deregulated Industry

- Suppliers can obtain the maximum price for their product competitively established in free

commodities market-type economy restricted only in the sense of the rules of exchange.

- Consumers of electric power can pay the lowest price for their purchase competitively established in a free commodities market-type economy restricted only in the sense of the rules of exchange. Note that this may work fine for large customers who can effectively trade at the commodities market to their advantage. Small customers cannot effectively do that, which raises the difficult question of how to establish the price of the power at individual homes, with the potential outcome to retain some kind of government regulation in this area.
- There is enough power available in the system to cover the current load of the system for emergencies of a first contingency class.
- The power supply quality is adequate for consumer satisfaction; that is, voltage and frequency are kept within an adequate viability band and sufficiently steady.
- The system has security to minimize outages.

6.1.2 Evolution from the Hierarchical Operation into Open Access Operation

In the changing power industry, balancing supply and demand in real time is generally market-based. Three qualitatively different market mechanisms are of interest: (1) the primary electricity market(s) for supplying anticipated demand; (2) various "ancillary" markets for ensuring that system conditions remain within prespecified limits as demand deviates in real time from its anticipated pattern; and (3) transmission markets for delivering power requested by (1) and (2).

These markets are necessary for ensuring that the system conditions remain within their technically acceptable limits as power is provided competitively. Here, only some fundamental changes needed in EPSE tools for serving the new industry are summarized.

In addition to the temporal decomposition-based hierarchies present in load dynamics, further temporal decompositions are emerging via the establishment of electricity markets whose on-line decision-making evolves at daily, hourly, and even near-real-time rates. Two observations are relevant here for effective on-line use of generation in deregulated industry: (1) the distinction between predicted and real time is no longer as pronounced as when unit commitment is done assuming demand to be known for the entire next day and (2) it is, therefore, conceptually difficult to "unbundle" the economic generation scheduling process, assuming the predicted load from the on-line control function for responding to unexpected load fluctuations.

Furthermore, some customers are willing to accept power interruptions in exchange for a lower price of electricity—that is, generation is beginning to be provided by some customers on a nonfirm basis. This is a qualitative change from the utility's unconditional obligation to serve and charge its connected customer the same price of electricity over time. This raises a fundamental question about the inherent temporal decomposition of load dynamics and the conceptual applicability of hierarchical power systems operation under competition.

Finally, a transmission grid is managed as a regulated monopoly in a multiownership environment, but is expected to serve markets (1) and (2), which are competitive. This asymmetry of regulatory structure within the single electric interconnection intended to be used in an open access manner, without recognizing ownership boundaries, is creating tremendous challenges for operating the transmission grid consistently. Because of this, systematic policy/regulatory frameworks for moving toward value-based transmission service need to be introduced.

6.2 EPSE for Operating the System under Open Access

Operating under open access implies, at least in principle, the ability for power suppliers to competitively serve customers across utility boundaries within an electric power interconnection. The hierarchical operation in regulated industry must be modified to facilitate delivering power across the boundaries of former control areas established in the old industry without endangering the reliability of the interconnection as a whole. As power is traded across the control areas, each control area must monitor these exchanges in order to balance the remaining needs for power to the customers that it serves as a provider of last resort. The interconnection is being used for power flow patterns different than the flow patterns expected under the originally intended system control and protection design. These market-driven exchanges could result in much stronger couplings among the control areas and, therefore, could require some degree of on-line coordination of flow exchanges between the control areas in order to operate the interconnection as a whole reliably. EPSE tools for coordinating control

areas while enabling power trading across control areas do not yet exist.

One possible approach to operating the interconnection under open access would be a market-based approach to (1) ensuring enough capacity, both generation and transmission, for reliable service and (2) giving incentives to the end users to adjust in an on-line way to the changing technical and/or economic conditions. An early vision of the 20th century electric power operation was introduced by Fred Schweppe: all end users react to variations in local frequency and voltage and the system remains in homeostasis, or balance. The success of this concept, borrowed from biology, must obey two key rules: (1) all end users must respond and (2) the right automation must be implemented. The ongoing industry restructuring has not yet provided a regulatory/policy framework in support of this technological vision.

Furthermore, although the technology for automated participation by the end users is available, it is not cost-effective when implemented by each end user, independent of its size and characteristics. Instead, what are available are cost-effective technologies for managing very large consumers or groups of smaller end-users. Although in concept there should not be any difference between one large end user of X megawatts and several smaller users whose total use is X megawatts, there is a very big difference between two end users of the same average X-megawatt energy consumption, where one end user is adaptive to the system conditions (by "shaving" its peak consumption by redistributing the needs to a different time of the day and/or by reducing its nonessential consumption during extreme system conditions) and the second end user is completely nonresponsive to the system conditions and requires an unconditional supply without considerations for the overall system conditions.

To implement price-responsive energy consumption on-line, communications begin to play a very different new role than in the hierarchical operation under regulation. For an open access system to work well, it becomes necessary to have on-line communication of important technical and/or economic information (1) between the aggregator of various end users and (2) between the aggregators and energy providers, transmission providers, and system operators as well as among several system operators within the interconnection. Note that, at least in principle, a bundled production could be provided by the sellers of power with the delivery service included or the aggregator at the end user's side would look for the best combination of subservices as needed by the end users represented by this aggregator.

A highly effective paradigm of this type has not been actively pursued due to the lack of regulatory policy incentives to differentiate quality of service and value of these differences. In today's industry under restructuring, there is hardly any incentive to the end users to respond to the system conditions, since the service is cost-based with the costs more or less equally distributed among all end users according to their average X-megawatt consumption. The final part of this section provides a possible vision of futuristic EPSE tools that, given the right policy incentives, could lead to the value-based provision of quality of service under open access.

6.3 EPSE for Risk Management under Open Access

As the industry reorganizes, it has become necessary to differentiate between the physical and the financial risks. Major physical risks concern system-wide failures like that experienced during the 2003 blackout, reflected in a fundamental inability of the system to operate as intended and to deliver according to the prespecified performance metrics. This could take place for a variety of reasons, such as (1) underdesign of system hardware for the perceived needs; (2) poor on-line IT-based monitoring, control, and protection coordination of various individual pieces of equipment; (3) human error; and (4) nonresponsive power consumption. The society must take it as given that some very-low-probability, potentially high-impact triggering events will happen. It is, however, not obvious at all how eliminating any of the reasons (1)–(5) would fully guard against widespread system failures. The individual relays and breakers very rarely fail to disconnect pieces of equipment that they are responsible for. However, in order to minimize the effects of triggering events on the system as a whole, the tradeoffs between designing an "optimal grid" for the anticipated use under normal and abnormal conditions and developing novel EPSE tools for managing these physical risks under open access must be understood and managed. No matter how robust the hardware design in place, its system-wide use is not going to be as effective as possible without good software tools.

The role of EPSE software tools in managing physical risks in complex electric power grids has been grossly underestimated. Consequently, the tools are

very rudimentary and very little technology transfer has been attempted. In particular, feed-forward software tools for scheduling available resources for the predicted load are well established for the regulated industry, as reviewed in Section 3. The software and hardware options for managing resources under open access are much more complex than in the regulated industry. EPSE tools for distributed decisions by market participants and by the system operators, in particular with the load being an active decision maker, must be developed. The old industry has been characterized by being truly risk-averse. As the levels of risk-taking become more diverse under open access, EPSE tools must be developed as a means of decision-making by those taking risks.

6.4 Toward EPSE-Supported Protocols under Open Access

Given a strong movement toward the industry restructuring along with an emergence of cost-effective technologies for producing, delivering, and consuming power in qualitatively different ways than in the past, it is essential to develop EPSE tools for flexible provision of service to the end users according to their choice. Instead of pursuing the rigid hierarchical control of the past and/or over-designing the system, an IT framework would provide flexibility in delivery and consumption.

The underlying technological weaknesses that led to the major blackouts of 1966 (Northeast), 1975 (Northeast), 1996 (California), and 2003 (Northeast) are best corrected with information and control technologies. The first weakness is simplistic equipment protection and control. When system conditions evolve to threaten individual pieces of equipment, such as a line, transformer, or generator, protection devices respond by removing that equipment from service. This increases the stress on other parts of the system, possibly causing their protection to act, and so on. The result can be a large-scale cascading blackout. A better alternative would be to shift resources to aid the equipment first threatened, avoiding a blackout altogether. This requires that local controllers of power plants, transmission lines, and consumer consumption act quickly in a coordinated manner to relieve system stress before protective action is required.

Unfortunately, controllers cannot identify emergency conditions and are not flexible enough to act in a coordinated manner, and the protection devices lack the information and decision-making abilities required to postpone their actions. The second weakness is the inability to quickly detect that the system is not operating as desired, because of equipment failure or unusual power demand somewhere within the very large and complex electric power grid. In particular, if individual operators could quickly recognize that their region is under stress, then they could adjust their own resources fast enough to keep operation under control or at least minimize the extent of a blackout. Today's operators do not have the information to do so because there is no on-line monitoring at the regional level or higher. Taken together, these two weaknesses result in a lack of information, flexibility, and coordination that will inevitably lead to future large-scale blackouts as demand increases. With economically minimal investment in information and control technology, this need not be the case.

To improve system operation, the protection and control of equipment, such as power plants, transformers, transmission lines, and loads, must first be improved. This is a challenge because the system response to protection and control actions under stress may be different than under the conditions for which the protection and controls were initially built and tuned. Typical assumptions under normal operation are that (1) the local effects of protection and control are much stronger than their effects elsewhere on the system and (2) producing more power when frequency and voltage drop always helps. These two assumptions are frequently violated when the system is under stress, requiring more on-line information about the rest of the system and more advanced logic to decide how to act.

Next, an on-line coordinated exchange of power between utilities and larger regions of the electric power grid in the United States and Canada must be implemented. This will allow the system operators to better manage large-scale system operation. Managing the entire interconnected grid on-line as a single system is not possible for a variety of technical and business reasons. Instead, a multilayer IT-based framework is required for the system to support the delivery of power between arbitrary generators and consumers. This framework must (1) allow all system users to adjust to changing conditions; (2) allow all consumers to communicate their short- and long-term demands for power and its delivery; (3) have clearly defined technical and contractual responsibilities for the performance of all users; and (4) monitor and control power exchanges between all utilities and regions. Such a framework would facilitate the evolution of the rigid grid of today to an

Internet-like grid in which the users decide when and how to use the system. Not only will this improve reliability, but it will permit value-based reliability in which users pay more (or less) for more (or less) reliable power.

The same IT-based framework for power system management can also support long-term forward markets for reliable service by providing current and future system needs for that service. The money paid in advance for reliable service could be invested in the information and control technology required to implement it. Having forward reliability markets would avoid unpopular regulatory decisions to increase the price of electricity without a good understanding of customer needs for reliable service and their willingness to pay for it. It would also promote the value-based evolution of the grid according to customer needs.

An adequately reliable power system will most economically come from investment in information and control technology. Improvements in system protection and control, built on an IT framework for on-line reliable service, and the forward markets for reliable service complement each other. One without the other does not work and both are long overdue.

7. A GLIMPSE INTO THE FUTURE: MORE SMOOTH AND SECURE ON A BUILDING BLOCK STRUCTURE

7.1 The Current Bulk Power Transmission Network

The electric power system in its present state is a dynamic system of enormous size coast to coast, operating at an equilibrium state that is stable under the slight perturbations imposed by normal load variations. However, faults or mistakes must always be expected even in the best of equipment—and even in humans. An abnormal sudden change like the loss of a large power-generating plant or a large, vital transmission line abruptly changes the system equilibria, including the current operating state, potentially drastically. While the system is trying to move automatically (too fast for human interference) to a new equilibrium, the huge difference in energy present in the network before and after the change between the two operating equilibria is left to swing freely over the system in giant energy waves, the postfault transient oscillation, which challenge the current, voltage, or power-carrying capacity, i.e., the backbone strength of equipment such as transmission lines, generators, and transformers. It is the system operators' duty to maintain a loading condition by their dispatch activity at all times for the existing loading of the system without system breakup for all fault contingencies. Through existing advanced technology including power electronics, computer, and communication, this effort can be successful most of the time, but not always, and one should not forget the new emergence of terrorist possibilities.

7.2 Reorganizing Bulk Power Transmission Network to Building Block Structures Individually Controlled by a Computer Control Center

Drastic dangers call for drastic remedies. The authors' group, led by John Zaborszky, has been developing such a drastic remedy by mostly retaining its currently used power equipment, but rearranging the structure of the interplay of the power system and its controlling computer and communication system for maximum effectiveness.

Recent events served as a reminder that the current power system is vulnerable to widespread failure caused by the failure of even one major component. This vulnerability derives from the fact that after such a failure the system becomes a substantially different one and the operating equilibria cease to be equilibria in the new system. However, the states in the new state space will generally lie in the region of attraction of one of the new equilibria, which in turn will lie quite close to their existing ones except in the disturbed area, so they should move to their new position through a dynamic transient unless the system is becoming unstable. The latter results from the fact that each of the components (building blocks) carries a large amount of energy at an equilibrium and in AC this energy is swinging across any connection at 120 cycles.

So, at either of the equilibria (before or after the event), each building block will carry two components of energy:

- Type 1: the steady state energy content of the building block in the new system after the event.
- Type 2: the difference between the energy content of the building block at the time of the event and the type 1 energy content.

Each of these should be available in the computer control center as it is planning the postevent operation of the system after the event.

7.3 The Outline of the Management of the Envisioned Approach

The proposed new, building block (for example, power plants or generators, or major loads, such as aluminum plant, capacitor banks) structure eliminates any direct control interaction between individual building blocks even if they are neighbors but not their physical dynamic interconnection through the bulk power network system. The only information and control command exchange exists between the control centers and individual building blocks before and after the disturbance.

Each of the individual building blocks in their current physical state contains an amount of energy of type 1. This energy will differ from the energy at the state assigned by the control center to the blocks. In effect, the distribution of the type 1 energy defines the operating state of the system.

The excess energy (type 2) becomes the free swinging power in the system postevent transient oscillation, unless it is eliminated by draining it out or in locally at each of the bulk transmission buses into storage capacitors and then fed back smoothly into the system by routine dispatch (such storage already exists sporadically in the power system). While the excess energy is thus drained out or in (if available in storage) at individual buses, the system voltages and current are sliding on smoothly under dispatch control without wild swinging with only a perturbation ripple, provided enough generation is available. If not, i.e., in an emergency, the central computer control will order dropping of loads in priority order and then they will be reconnected when possible.

In fact, the system may already be broken up into disjoint pieces (e.g., in a disaster situation). If so, the building block structure allows the control centers to make the separate pieces by themselves viable by load dropping and set them up like "individual power companies" to run independently of one another while still connected to the control center until their regular connection can be restored. This approach outlined above can become an effective defense in emergencies of the 9/11 or the New York 2003 type.

7.4 Summary of the Process for Building Block Use Operated and Controlled by the Computer Control Center

In summary, the envisioned building block structure of the power system has the following distinguishing features:

- The system is restructured as a mosaic of building blocks, such as generators, power plant buses, and transmission lines.
- Building blocks are connected only to their neighbors.
- Each block has only one single control command connection going to the system's computer control centers. There is no control command connection, i.e., input, directly between two building blocks, even if they are direct neighbors physically.
- The one single communication between each individual building block and the control center carries full report of the dynamic state of that particular building block to the control center and control command instruction to the block.
- The control center sends to each building block a command to adjust one particular system state variable (located inside in that block) to an assigned value, using a single-variable feedback loop control producing a single control signal input generated independently within the building block for setting the state variable of the block.
- On the basis of block-by-block information received by the control center about components of the system state in each block and the information the center has about the demands on the system, the control center computes the type 1 energy content required for stable operation of the system in each of its blocks.
- Note that this computation is simply the steady-state stable "load flow" for the system.
- Block by block, this information is deducted from the present energy contents of the block.
- This difference is drained in or out (depending on whether it carries a plus or minus sign) of the storage equipment at each particular block.
- The result is that the system has slid over into its desired steady state value.
- No violent transients exist to cause new failures.
- Note that on an all-DC bulk power system, this result derives automatically but it applies as described on a conventional mixed AC and DC bulk power system—with the addition of some more power electronic equipment.

In either case (all HV-DC or conventional bulk transmission), the dynamics of the system trajectories in the state space will change instantly and smoothly to that of the postevent system composition without transient waves but the energy controls of the energy storage devices (typically capacitor banks) will shift virtually unilaterally, to its post event form.

Note the following:

- The above assumes the system to be linear around its operating equilibria and that its response is instantaneous, assumptions that are true only approximately. It needs to be proven that on the actual systems this would cause only a tolerable perturbation around the operating point in case of faults.
- This approach exploits the full potential of power electronics to achieve maximum possible smoothness and security of the system operation without violent transient swings that can cause the spreading of major faults (e.g., East Coast 1965, 2003).
- This, however, requires installation of some power electronics, computer, and storage equipment, which need to be properly analyzed.
- The economy of such full restructuring of the current bulk power system needs to be established to fully utilize the current technology of power system electronics, computers, and communications, even if it requires only the addition of a moderate amount of equipment but major restructuring of their operation into a building block base.

In conclusion, as briefly summarized here, this approach assumes linearity and instant response (both of which can only be approximated, leaving the question: how well?) and assumes that it would be possible to drain out the type 2 energy at each building block so that the system would find itself in the new equilibrium position with no transient. Without any such draining process, as is happening today, the type 2 energy differences create a violent transient, which is proven to cause new faults since it creates highly abnormal voltages, currents, etc., on the equipment until it is dissipated through the line losses and radiation.

With what is proposed here, the system—that is, the bulk power transmission network—would possess a smoothly varying equilibrium state without any over-voltages or currents and hence without the spreading of the disturbances and system breakup following a major fault as in New York 2003 or a 9/11-type attack.

Glossary

cost allocation The process of allocating commission-approved utility cost of service among customer classes based on demand characteristics or other similarities.

cost of capital Percentage return that investors require for the use of their money.

cost of service Total amount of dollars needed to supply the utility's customers, including operating and maintenance expenses, taxes, depreciation expenses, and a fair return on investment.

franchise Exclusive territorial rights granted by state or local authority.

prudent investment test A regulatory standard that requires that costs recovered from customers by a regulated public utility must have been reasonable given what was known or knowable at the time the costs were incurred.

rate base A measure of a utility's total property value, including plant, equipment, materials, supplies, and cash; excluded are accumulated depreciation, amortization, deferred taxes, and customer-provided capital.

rate case Formal process used by state and federal commissions to determine and set rates.

rate design The rate structure or tariff schedule devised for each customer class or subclass; it is intended to collect the cost of service allocated to the customer class or subclass.

rate of return The return on investment received by the utility or its investors; the allowed rate of return is the commission-approved percentage return on the value of the rate base the utility is given an opportunity to earn on its investments that are used and useful for public service.

revenue requirement The total expenses, or the cost of service, determined by a commission to be needed to provide service to the customers.

traditional regulation A form of economic or price regulation conducted by a governmental agency or commission that estimates the regulated firm's cost of doing business and determines a "just and reasonable" price for consumers based on approved costs, including a fair return.

used and useful test Regulatory standard for utility investments and expenditures that must be met to be included in the rate base or recovered as expenses from customers that specifies that investments and expenditures must be used and useful for public service.

Traditional regulation as applied to electric utilities is a form of economic or price regulation that evolved and often changed form over a period of more than 100 years. Also called rate base, cost of service, cost-based regulation, or rate-of-return regulation, this form of regulation is a method that attempts to estimate the regulated firm's cost of doing business and derive a "fair" price for consumers. The concept of public utility regulation was developed from the common law prohibition of unfair competition. It was applied to many industries, including the railroad industry beginning in the mid-19th century and later urban transit (streetcars and buses), telephone, water transportation, manufactured and

natural gas, and water utilities. An important goal of this type of regulation is to balance the interests of the firm while protecting customers from monopoly prices and other abuses. The term "traditional regulation" is used here with the caveat that many industries and state and federal regulators have abandoned or significantly modified this basic form of regulation during recent years for one or more sectors. Charles Phillips, Jr., noted that utility regulation is an economic, legislative, and legal concept. These themes are repeated often when regulatory questions arise. Economic concepts are used for rate design, determination of rate of return, and analysis of company incentives for cost control and behavior. Legislative involvement from the enabling statutes, statutory changes made in response to economic conditions and technology changes as well as through the political process, and legal concepts form the basis of regulation and are grounded in constitutional law and set the boundaries for commission authority and utility actions. Other disciplines are also involved in influencing regulation, especially accounting through accounting standards and reporting requirements and engineering through the prominent technical complexities of power generation and delivery.

1. HISTORY OF TRADITIONAL REGULATION

There is some difference of opinion about the origin of traditional utility regulation in the electric industry. Some have argued that it was due to the efforts of Progressive Era reformers who were crusading against monopoly abuses in many industries during the late 19th century. Others maintain that it was the industry itself that decided that regulation was better than either "ruinous" competition or the possibility of government acquisition. Because there is strong evidence to support both views, it is likely that its origin is one of those points in history where opposing interests converge to support a similar solution. However, once a common frame of reference was reached, the actual implementation of the regulatory model was often less congenial.

The regulation of the electric industry generally followed the changing structure of the industry. At the beginning of the industry's history, there was little regulation and it was often thought to be unnecessary. Electric power was seen as a means to further economic development, much as railroads were seen a few decades earlier. The main use for electric power during the late 19th century was for industrial purposes and a few wealthy households. Franchises were granted by municipalities, and rate limits were sometimes set by local governments. Early in the 20th century, most of the power was still generated for industrial use and was produced at the industrial site that used the power. However, central station power, or utility production, became more prevalent and eventually became the leading form of production by the 1920s.

Along with the rise of central station power production and the consolidation of the industry into larger regional companies due to economies of scale in the production and delivery of electricity, utility borders expanded beyond municipalities. As a result, regulation shifted to the state level, beginning in 1907 in New York and Wisconsin and spreading to nearly every state by the 1920s. Large regional and multistate holding companies formed, and investor and consumer abuses were rampant, peaking in 1929 with the financial collapse of the Insull companies. The congressional and regulatory response was to force the breakup of the large holding companies and to place restrictions on the operations and management structures of the remaining regional companies (through the Public Utility Holding Company Act of 1935). This marked the beginning of federal involvement in the industry that continues to the current day. However, state commissions continue to be the primary regulator of retail rates for investor-owned and regulated utilities in the United States.

2. THE UTILITY FRANCHISE

During the late 19th century, it was generally decided that efficient competition was not feasible or practical for the developing electric industry. Rather than allow redundant systems and parallel distribution lines (which occurred in some locations where competing electric companies had their own lines), local municipalities and (later) state governments granted exclusive territorial rights to utilities. This was and is done through an agreement with state or local authority by franchise territorial exclusivity laws, a certificate of public convenience and necessity, or both. All 50 states had laws setting up exclusive retail marketing areas for investor-owned utilities, and many states provided specific service area assignments under territorial exclusivity statutes. These territorial exclusivity statutes provide a

utility with the exclusive right and obligation to serve in an identifiable service area. Many states make service area assignments through the commission granting the utility a certificate of public convenience and necessity.

Because this sanctioned monopoly was by design the only supplier in the area, the utility was required to serve all customers in its service area. In general, utilities have historically had an obligation to serve all retail customers requesting service and to make the investments necessary to provide this service on demand (with limits on this obligation for new customers requiring new lines). To meet this obligation to serve, utilities made investments and entered into legal obligations, such as construction and purchased power contracts, and usually have rights of eminent domain for the construction of new power lines and other facilities. The obligation to serve derives from the utility being granted an exclusive public utility franchise. The requirement to serve is in exchange for an exclusive but revocable right or privilege to serve an area.

In addition to the obligation to serve all who apply for service within their franchise or service areas, public utilities have three other main responsibilities. First, utilities must provide safe and reliable service. Second, they may not engage in undue price discrimination. The prohibition against undue price discrimination requires that all similarly situated customers receiving identical service must be served on the same terms and conditions and for the same price (usually enforced through a required standard tariff filing). Third, utilities may charge only just and reasonable rates and may not earn monopoly profits with rates determined by a commission. What constitutes just and reasonable rates is determined by the regulator, whose decisions are subject to judicial review. These requirements are designed for the express purpose of limiting the potential for monopoly abuse. In return for undertaking these obligations, utilities are granted an opportunity (but not a guarantee) to earn a reasonable return on their prudent investment and to recover their prudently incurred expenses.

The granting of a certificate to serve, along with the accompanying obligations to serve and other legal interpretations and evolving reinterpretations embodied in state and local statutes and case law, constitutes what has become known as the regulatory compact. The regulatory compact does not and never did exist in a written form; rather, it was formed through a series of court cases and commission actions and practices. The regulatory compact is, as Justice Oliver W. Holmes described it in 1912, a balancing of a utility's constitutional rights and its responsibilities.

3. THE REGULATORY PROCESS

The general procedure used to set rates under traditional regulation is through a formal rate case. The full rate case is a quasi-judicial procedure similar to a court proceeding and follows procedures proscribed in the public utility commission's state or federal enabling statutes and the commission's own administrative procedures. Rate cases can last up to a year or longer but are sometimes time limited by statute. Typically, testimony is presented by the participants' witnesses, and cross-examination may be done. A full rate case for a large electric utility may involve thousands of pages of testimony from expert witnesses, hearing transcripts, cross-examination, reply and rebuttal briefs, re-cross examination, and commission statements and decisions. A decision of the commission can be appealed to state and federal courts, which can take several years to resolve the issue. Although deference is often given to the regulatory authority on findings of fact, decisions are sometimes overturned on procedural grounds or due to questions of statutory or constitutional interpretation.

To avoid the time and expense of the full proceedings, settlements may be reached among the parties to the case. Once rates are established, automatic adjustments or rate modification may also occur without the formal rate case procedure. During periods of escalating costs and plant and equipment construction, rate cases may be common and may even overlap or run end to end. However, during periods of stable input costs, low inflation, and limited building activity, regulated firms might not request a rate adjustment for many years.

Rate cases can be initiated by the regulated firm or the commission, and in some states and under certain circumstances, others can initiate rate cases as well. Besides the commissioners, commission staff, and the regulated company, other participants in a rate case may include advocates for large and small consumers, environmental groups, and other "intervenors." Commissions conduct other types of hearings and investigations besides rate cases to consider commission procedures or possible rule changes, certificate applications, utility asset transfers, and other matters.

4. THE REVENUE REQUIREMENT FORMULA

From a purely functional and operational viewpoint, at the heart of traditional regulation is a deceptively simple formula—the revenue requirement formula. The revenue requirement is an approximation of the regulated company's total expenses to provide service to its customers and can be written as follows:

Revenue Requirement
= Operating and Maintenance Expenses
+ Depreciation and Amortization Expenses
+ Taxes
+ [Gross Property Value
− Accrued Depreciation]
× Allowed Rate of Return.

The part of the formula in brackets, gross property value minus accrued depreciation, is referred to as the rate base. Both the rate base and the rate of return are discussed in more detail in the next two sections. Operating expenses include wages, salaries, fuel, advertising, and regulatory costs. Also included are maintenance expenses, depreciation and amortization expenses, and federal, state, and local taxes. Expenses are also discussed later. The revenue requirement formula is designed to provide the regulated firm with an opportunity to recover its investments and expenses to serve its customers. Unfortunately, applying the formula is not just a matter of plugging in the numbers and getting the "correct" answer. Although the formula is straightforward, determining the value for each of the components has been shown, through decades of experience, to be a complex, contentious, and time-consuming task.

Before determining the value of each component, a "test year" or base period must be established. If a historic test year is used, as is most often the case, a 12-month period prior to the filing of the rate case is chosen. Alternatively, a future or forecasted test year, or a "rolling" test year, is used. In any case, the aim is to establish a representative sample of the utility's sales revenues as well as its expenses, taxes, and other costs to serve its customers.

5. RATE BASE

The rate base measures the total value of the firm's property, including plant, equipment, material, supplies, and cash, and may include fuel inventories. Excluded are accumulated depreciation, amortization, deferred taxes, and customer-provided capital. An average rate base for the test year is typically used rather than a value at the end of the test year.

Although all the components of the revenue requirement formula are often contested and argued during rate-making proceedings, the valuation method and what investments are to be allowed in the rate base have been the most contentious and litigious part of the formula over the years. This is because the determination of the size of the rate base often involves large investments that have a significant impact on rates and because a certain amount of subjective opinion and discretion is used to determine it.

The methods and procedures developed over the years to determine rate base value exemplify the fact that traditional regulation is based largely on case law and legal precedent. Before 1900, regulation was price based and set by legislatures or by franchise bargaining by municipalities with companies more often than it was based on the value of companies' properties. In an early and important case in regulatory law, *Munn v. Illinois* (1877), the Supreme Court suggested that although private property cannot be taken away without due process, legislatures can change the law. If there are "abuses by legislatures," the solution was for "the people [to] resort to the polls, not to the courts." This left the matter of regulation to be decided by legislatures and not the courts. The *Munn* case marked the beginning of the regulation of private property held by businesses that are "affected with a public interest," a phrase cited by the Supreme Court with an origin back in 17th-century British common law. Although many of the businesses that were regulated during the 19th and early 20th centuries are no longer regulated or have since faded away (e.g., bakers, innkeepers, milk and ice delivery services), the basis of electric utility regulation still used today by most states has its origins back in the case law that formed the public utility concept.

The judicial noninvolvement of *Munn* was clearly set aside in 1898 by the Supreme Court's decision in *Smyth v. Ames*. In the *Smyth* case, the court laid out its idea as to how utility property should be valued as follows: "The basis of all calculations as to the reasonableness of rates to be charged by a corporation … must be the fair value of the property being used by it for the convenience of the public." Originally, the court had in mind six specific measures of value and allowed for others as well.

This marked the beginning of the "fair value" doctrine. This case was used as a means to determine the rate base for nearly a half-century. Subsequent cases clarified what was meant by fair value. What was upheld by the courts was that fair value was to be defined as either original cost (i.e., the amount actually paid for installing the plant and equipment less accumulated depreciation plus improvements) or reproduction cost (i.e., the cost of plant and equipment estimated at market price levels prevailing at the date of valuation less depreciation).

For the railroad company at the time of *Smyth,* the original cost was higher than the reproduction cost because the investments were made during and just after the Civil War when costs were higher than during the 1890s. The state of Nebraska, represented by William Jennings Bryan, advocated the lower reproduction value. The Supreme Court generally also favored reproduction cost valuation around the turn of the 20th century because of the difficulty in determining original cost (due to different accounting practices and possible fraud). Later, during periods of inflation, positions changed whereby companies supported a reproduction cost standard while regulators and consumer representatives advocated original cost. The principle of reproduction cost remained firmly in place with a majority in the Supreme Court through the late 1920s.

According to Emery Troxel, "the inexact, variable, and sometime inexplicable meaning of fair property value" made determining rate base value extremely difficult. The subjective nature if the calculations inevitably led to the various interested parties coming up with values that differed widely. In an important judicial turning point, Justice Louis D. Brandeis wrote a separate concurring opinion (together with Justice Holmes) in *Missouri ex rel. Southwestern Bell Telephone Co. v. Missouri Public Service Commission* in 1923 that began the move away from reproduction cost. Brandeis stated that he believed that *Smyth v. Ames* was "legally and economically unsound" and that using this method was a "laborious and baffling task."

But it was not until 1944 that the Supreme Court deemphasized the importance of finding a rate base value and the valuing methodology and placed more emphasis on the "end result" of a commission's decision. In *Federal Power Commission v. Hope Natural Gas Co.,* the Supreme Court stated,

> *It is not theory but the impact of the rate order which counts. If the total effect of the rate order cannot be said to be unjust and unreasonable, judicial inquiry under the [Natural Gas] Act is at an end. The fact that the method employed to reach that result may contain infirmities is not then important. … Rates which enable the company to operate successfully, to maintain its financial integrity, to attract capital, and to compensate its investors for the risks assumed certainly cannot be condemned as invalid, even though they might produce only a meager return on the so-called "fair value" rate base.*

In other words, the focus should be on the "end result," not on the specific property of the utility or on a rate base valuation formula. This allowed state and federal regulatory authorities the discretion to also use an original cost standard based on "prudent investment," that is, original cost minus fraudulent, unwise, or extravagant expenditures. The *Hope Natural Gas* case had the effect of changing the emphasis from rate base valuation methodology to return on investment.

To be included in the rate base, the investment must be both "prudent" and "used and useful" to the customers being served. The prudent investment test or standard establishes that costs that were reasonable at the time they were incurred, and given the circumstances and what was known or knowable at the time, are to be included in the firm's rates. This provides the utility with an opportunity to recover these costs. Capital costs are recoverable along with a reasonable return on equity. Reasonably incurred operating costs are also included in the revenue requirement. In general, investments and expenditures have a "rebuttable presumption" that they are prudent when incurred; that is, they are presumed to be prudent unless it can be demonstrated otherwise. Regulators can consider cases of "hidden" imprudence, even if the investments or expenditures are already in the rate base, but are required to consider what was known or knowable at the time the decision was made; in other words, there should be no "Monday morning quarterbacking."

The used and useful test is a much older test established in law. This test holds that utility investments and expenditures must be used and useful to the customers the company serves to be included in the firm's rate base. Also, investments that are no longer used and useful to the public because they are either technologically or economically obsolete can be excluded from the rate base. The used and useful test is intended to prevent a regulated company from deliberately overinvesting in plant and equipment to inflate the rate base and to discourage a utility's investment in assets that will not provide a tangible useful service to its customers. Investments that were once determined to be not

used or useful and were excluded from the rate base may later be allowed in the rate base if conditions change. An example would be if a utility's sales have increased since the last rate case such that additional capacity is needed to serve the customers. In such a case, it may be determined that a previous investment that was excluded from the rate base is now used and useful and should be included in the recalculated rate base.

An additional controversial issue in the determination of the company's rate base is the treatment of plant under construction or "construction work in progress" (CWIP). An issue is how much, if any, of CWIP should be included in the rate base calculation. This treatment of plant under construction, which for electric utilities can be considerable relative to the size of the firm, varies by jurisdiction. Factors that regulatory authorities use to decide whether to add CWIP to the rate base include whether the completion date is near for the work under construction, the project is of a short duration, the company's investment is relatively significant so that excluding it could impair the financial health of the company and its ability to raise capital, the construction project is for a certain type of investment (e.g., pollution control equipment), and the interest charges would be a large portion of the company's earnings. Some jurisdictions will not allow CWIP in the company's rate base at all because, consistent with the used and useful standard, they believe that current rate payers should pay only for facilities that are currently in use for public service. A related and historically older mechanism that state commissions have often used is the "allowance for funds used during construction" (AFUDC), which provides for recovery of the cost of capital for plant under construction once that plant is in service. Because AFUDC was not recovered from customers until the plant was in service, it has been generally regarded as less controversial than CWIP, particularly when the construction costs were viewed as not being excessively burdensome.

In summary, *Munn v. Illinois* laid the constitutional foundation for the regulation of businesses that are "affected with a public interest" such as electric utilities. *Smyth v. Ames* began more judicial involvement and efforts to establish reasonable rates based on fair value. Finally, *Federal Power Commission v. Hope Natural Gas Co.* switched the emphasis from finding a rate base value and the valuing methodology to the importance of obtaining a fair and reasonable end result of the regulatory process.

6. RATE OF RETURN

Alfred Kahn points out that every part of the regulatory process determines the level of allowed earnings for the regulated company. The regulated company's earnings are affected by what investments are included in the rate base, the allowed depreciation methodology, what expenses are allowed to be recovered, and the timing of the recovery, among other factors. But when the commission determines the allowed rate of return, it is explicitly determining the return on the company's property used to serve the public. Kahn noted, as observed by the Supreme Court in the *Hope Natural Gas* case, that there is no scientifically correct allowed rate of return. Commissions must exercise their judgment to determine a "zone of reasonableness," again applying the just and reasonable standard and balancing utility shareholder rights with protecting the public from monopoly abuses.

When a regulatory authority sets the company's allowed rate of return, the authority is determining the return that the utility will be allowed to earn on the rate base, beyond the operating costs and expenses that the company is also allowed to recover. This provides the utility with an opportunity to earn the allowed return, but it does not guarantee such a return. Because conditions (e.g., utility sales) may be different from what was assumed for the test year when the rate of return was set by regulators, the actual return earned by the utility may be different. The utility is not protected from losses due to mismanagement or adverse business conditions. The allowed rate of return refers to the percentage return on the rate base the regulator approves, which may be different from the rate of return received by investors or the utility from the total investment of the utility. Return refers to the total dollars that the utility receives or that investors receive in interest and earnings. In general, there is no provision for retroactive rate making, that is, making up for returns that were allowed but were not received by the utility.

The case law history again played a significant role in determining the method of setting the rate of return. An early and influential case was *Bluefield Water Works & Improvement Co. v. Public Service Commission of West Virginia* from 1923, when the Supreme Court outlined the major elements that regulators have considered over the years when determining rate of return. These elements include that (1) the return should be "reasonably sufficient" to maintain the financial soundness of the utility; (2)

the return should be adequate to maintain the company's credit sufficiently to allow it to raise money necessary for public service, assuming the company is operated efficiently; and (3) the utility should be allowed to earn a return on the value of the property dedicated to public service comparable to that being made on similar investments in unregulated businesses with similar risks, but it is not entitled to earn profits in excess of that. On this last point, the court stated that a public utility "has no constitutional right to profits such as are realized or anticipated in highly profitable enterprises or speculative ventures." The court also noted that a "rate of return may be reasonable at one time and become too high or too low" due to changing financial and business conditions.

In summary, the legal standard is that rate of return should not be confiscatory; rather; it should justly, but not excessively, compensate the utility for use of the shareholders' property. The company is obligated to operate efficiently, invest prudently, and control expenses reasonably. Again, when considering these factors, the regulatory authority attempts to balance the interests of the company's investors with those of the rate payers.

In terms of economic theory, the company should be allowed to earn a "normal" profit, that is, what it could earn on its investments if it were a business with similar risk and capital structure in a competitive industry. This should allow sufficient return on investment so that the utility can compensate its investors for the use of their money, that is, the investors' "opportunity cost."

A utility's actual return to its investors and its cost of capital are determined by financial markets. An investor's return is the sum of the yield of a security (stocks or bonds) and the growth (or loss) of that security. Both yield and growth are dependent on the security's price, which may change each regular business day in the financial markets. If a utility is perceived to be more risky because, for example, investors believe that the firm is less likely to maintain its dividend, the price of its stock will decline. In such a case, investors who hold the utility's stocks or bonds lose part of their investment (on paper at least). The expected return on such an investment increases, and new investors now require an additional risk premium to become or remain investors in the firm. Overall, investments of similar risk will be priced in financial markets to have equivalent expected returns to investors. For example, if something occurs that lowers risk, a security's price will rise, thereby decreasing its yield. Conversely, if risk increases, the price will fall and the yield will increase.

Traditionally, from an investor's standpoint, electric utility stocks and bonds have been considered "quasi-fixed income" securities. Their traditional monopoly status and relatively inelastic demand meant that they were a relatively safe and a steady income source. Growth potential was not the main reason why investors purchased these investments. In general, it was viewed that there was limited opportunity for growth either within or outside the utility's service territory but that the risk of a loss was low as well. This view has changed as the industry is being transformed into a more competitive structure. However, when and where traditional regulation is applied, investor service and rating agencies observe and analyze carefully the results of the regulatory process and how the regulated companies are treated. A key factor they watch is where the allowed rate of return is set.

Leonard Hyman traced historical rates of return and found that between 1915 and 1929 they were in the range of 7 to 8%. During the Depression years of the 1930s, they dropped to the range of 5.5 to 6.0% and remained there until the mid-1960s. After the mid-1960s, because of rising interest rates and inflation, rates of return rose and peaked during the late 1970s and early 1980s. It is not always clear how commissions determined rates of return early on; perhaps they were using prevailing business and interest rates of the time. During the latter half of the 20th century, it became more common for commissions to base the rate of return on the utility's cost of capital.

Table I illustrates how the cost of capital can be determined. Assuming a capital structure of 50% debt and 50% equity (weighted for preferred and common equity), where the utility raises $500,000 from borrowing at 4.0% and another $500,000 at 6.0% from equity, the weighted cost of capital would be 5.0%. In practice, determining the cost of debt and preferred stock is relatively easy because the interest rate on debt and preferred dividends are fixed. However, determining the return on common equity is not so straightforward and has had the affect of increasing the complexity of determining an allowed rate of return considerably. Because common equity is usually a significant part of an electric utility's capital structure, it is important to gauge the return on common equity as accurately as possible.

Hyman described four methods used to estimate return on the common stock equity. First is the comparable earnings method, which is based on

TABLE I

Debt	500,000	4.0	20,000

returns on equity of comparable businesses in terms of risk and capital structure. Among the limitations to this approach are that it is difficult to reach an agreement on a sample distribution of comparable companies and that the results are dependent on the selection of companies picked by the interested party in the case. The second approach is the discounted cash flow technique, which is an attempt to objectively estimate a market cost of capital. This is based on the premise that the price of a common share equals the present value of the sum of all future income to be received from the share. This method also has limitations that stem from assumptions used in the estimation. A third approach is the capital asset pricing model. This method divides the return on investment into a risk-free return and an added return for risk and attempts to estimate investors' expectations of a future return from the past performance of stocks with similar characteristics. The fourth method is a group of three financial integrity approaches: (1) set a return to produce a necessary interest coverage ratio, (2) provide equity with a return set at a fixed amount above current debt costs, and (3) provide a return on equity designed to keep the common stock price at or slightly above book value.

These approaches used to determine the rate of return are complex and vary widely by jurisdiction. In actual practice, there are wide gaps among the theory of how rate of return should be determined, opinions on how it should be done, and what in practice is actually done. It is widely recognized that although regulatory authorities may use information from the four methods or other approaches to help inform them of the cost of capital, they still must rely on discretion and judgment, guided by the extensive legal history, to decide on a just and reasonable rate of return within a zone of reasonableness. This explains why the process of determining a rate of return has been described as more like informed conjecturing than like exact science.

7. EXPENSES

As described previously, the total revenue requirements calculation also includes operating and maintenance expenses, annual depreciation expense accrual, income taxes, and other taxes. For electric utilities, fuel and purchased power are typically the largest expenses. A problem with establishing a representative or historic test year is that it is likely that conditions will change, particularly during periods of inflation or fuel cost changes. Of course, changes can either increase or decrease the utility's cost of service. When the utility's earnings decline and it is unable to earn the allowed return on investment, this is referred to as attrition. To remedy this, states may use attrition allowances or use a partially forecasted test year to adjust the rate base or expenses.

Some expenses, such as fuel costs, are nearly certain to change and are very difficult to forecast with any accuracy. This became especially apparent during the rapidly increasing fuel price increases of the 1970s. As a result, most states use automatic adjustment mechanisms that periodically adjust companies' fuel expenses and rates. This allows a utility to recover increased fuel costs without having to go through the time-consuming process of a full rate case. Other expenses have been added to the adjustment mechanism over time, for example, for recovery of purchased power costs.

8. COST ALLOCATION AND RATE DESIGN

Once the total revenue requirement has been determined, the rates charged for each customer class are derived through a two-part process of cost allocation and rate design. The first part allocates the cost of service for each customer class, usually through a cost-of-service study. Customers with

similar patterns of use are grouped into customer classes. For electric service, the general customer classes are residential, business (commercial and industrial), lighting, and miscellaneous. Each general class is often also divided into subclasses. Examples include standard residential service, residential with electric space heating, and small and large industrial and commercial classes. Electric utilities in the United States typically have one to two dozen or more customer tariffs for each subclass with optional service categories such as interruptible, time of use, conservation, or other special rates. A guiding principle of cost allocation is that the rates customers pay should correspond with the costs of serving those customers.

The next step is to design the individual rates for each customer class to provide the utility with an opportunity to collect the authorized revenue requirement. Electric utilities typically have three main components of the customer's rate (often called a rate schedule) for each customer category. First are customer charges that are for costs incurred to serve the customer independent of the amount used such as metering equipment, meter reading, billing, and distribution line. Customer costs vary not by the amount for power used but by the type of customer; these charges are usually expressed in dollars per meter per month. Second are demand charges that are for the fixed costs of plant and equipment capacity needed to meet the customers' maximum or peak demand, usually calculated in terms of kilowatts per month. Third are energy charges that are intended to recover the cost of operation and that vary with the amount of power used such as fuel, labor, and materials. Energy charges are usually in cents per kilowatt-hour and are often seasonal, that is, higher during the summer when demand is higher and power plants with higher operating costs are used to meet demand. Additional charges may be added for an automatic fuel adjustment, conservation or renewable program cost, federal- or state-mandated environmental equipment cost, and/or commission-approved or -mandated programs for low-income household assistance.

The rate schedule will vary by customer class and specifies rates by season, volume use, any discounts, and any additional charges. Seasonal rates are usually used to allow higher prices during the summer (for summer-peaking utilities, e.g., June through September). A uniform rate applies a constant energy charge no matter how much is consumed. If the per unit energy charge falls as quantity consumed increases, this is a declining- or decreasing-block rate (e.g., the first 600 kilowatt-hours per month are 6 cents per hour and each additional kilowatt-hour is 5 cents per hour). Finally, with an increasing-block rate structure, the per unit rate increases as quantity consumed increases.

James C. Bonbright outlined eight "criteria of a sound rate structure" that identify desirable characteristics that regulators have used, or at least should use, to develop rate structures. These criteria were described by Charles Phillips as follows:

1. The related "practical" attributes of simplicity, understandability, public acceptability, and feasibility of application
2. Freedom from controversies as to proper interpretation
3. Effectiveness in yielding total revenue requirements under the fair return standard
4. Revenue stability from year to year
5. Stability of the rates themselves, with a minimum of unexpected changes seriously adverse to existing customers
6. Fairness of the specific rates in the apportionment of total costs of service among the various consumers
7. Avoidance of "undue discrimination" in rate relationships
8. Efficiency of the rate classes and rate blocks in discouraging wasteful use of service while promoting all justified types and amounts of use (a) in the control of the total amounts of service supplied by the company and (b) in the control of the relative uses of alternative types of service (e.g., on-peak vs off-peak electricity)

These principles are widely accepted and used by regulators as guidelines for developing a rate structure. Phillips noted that these principles are broad and ambiguous but are of value because, as Bonbright noted, they are useful for reminding regulators of considerations that might be neglected and for suggesting reasons why practical rate design does not "readily yield to 'scientific' principles of optimum pricing." As with determining the allowed rate of return and other decisions, regulators must again rely on their informed judgment when designing the rate structure.

9. LIMITATIONS OF THE TRADITIONAL APPROACH

Many observers would argue that traditional or cost-based regulation has performed satisfactorily under

many different conditions in terms of cost to consumers, reliability of service, and determining a "fair" outcome. This form of regulation was shown to be adaptable and able to deal with a wide range of crises and challenges placed before it over nearly a century of experience. However, it has come under intense criticism from many observers. One of the more common and persistent limitations pointed out by critics is the lack of incentive a utility has to minimize and control its cost under a cost-based system of regulation. Regulators can attempt to oversee and scrutinize the utility's management and operation of its system, but they cannot possibly impose the same level of cost control that competitive pressures exert on a competitive firm. Other criticisms include the relatively high administrative cost (from being overly cumbersome, legalistic, and bureaucratic), the lack of incentive for a regulated utility to use innovative technologies or rate structures, and the tendency for the utility to attempt to overcapitalize in rate base investments under certain conditions.

In response to these criticisms, regulators have been introducing more incentive- or performance-based mechanisms to ameliorate the reduced incentive to control costs under traditional regulation. The idea of introducing stronger incentives into the regulatory process is not new. For example, the used and useful and prudent investment standards were designed to induce more cost control in utility investments. During more recent years, regulators have used commission-ordered company audits, performance incentives to induce increased plant efficiency, industry benchmarking standards to compare a utility's performance with that of other utilities, price cap regulation that sets rates for several years (with annual productivity and inflation adjustments) and allows the utility to retain any gain (or loss) from improved cost efficiency, and profit-sharing arrangements based on performance.

Much of the electric supply industry's attention recently has been placed on the restructuring of the industry to increase competition in wholesale and (in some states) retail markets. However, traditional regulation continues to be an important regulatory tool. Currently, most states continue to use traditional or cost-based regulation for all electric utility services and will likely continue to do so for the foreseeable future. States that have changed to retail access, allowing retail customers to choose their suppliers, have abandoned cost-based regulation for generation service but will likely continue to use cost-based methods for the distribution services offered by their local distribution utilities.

10. SUMMARY AND CONCLUSIONS

It was recognized that under traditional monopoly franchise regulation and rate making, electric utilities and other regulated companies were subject to a regulatory compact or, as Justice Holmes referred to it in 1912, a "bargain." Based on historical case law and more than a century of development and change, this compact can be summarized as the careful balance between compensatory rates and confiscation of utility property that provides a utility with an opportunity to earn a reasonable return on its investment in exchange for providing safe and reliable power at reasonable cost to all customers who request service. This opportunity is held in check by the used and useful and prudent investment tests as well as by competition from government ownership, fuel substitutes, self-generation, and (more recently) incentive- or performance-based rates and competition from other suppliers. This compact has been rebalanced occasionally to accommodate changing conditions in the industry from economic impacts and technological change. Over decades, state and federal commissions have developed procedures to implement the laws passed and have refined the regulatory mechanisms to determine what investment and operating costs should be recovered, set a return that the regulated company should be allowed to earn on its property, and determine rates for consumers. State and federal commissions have used incentive- and performance-based mechanisms to improve operating efficiency and investment decisions. The recent move to competition for generation nationally and by some states notwithstanding, many aspects of traditional regulation are still in use by most states and will continue to be used for the noncompetitive segments of the industry, such as transmission and distribution services, for the foreseeable future.

adequacy The ability of the electric systems to supply the aggregate electrical demand and energy requirements of their customers at all times, taking into account scheduled and reasonably expected unscheduled outages of system elements.

bulk electric system The part of the system that encompasses the electrical generation resources, transmission lines, interconnections with neighboring systems, and associated equipment, generally operated at voltages of 110 kV or higher.

distribution system The part of the power system that functions to move electric energy from the bulk supply points to individual consumers.

embedded generation The generation sources that feed into middle- or low-voltage distribution networks.

generation system The part of the power system that functions to convert different forms of primary energy in electric energy.

reliability The ability of a technical system to perform its function properly, for the period of time intended, under the operating conditions intended.

restructuring The transformation process of the electric power industry, from vertically integrated monopoly utilities to market-oriented structures.

security The ability of electric systems to withstand sudden disturbances, such as electric short-circuits or unanticipated loss of system elements.

transmission system The part of the power system that functions to transport electric energy from generation points to bulk supply points.

Power system reliability is the field of engineering devoted to assessing the adequacy and security of power systems. Adequacy is defined as the ability to meet the aggregate electrical demand and energy requirements of customers at all times, taking into account scheduled and reasonably expected unscheduled outages of system elements. Security is the ability of electric systems to withstand sudden disturbances. It is generally understood that adequacy assessment involves steady-state consideration of the systems, whereas security assessment must include analysis of the dynamic system behavior following disturbances. This article deals with the problem of bulk power system adequacy assessment, involving both transmission and generation systems.

1. INTRODUCTION

The behavior of technical systems is conditioned by internal and external factors, many of them of stochastic nature, that can lead to system failure. In order to evaluate the reliability of a system, possible system states should be identified, the ability of the system to perform its function in each of these states should be analyzed, and probabilistic measures about the occurrence of system states should be calculated. The function of a power system is to supply consumers with electric energy economically, at any time and location, observing reliability and quality standards. The practical economic impossibility to store significant amounts of electric energy implies that a balance between generation and load, including network losses, must be maintained at all points in time.

According to the North American Electric Reliability Council, the reliability of the interconnected bulk

electric systems is defined through adequacy and security. Both adequacy and security are affected by stochastic events. It is generally understood that adequacy assessment involves steady-state consideration of systems, and that security assessment must include the treatment of the dynamic system behavior following disturbances. Tools for adequacy assessment, based on probabilistic procedures combined with methods for steady-state power system analysis, involve the solution of large nonlinear equation systems. The analysis of power system security requires that sets of differential equations describing the dynamic system behavior be solved. Even considering the powerful computers available today, the combination of dynamic analysis with probabilistic procedures leads to very time-consuming calculations. Generally, security analysis of power systems is carried out within a very short time frame after a disturbance, disregarding the possibility of multiple independent events.

The typical structure of a power system includes the subsystem generation, transmission, and distribution components. Generation and transmission affect bulk power system reliability and are the focus here. The most important types of studies of bulk power system reliability involve generation system reliability and composite-generation and transmission-power system reliability.

During the last 20 years of the 20th century, the industry of electric power supply underwent a great structural transformation, going from a regulated, vertically integrated monopoly to a more competitive industry that is thought to be better suited to provide service more efficiently. The ongoing restructuring process, however, adopting different structures in different regions, generally involves privatization and unbundling of generation, transmission, distribution, and retail activities. The change of paradigm in the electric industry, from minimizing total system costs to maximizing system-participant profits, can strongly affect system reliability. Because most of the tools for reliability assessment currently in use have been adapted from those developed for vertically integrated systems, it is relevant to question the impact of change on reliability.

2. GENERATION SYSTEM RELIABILITY EVALUATION

The aim of generation system reliability calculations is to find the generation capacity needed to achieve a desired (often called optimal) reliability level. Because electricity cannot be stored economically in large quantities, uncertainties affect the amount of load to be supplied, and components are subject to unscheduled outages, it is necessary to have generation reserve for a reliable service.

A first approach in generation reliability evaluation assumes that network components are substantially more reliable, compared to generation units, and that those networks have enough redundancy. In this context, a fundamental simplification can be made, assuming that power can be moved unconstrained from suppliers to consumers.

2.1 Reliability Criteria and Indexes

The optimal reliability level can be obtained, minimizing the total cost, including reserve and outage costs. With increasing reserve, the utility costs will increase due to the investments needed and the outage costs will decrease, and vice versa. The actual determination of the optimal reliability level requires knowledge of outage costs. This is problematic because it involves both objective measurable quantities and subjective perceptions of customers. Generally, the reliability level to be maintained is determined on the basis of estimation of outage costs by regulatory agencies, which set planning and operation standards to guarantee quality, reliability, and security of the service.

Historically, deterministic criteria, such as a percentage of the peak load or the capacity of the largest unit dispatched, were used to define generation reserve requirements. Then, probabilistic criteria were developed and implemented to take into account the stochastic nature of factors affecting reliability. One of the most widely used reliability indexes for generation systems is loss-of-load probability (LOLP), which is the probability of the customer load being greater than the available generation capacity. Other well-known reliability indexes are loss-of-load expectation (LOLE), generally given in number of days per year on which the peak load is expected to exceed the available generating capacity, and expected energy not served (EENS), which gives the expected megawatt-hours not supplied due to capacity shortages in a given time unit (a year, for example).

2.2 Reliability Calculation

The first step in reliability evaluation of generation systems is the modeling of the stochastic behavior of generation units. Many different generator models for reliability studies have been developed, varying in

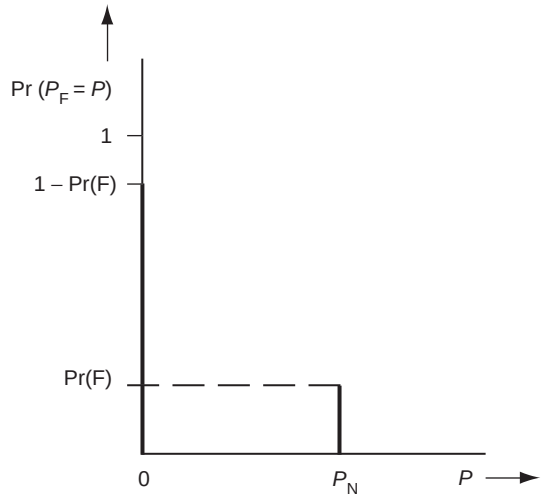

FIGURE 1 Simplified two-state generator model.

the degree of sophistication to describe the actual behavior of generating units. From the system viewpoint, it is important to identify those generator states in which reserve is needed because the generator is not able to supply load. These states can be combined to form the failure state, obtaining a two-state generator model such as the one depicted in Fig. 1. Given the failure probability function $\mathrm{Pr}_i(\mathrm{F})$ of each generator i in the system and assuming independent behavior of generators, the cumulative probability function of unavailable capacity, $\mathrm{F_F}(P) = \mathrm{Pr}(P_\mathrm{F} \geq P)$, can be calculated through simple convolution of the probability functions of all generators in the system. Figure 2 shows the qualitative form of the function $\mathrm{F_F}(P)$.

The reserve capacity P_R of a generation system is defined as the difference between installed generation capacity and maximum load to be supplied. For a given value of P_R, LOLP can be calculated as the value of $\mathrm{F_F}(P)$ for $P = P_\mathrm{R}$ (Fig. 2). According to its definition, LOLP is the probability that the system cannot fully supply the customer load. This happens when the outage capacity exceeds the available reserve. Because the load is known only as a forecast value, it should be modeled through a probability distribution. Usually a normal distribution with mean equal to the forecast value is used. Assuming independence of generation and load, the probability function describing the stochastic load behavior can be included in the convolution calculation to evaluate the function $\mathrm{F_F}(P)$. On the other hand, if a maximum acceptable value of LOLP, called here $\mathrm{LOLP_{max}}$, is given, the generation reserve, P_Rn, needed to achieve the reliability level defined through $\mathrm{LOLP_{max}}$ can be obtained as indicated in Fig. 2. With the exception of the simpler, deterministic approaches, this is probably the most common methodology used by system operators to calculate generation reserve requirements.

LOLE is determined as the annual average value of LOLP calculated for each daily peak load in the year, multiplied by the number of days in the year. The weakness of the indexes LOLP and LOLE is that they do not give any information about the severity of a failure. The index EENS overcomes this problem, encompassing probability and severity of the failure, and can be calculated using the yearly load duration curve shown in Fig. 3. For each value of available generation capacity $P_\mathrm{A} = P_i$, with probability $\mathrm{Pr}(P_\mathrm{A} = P_i)$, there is an energy deficit value, $E_{\mathrm{d}i}$, such that

$$\mathrm{EENS} = \sum_i E_{\mathrm{d}i} \cdot \mathrm{r}(P_A = P_i).$$

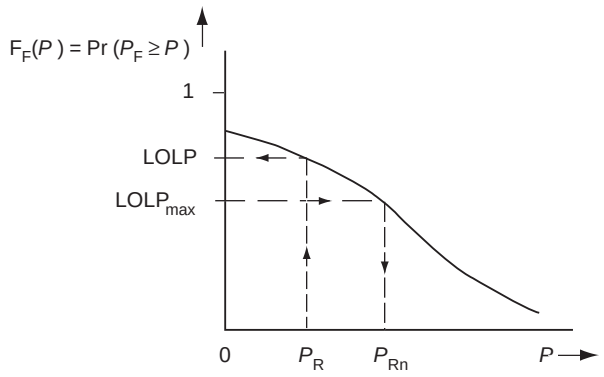

FIGURE 2 Loss-of-load probability and reserve requirement calculation.

2.3 Embedded Generation

An increasing concern about environmental issues has led many governments to establish incentives for

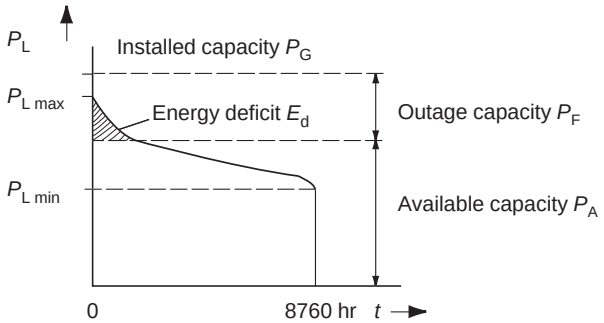

FIGURE 3 Calculation of expected energy not supplied.

clean generation using renewable energy sources such as sun or wind. Unlike large conventional generation units, small solar or wind generators often feed into the distribution networks, creating a completely new set of problems. However, reliability studies of systems with sizable participation of embedded generation should consider this type of generation. Even when network constraints are neglected, typical in reliability evaluation of generation systems, some new problems arise: (1) prediction of embedded generation output is no easy task because often embedded generation is not dispatched by the system operator; (2) primary sources, especially wind, are highly variable and difficult to forecast; (3) there are dependencies in the behavior of generators, and loads are correlated with the availability of primary energy sources, notably the sun; and (4) frequently, distributed generators are not permitted to generate if the distribution network they are feeding into is disconnected from the bulk power system. Although some efforts have been made in order to overcome these problems, further work is needed to develop models that properly consider the contribution of embedded generation in reliability studies of generation systems.

3. COMPOSITE GENERATION AND TRANSMISSION RELIABILITY

Generation systems without the constraints that originate in transmission networks connecting generation with load points were considered in the previous section. Because actual transmission systems are not 100% reliable and have limited transport capacity, reliability evaluation of bulk power supply requires consideration of both generation systems and transmission networks. The distribution of power flows in the transport network follows Kirchoff's laws, which, together with network impedances, generator outputs, and bulk supply point loads, determine the loading of each transmission line in the system and the nodal voltages. A load flow model, one of the most powerful tools for power systems analysis, allows the calculation of voltages and load flows in transmission networks.

The function of the composite system is to generate enough energy to satisfy the load and to transport it to the supply points. As already stated, reliability analysis includes adequacy and security evaluation. Security evaluation requires analysis of the dynamic behavior of a system when disturbances lead to changes of the system state. Although the subject of intense research, probabilistic assessment of the dynamic behavior of power systems has not yet reached the maturity needed for successful implementation in real power systems. Adequacy studies analyze power system states from a steady-state viewpoint using a load flow model. A system state will be termed adequate whenever it has enough generation available to supply the customer load fully and has the ability to transport the energy from the generating plants to the supply points, observing voltage and thermal limits. Dynamic constraints are often taken into account indirectly through reduction of transmission line transport capacity limits on the basis of stability considerations.

3.1 The $(n-1)$ Criterion

The most frequently used approach to assess adequacy of transmission and composite systems is the so-called $(n-1)$ criterion, which states that a system must be able to withstand any single contingency without affecting functionality. Using load flow calculations, all system states, including one major component (generator, line, or transformer) forced out of service, are examined. If the system load is fully supplied, satisfying all constraints (including active and reactive generation limits, nodal voltages, and thermal or stability capacity limits), the considered state is deemed adequate. Otherwise, the state is considered inadequate. Then, reinforcements are proposed until all $(n-1)$ states fulfill the adequacy criterion.

The appeal of the $(n-1)$ criterion derives from its simplicity. The $(n-1)$ criterion is also the most frequently used approach to composite systems security analysis. Replacing the steady-state load flow analysis of each $(n-1)$ state by a dynamic behavior analysis following each possible single failure of the system, the system states can be classified as secure, when all constraints are satisfied, or insecure otherwise.

The weakness of the $(n-1)$ approach to composite system adequacy assessment is that it considers neither the probability of the analyzed states nor the magnitude of the problem in case of inadequate states. It must be pointed out that the $(n-1)$ criterion neglects all multiple contingencies regardless of their probabilities. An extension of the approach to consider multiple contingency states and the introduction of load point-related, individual component-related, and system wide reliability indexes help to overcome these problems. Regarding the

severity of the problems, the $(n-1)$ criterion can be extended to consider a more detailed classification of the system states: (1) a system state with fully supplied load, no constraint violations, and fulfilling the $(n-1)$ criterion is termed the normal state; (2) when the load is fully supplied, no constraint is violated but the $(n-1)$ criterion is not fulfilled, the state is called the alert state; (3) if the load is fully supplied but there are constraint violations, the system state is designated as an emergency state; and (4) any state with load curtailment is called an extreme emergency state. Probabilistic indexes can be calculated for each of these states.

3.2 Reliability Indexes

System-wide reliability indexes reflect the average adequacy of the composite system but do not give any information about reliability as observed at individual bulk supply points. Therefore, it is important to use a combination of both system-wide and supply point-related indexes to describe the reliability of composite power systems. A variety of different indexes have been proposed, including probability, frequency, and duration of failures, load not supplied, energy curtailed, etc. Only a few of them are presented in Table I as examples of often used reliability indexes. For each specific reliability study, the more appropriate reliability indexes should be selected.

Probability indexes can be calculated for a given load state, as in the case of the index LOLP in the previous section, or as average values for a given time period, as in the case of LOLE. It is obvious that energy-not-supplied indexes require the consideration of a certain time period. Because the load state of a power system changes with time, leading to changes in the generation units scheduled to supply load and in the network state, any calculation of average reliability indexes requires definition and analysis of representative load states for the time period of interest.

TABLE I

Reliability Indexes

System-wide indexes	Supply-point or component-related indexes
Probability of failing to fully supply the system load satisfying all technical constraints	Probability of failing to fully supply the load at a given bulk supply point
Probability of any capacity limit violation	Probability of capacity limit violation for a given component
Probability of any voltage limit violation	Probability of voltage limits violation at a given network node
Expected energy not supplied for the whole system	Expected energy not supplied for a given load point

3.3 Reliability Calculation

There are six essential steps in the procedure for reliability evaluation of composite power systems.

3.3.1 Definition of Representative Load States To Be Considered

The question about the load states to be considered depends on the aim and scope of the study. If, for example, the probability of the system not being able to supply the load fully at a given point in time (usually the peak load) is desired, the load at that time point is to be considered. When the expected value of energy not supplied in a given time period is required, many load states representing the possible load conditions in that period must be studied.

3.3.2 Active and Reactive Power Dispatch

Once the load states are defined, it is necessary to schedule the operation of the generation system to supply the load. This has been done in the vertically integrated industry using well-known and generally accepted optimization methods. In the new competitive environment, generators submit to the Independent System Operator (ISO) bid prices at which they are willing to sell energy, and the ISO allocates the resources economically.

3.3.3 Load Flow Analysis

Given the loads and the generation scheduling, a load flow analysis is performed in order to verify compliance of technical constraints, such as transport capacity limits or supply point voltages.

3.3.4 Contingency Simulation

Contingency simulation is the heart of composite systems reliability evaluation and is based on a load flow model. It aims to find out the system states in which there are load curtailments, constraint violations, or both. The selection of the system states to be analyzed can be made using simulative or analytical techniques. Simulative techniques, usually called Monte Carlo methods, are based on the use of computer-generated random numbers to determine the state of each system component. Outages of

components with high failure rates are likely to be simulated more frequently, compared to outages of more reliable components. The simulation process produces a sample of the possible behavior of the system. Reliability indexes are calculated through statistical evaluation of this sample. The number of simulations required to obtain a representative sample can be calculated as a function of the desired accuracy of results.

In the analytical approach, the system states are enumerated, generally in an increasing order of contingency level, stopping either after a given contingency order or when the state probability falls below a given value. Power system components are very reliable, implying that for increasing contingency order, state probabilities rapidly become very small. For each system state, selected either through simulation or enumeration, probabilistic measures regarding its occurrence are calculated and a load flow analysis is performed to verify if any constraint is violated. In case of constraint violations, the procedure must mimic the operator behavior, determining and simulating the introduction of remedial actions. The impact of these corrective actions is then studied through a new load flow calculation. After all corrective possibilities for a given contingency state have been used, the remaining constraint violations determine that the analyzed state is a failure state.

3.3.5 Corrective Actions

The simulated corrective actions must reflect with reasonable accuracy the actual possibilities of the operator in a real system. The possibilities of the system operator include modification of active and reactive power dispatch and change of the network topology through connection or disconnection of transmission facilities. Optimization tools with the objective of operating cost minimization can easily include the possibility of changes in generation dispatch to satisfy technical constraints. It is not so easy to consider topology modifications because of the discrete nature of this problem. The most popular tool used by power engineers to obtain an economic dispatch considering network constraints is optimal power flow (OPF). OPF is an extension of the well-known simple economic dispatch (ED). The objective function of ED is minimization of generator operating costs subject to the constraints that generator output must be within technical limits for each generator and the total output of the dispatched generators must equal the system load, including transmission losses. OPF adds to the economic dispatch a set of alternating current (AC) power flow equations as equality constraints. The solution of the OPF problem is an operating plan with minimal costs and a complete load flow solution. A further development of OPF is the so-called security-constrained OPF, which introduces inequality constraints on power flows and voltages.

Security-constrained OPF allows the calculation of optimal corrections of active and reactive generation aimed to eliminate or mitigate violations of power flow or voltage constraints. Attempts are being made by researchers to develop accurate and robust procedures to determine corrective actions, including all possibilities available to system operators using different modeling approaches, such as expert systems or other artificial intelligence tools. The reliability indexes must reflect the constraint violations remaining after exhausting the possibilities regarding corrective actions.

3.3.6 Calculation of Reliability Indexes

Once the preceding five steps have been carried out, the system states selected through enumeration or simulation can be classified either in normal operative states or in problem states because the load is not fully satisfied or constraints are violated. For any specific class of adequacy deficiency, insufficient generation, or network violations, system-wide, component-, or node-related probabilistic measures such as probability, frequency, or duration can be calculated. The load flow analysis provides the results necessary to link these reliability parameters to the severity of the deficiency. For example, for a bulk supply point, probabilities can be calculated for states with load curtailment exceeding prespecified values.

4. ELECTRIC POWER INDUSTRY RESTRUCTURING AND RELIABILITY

Before successful restructuring in other industry branches led to significant changes in the electric power industry organization and structure, beginning in Chile in the early 1980s and then in Britain in 1988, the most common organizational forms of electricity supply were the state-owned monopoly and the monopoly franchise system with vertically integrated utilities. Reliability planning in these systems was done in similar ways. In state-owned monopoly systems, the supply duty is generally established by law, requiring that all customers are reliably supplied, with costs as low as possible. Because the whole system is owned by the state,

central planning, including generation and transmission, is the natural way to achieve high reliability while minimizing total costs. All necessary data are available to the power company and the problem is easily formulated as an optimization problem with total cost minimization as the objective function, subject to technical and reliability constraints. The reliability constraint is formulated as an inequality, requiring that a reliability index, typically loss-of-load probability or expected energy not supplied, does not exceed a prespecified limit.

A vertically integrated utility does its planning much in the same way as the state monopoly. In its geographically delimited concession region, the vertically integrated utility has to economically supply the customer demand subject to the same constraints as the state-owned monopoly. Reliability standards are set by the state through regulatory agencies and electricity prices to end consumers are regulated on the basis of audited costs and a guaranteed rate of return.

New generation technologies, notably high-efficiency gas-fueled combined cycle thermal plants, broke the notion that scale economies made electricity production a natural monopoly. This, combined with the fact that a regulated monopoly has little incentive to reduce its costs because any reduction is passed on to the consumers through adjustment of the regulated prices, and the success of deregulation in other industry branches, such as telecommunications and airlines, led to the movement toward restructuring in the power industry. On the other hand, there is a feeling that the high reliability standards used in the vertically integrated industry, state or private owned, have sometimes led to overcapacities that probably increase costs beyond the values consumers would be willing to pay for reliability.

In the new deregulated environment, there is no more central planning. Regarding generation investment, instead of central planning it is expected that economic signals will play a fundamental role in defining location, capacity, and time of investments. Concerning short-term operation, it is necessary to have a set of market rules such that reliability-related products can be commercialized in a more flexible and competitive way. It is expected that the adequacy of generation systems is a problem that can be properly addressed in a framework of competitive market rules, in both long-term planning and short-term operation.

Transmission systems are essentially different from generation systems due to the factual impossibility of direct competition. Because of the large investments required and the problems in finding new sites for high-voltage lines, transmission systems will continue to be seen as natural monopolies. How to assure reliability in the long term under the new industry environment is yet an open problem. Even though there is no consensus about the solution to this problem, currently there is an ongoing discussion about considering transmission as a sector that can be contemplated as a performance-based industry rather than a guaranteed rate-of-return industry. With this change in regulation plus the implementation of new transmission technologies such as flexible AC transmission systems (FACTS) and the acceptance of distributed generation, competition for some of the transmission reliability-associated products can be expected.

On the other hand, in the short term, for a given transmission network, the real questions are reserve requirement calculation and reserve allocation procedures. Adequacy problems derived from transmission bottlenecks or transmission failures lead to undesired supply interruptions and highly volatile prices. This problem is much more severe in cases in which demand plays a passive role. To be consistent with the aim of competition in power systems, procedures for reserve allocation should be able to consider explicitly reliability requirements submitted by the demand. Composite systems reliability analysis should be further developed on the basis of the fundamentals discussed here, with the aim to provide tools for proper reliability-related risk management for both system operator and market participants. The ISO needs reliability analysis tools to define the reserve requirements on the basis of the desired reliability level, and market participants need tools to be able to manage their exposure to dispatch risks for any kind of generation capacity. On the basis of this analysis, a market participant can optimize bids for energy and reserve on a portfolio basis.

Efforts to identify and quantitate possible health hazards of exposure to power frequency (50/60 Hz) magnetic fields include both epidemiology studies of human populations and hazard identification and mechanistic studies performed in experimental model systems. The results of these studies demonstrate that magnetic field exposure induces no systemic toxicity in humans or in experimental animals. Similarly, magnetic field exposure has no adverse effects on reproduction or fetal development in humans or in animal models that are commonly used for hazard identification. Magnetic fields do not induce mutations or chromosome damage in standard genetic toxicology test systems, and extensive studies in a wide range of animal models provide no clear evidence that magnetic field exposure is oncogenic in any test system. Epidemiology studies suggest a small increase (relative risk ≤ 2.0) in the risk of leukemia in children exposed to magnetic fields; this increase is not seen in other sites in children, or in any organ site in adults. Because no compelling biological mechanism has been identified through which magnetic fields may induce neoplasia or other adverse health effects, further studies are required to determine whether magnetic fields are causally linked to childhood leukemia.

1. INTRODUCTION

Over the past two decades, the possible relationship between human exposure to power frequency (50 and 60 Hz) electromagnetic fields (EMF) and adverse health outcomes has generated significant interest in both the scientific community and the general population. In the late 1970s and early 1980s, several epidemiology studies were published whose data suggested that adverse health effects may be seen in human populations receiving either occupational or environmental (i.e., residential) EMF exposures. Health effects associated with EMF in these studies included reproductive dysfunction, increased risk of birth defects and other developmental anomalies, and increased risk of cancer in several sites. These suggestive epidemiology data stimulated a large number of additional epidemiologic and experimental investigations, whose goals are to (1) confirm or refute the existence of specific health hazards of EMF exposure and (2) where such hazards are demonstrated to exist, identify EMF flux densities at which adverse health effects are observed, in order to quantify the risks of human exposure to EMF.

effects of EMF can be divided into three general categories:

1. Epidemiology studies, in which the risk of a disease is compared in human populations with different levels of EMF exposure
2. *In vivo* experimental studies (animal bioassays), in which the risk of disease is compared in groups of experimental animals with different levels of EMF exposure
3. Mechanistic studies, in which the effects of EMF exposure on biochemical, molecular, or other disease-associated end points are evaluated using experimental animals or *in vitro* model systems

Each category has important strengths and limitations that should be considered in the overall interpretation of EMF bioeffects data.

1.1 Strengths and Limitations of Epidemiology Studies of EMF

Clearly, the most important strength of epidemiology studies is that they are investigations of human responses to EMF exposure. As such, no interspecies extrapolations are required, and the EMF flux densities being investigated in epidemiology studies are, by definition, "real world." For these reasons, any observation of a strong positive association between EMF exposure and risk of a specific disease would provide compelling evidence of a relationship between the exposure and that adverse health effect. Conversely, however, epidemiology studies are limited in that they can only demonstrate associations between an exposure and disease risk. Epidemiology cannot provide conclusive demonstrations of causality: spurious associations may be identified in epidemiology studies, and weak causal associations may be missed due to limited statistical power.

A critical factor that must be assessed in the interpretation of EMF epidemiology studies is the accuracy and relevance of the exposure metric on which comparisons are based: Is the estimate of EMF exposure developed using (in order of decreasing desirability)

- Measurements of EMF flux densities to which an individual is actually exposed, as obtained by a personal dosimeter?
- Measurements of EMF flux densities present at a relevant location in the home or work site?
- Measurements of EMF flux densities made at a constant point outside of the home ("front door" measurements)?
- An imputed or calculated level of EMF exposure that is based on job classification, residential wire code, residential distance from a power line or substation, or other metric?

It has been demonstrated that EMF exposures that are measured or imputed using different strategies can vary substantially; more specifically, important criticisms have been raised concerning the accuracy of residential wire codes that have been used widely as a surrogate for residential EMF exposure levels and job title classifications that have been used as an estimator of occupational EMF exposures.

A parallel consideration is the temporal variability of EMF measurements: Does today's measurement of an EMF flux density in a house or other location provide an accurate estimate of the magnetic field environment that was present in the same location 5 years ago, 10 years ago, or at some other earlier time that is relevant to the etiology of the disease in question? Because EMF flux densities in any specific location can demonstrate considerable temporal variability, the ability of such measurements to support retrospective epidemiology studies remains an important issue.

1.2 Strengths and Limitations of Experimental Studies of EMF

The strengths and weaknesses of studies of the effects of EMF on disease induction in experimental animals are essentially opposite of those seen in epidemiology studies. Because animal bioassays are performed in a nonhuman test system, interspecies extrapolation of study data is required. In addition to possible species differences in response, field strengths studied in animal bioassays often greatly exceed those seen in human exposures and may thereby induce artifactual responses by overwhelming a physiologic system. These two factors provide the most important limitations to the use of experimental animal data to assess the potential risk of human exposure to EMF or any other exogenous agent.

Conversely, however, several factors provide important support for the use of animal models in EMF hazard assessment. A number of animal model systems that have been used in studies of EMF toxicology are also used widely in the safety assessment of pharmaceuticals, environmental chemicals, and other agents to which humans receive broad population exposure. These model systems are well-characterized, have extensive historical databases, and have been shown to be generally

predictive of human responses. Animal studies also provide the opportunity to conduct bioassays under precisely controlled and monitored exposure conditions and to incorporate statistical considerations into study designs. In consideration of the difficulties associated with EMF exposure assessment in epidemiology studies, the ability to conduct animal studies under rigorously controlled exposure conditions is a major strength of this approach to hazard identification. Finally, through the use of genetically engineered animal models, possible effects of EMF on susceptible subpopulations can be investigated. Studies in such susceptible subpopulations may identify hazards that cannot be identified in normal animals or humans, but that may substantially increase the risk of disease in individuals with a genetic predisposition, preexisting condition, or other factor that increases disease risk.

1.3 Role of Mechanistic Studies in EMF Hazard Assessment

The results of mechanistic investigations performed in experimental animals or *in vitro* model systems provide critical data that can establish the biological framework in which observed health effects of EMF can be interpreted. Although identification of a mechanism of action for a toxic agent is not essential for hazard identification, elucidation of one or more biochemical, molecular, or cellular pathways through which an agent exerts biological effects will clearly strengthen hazard assessments developed on the basis of epidemiology and animal bioassays.

Conversely, should the results of epidemiology studies and animal bioassays be negative or conflicting, the identification of a clearly definable mechanism of action can both (1) provide a rational biological context for hazard identification and (2) support the design of optimized hazard identification studies. However, should the results of epidemiology studies and animal bioassays be negative, the lack of an identified biological mechanism of action further weakens the assertion that a substantive human health hazard exists.

2. GENERAL TOXICITY STUDIES OF EMF

In consideration of the absence of documented case reports of systemic EMF toxicity, it is generally agreed that acute, subchronic, or chronic exposure to EMF causes little or no systemic or generalized toxicity in humans. Because certain occupational environments contain "high field" areas in which EMF flux densities exceed those of residential environmental by tens to hundreds of fold, it is logical to expect that such high field environments would be the primary sites of any observed EMF toxicities. However, no case reports of EMF-associated generalized toxicity or malaise in any exposed worker have been published.

The lack of systemic toxicity of EMF exposure is further supported by the results of acute and subchronic animal bioassays conducted in rodent models. Although occasional instances of statistically significant differences from sham controls have been reported, no clear pattern of EMF toxicity identifiable by effects on animal survival, clinical observation, body weight, food consumption, hematology, clinical chemistry, or histopathology has been reported.

As such, no evidence of generalized toxicity associated with EMF exposure has been identified in studies of either humans or experimental animals. On this basis, it can be concluded that EMF exposure presents little or no hazard of systemic acute, subchronic, or chronic toxicity.

3. DEVELOPMENTAL AND REPRODUCTIVE TOXICITY STUDIES OF EMF

Investigations into the possible developmental and reproductive toxicity of EMF were stimulated by early reports of teratogenesis in chick embryos exposed to high EMF flux densities. Although the processes of prenatal development differ substantially in chickens and in humans, the induction of terata in early chick embryos has been interpreted by some investigators as supporting the hypothesis that EMF is a teratogen. By contrast, however, teratologists who use animal models to develop human hazard assessments for chemical and physical agents have questioned the value of the chick embryo model for human hazard identification.

The early teratology data generated in chicken models were extended by reports of small increases in the incidence of birth defects and spontaneous abortions in women who used electric blankets and electric waterbed heaters during pregnancy. These early findings were hypothesis generating, but were limited in that they were retrospective studies that

included no measurements of EMF exposure. Furthermore, the design of these studies essentially precluded the separation of possible EMF effects from possible thermal effects associated with the use of an electric blanket or bed heater.

Since the publication of these early findings, a large number of epidemiology studies have been performed to investigate the hypothesis that EMF exposure is a risk factor for teratogenesis. These studies have examined the incidence of birth defects, growth retardation, and premature delivery, among other end points, in the offspring of women who used electric blankets or electric bed heaters during pregnancy. Other studies have examined rates of these abnormalities in pregnant women with different levels of residential EMF exposure and in pregnant women with different measured or imputed levels of occupational EMF exposure. In general, although occasional EMF-associated differences have been reported, the results of these studies failed to confirm the hypothesis that EMF exposure during pregnancy is a significant risk to the developing fetus. In most studies, no statistically significant relationships were found between EMF exposure and the risk of birth defects or other developmental abnormalities, regardless of whether the increased EMF exposure resulted from the use of an electric blanket or bed heater, from a higher level of EMF in the residential environment, or from EMF exposures that occurred as a result of employment.

Supporting these epidemiologic data are the results of more than a dozen teratology studies that have been conducted in animal model systems. In this regard, it is essential to note that the rodent models and study designs used in the EMF teratology studies are used routinely to evaluate the possible teratogenicity of pharmaceuticals and environmental chemicals; these models have been validated extensively and have been shown to be generally predictive of human responses. The results of these studies, which have been conducted by several different teams of investigators in several countries, have been uniformly negative. When the negative results generated in these experimental evaluations of EMF teratogenesis are considered together with the negative results of most epidemiology studies, the overwhelming majority of available teratology data do not support the hypothesis that EMF exposure during pregnancy constitutes an important hazard to the developing fetus.

As was the case with teratology studies, no body of evidence exists to implicate EMF as a significant risk for fertility. Although the total number of available studies is small, no evidence of reduced fertility has been reported in either men or women receiving occupational exposure to high levels of EMF. Although the number of experimental studies of EMF and reproductive function is similarly small, animal studies of male and female fertility are similarly negative. These studies, which commonly involve exposure of several generations of rodents to the test agent, have failed to identify any decreases in fertility in either male or female animals exposed to EMF.

4. IMMUNOTOXICITY STUDIES OF EMF

Evaluation of the possible effects of EMF exposure on immune function is important to support our understanding of the possible role of EMF in carcinogenesis and as a modifier of host resistance to infection. Any reproducible down-regulation of immune function in EMF-exposed animals could have important consequences in terms of the host's ability to resist infectious disease challenge or to provide effective immune surveillance against neoplastic cells.

The body of studies in which the influence of EMF on immune function parameters has been evaluated is small and is almost entirely limited to studies conducted using rodent model systems. In these studies, a battery of immune function assays (lymphoid organ weight, lymphoid organ cellularity, lymphoid organ histology, B- and T-cell mediated immune responses, NK cell function, lymphocyte subset analysis, host resistance assays) was performed on mice and/or rats exposed to magnetic fields for period ranging from 4 weeks to 3 months. In these studies, no alterations were found in lymphoid organ weights, lymphoid organ cellularity, or lymphoid organ histology; similarly, no deficits in T-cell function or B-cell function were identified, and lymphocyte subset analysis did not reveal any effects of EMF exposure. Interestingly, however, a statistically significant suppression of NK cell function was seen in two studies performed in female mice; this alteration was not seen in male mice of the same strain, nor in either sex of rat evaluated in a parallel study.

Although the authors conclude that this suppression of NK cell function is real, it appears to have little or no biological significance. The primary role of NK cell appears to be in immune surveillance against cancer cells. However, completely negative results were obtained in a 2-year carcinogenesis bioassay of EMF performed in the same strain of mice that demonstrated the reduction in NK cell

function. Because the deficit in NK cell function was not associated with an increase in cancer risk, it is concluded that either (1) the quantitative reduction (~30%) in NK cell function induced by EMF is too small to be biologically significant or (2) other arms of the host immune system were able to perform required immune surveillance in these animals.

5. GENETIC TOXICITY STUDIES OF EMF

The possible activity of EMF exposure in the induction of genetic mutations, DNA breaks, and other types of DNA damage is a key mechanistic consideration that underlies the interpretation of data relevant to the possible activity of EMF as a carcinogen. Although nonmutational mechanisms may also be responsible for carcinogenic activity, mutation and DNA damage are a common mechanism of action for carcinogens. As such, any evidence of genetic toxicity for EMF would have substantial implications for its potential activity as a risk factor for human cancer.

Numerous studies have been performed over the past 20 years to investigate the hypothesis that EMF exposure induces mutations or other genetic damage. Studies to evaluate the possible genetic toxicity of EMF have been performed using a broad range of experimental model systems, including *in vitro* bacterial mutagenesis assay systems (such as the Ames test), *in vitro* mutagenesis and DNA damage test systems using mammalian cells, and *in vivo* assays of DNA damage. A substantial number of the *in vitro* genetic toxicology studies of EMF have been performed using test systems that are used widely in the safety assessment of pharmaceuticals and chemical agents. As such, a large database exists to support the utility of these assays to predict *in vivo* responses.

The results of the overwhelming majority of genetic toxicology studies published in the peer-reviewed literature have been negative; as such, a broad assessment of the genetic toxicology database does not support the hypothesis that EMF is genotoxic in either bacteria or in mammalian cells. Virtually all genetic toxicology studies that have been performed using what are considered to be "standard" genetic toxicology test systems (bacterial cell mutagenesis [Ames test], mammalian cell mutagenesis, micronucleus assays) have generated negative data; the quantity of negative genetic toxicology data for EMF in these test systems would ordinarily be sufficient for a federal regulatory agency to consider EMF to be nonmutagenic.

It should be noted that not all genetic toxicology studies of EMF have been negative. Positive evidence of genetic toxicity has been obtained under certain very limited experimental conditions (i.e., electric shocks and spark discharges) associated with power frequency electric fields; however, these specialized situations are not encountered in most residential or occupational environments and therefore appear to be a little relevance to overall EMF hazard assessment. Most other positive reports have involved studies in nonstandard experimental systems whose relevance to human hazard identification is unclear. A few positive results have been obtained in studies using test systems in relatively wide use in the genetic toxicology community; however, efforts to replicate the positive data have failed.

Aside from specialized situations that are not encountered in routine residential or occupational environments, there is no consistent body of experimental evidence that demonstrates that either power frequency magnetic fields or a combination of power frequency magnetic + electric fields (nonshocking and nonsparking) induce mutations, DNA breaks, or other DNA damage in any standard genetic toxicology test system. On this basis, it is generally accepted within the scientific community that power frequency EMF is not genotoxic.

6. ONCOGENICITY STUDIES OF EMF

Although other possible health effects of residential or occupational EMF exposure are clearly of concern, the primary focus of most EMF hazard assessment studies has been to determine whether exposure to EMF increases the risk of cancer or other neoplasms. The majority of epidemiologic studies of EMF published by the end of the 20th century have been focused on cancer end points. Similarly, a large fraction of experimental resources dedicated to studies of EMF action have been directed toward the question of cancer hazard assessment.

6.1 Epidemiology Studies of EMF and Cancer

Although the results of a number of individual epidemiology studies have provided suggestive evidence of the potential oncogenicity of EMF, the

total body of epidemiologic data linking EMF exposure and cancer risk is by no means conclusive. The results of several EMF epidemiology studies published in the late 1970s and early 1980s suggested that EMF exposure may be a risk factor for cancer of the brain, breast, and hematopoietic system. However, other epidemiologic studies of similar populations failed to confirm these findings, and no clear picture has emerged from this body of literature.

Since 1990, nearly 100 epidemiology studies and meta-analyses designed to investigate the possible association between occupational or residential exposure to magnetic fields and cancer risk have been published. The experimental methods used in these studies are often substantially improved in comparison to methods used in earlier investigations; specific areas of improvement include the use of larger sample sizes and substantial improvements in EMF exposure assessment. However, despite these improvements in epidemiologic methods, EMF cancer epidemiology studies continue to generate both positive and negative results. When considered together, the results of these studies are insufficient to either clearly support or refute the hypothesis that exposure to EMF is a significant risk factor for human cancer in any organ system.

The most comprehensive evaluation of the possible carcinogenicity of power frequency magnetic fields was that published by a working group assembled by the International Agency for Research on Cancer (IARC). The conclusion of this group, which reviewed essentially every epidemiology study of EMF and cancer that has been published in a peer-reviewed journal, was that limited evidence exists to support the hypothesis that EMF exposure is a risk factor for childhood leukemia. The increased risk of childhood leukemia associated with EMF exposure is small (relative risk of <2.0), but is a generally consistent finding across a relatively large number of epidemiology studies. By contrast, however, the conclusion of this group was that the sum of the epidemiology data is inadequate to support the hypothesis that EMF exposure is a significant risk factor for leukemia or any other type of neoplasm in adults and is inadequate to support the hypothesis that EMF exposure is a significant risk factor for any type of malignancy other than leukemia in children. As such, the IARC panel concluded that suggestive evidence of EMF oncogenicity exists only for childhood leukemia and not for any other neoplasm in either children or adults.

Because the increased risk of childhood leukemia in EMF-exposed groups is small, epidemiology studies are continuing in order to quantify more precisely the risks involved, and to confirm that this observed elevation in leukemia risk does, in fact, result from EMF exposure and is not the result of some confounding factor.

6.2 Experimental Studies of EMF and Cancer

In situations where epidemiology does not support the conclusive identification and quantitation of the potential risks associated with exposure to an environmental agent, laboratory studies conducted in appropriate experimental model systems increase in importance. Well-designed and controlled animal studies permit evaluation of biological effects *in vivo* under tightly controlled exposure and environmental conditions, as well as in the absence of potential confounding variables. In consideration of the conflicting results of EMF epidemiology studies and difficulties associated with exposure assessment in such studies, animal studies may provide the best opportunity to identify effects of EMF exposure that could translate into human health hazards.

6.2.1 Assessment of the Possible Oncogenic Activity of EMF as a Single Agent

Several teams of investigators have published the results of studies that are designed to investigate the possible oncogenic activity of chronic exposure to EMF alone (as opposed to EMF exposure in combination with simultaneous or sequential exposure to other agents). These studies have generally been conducted using the chronic rodent bioassay design, a standardized study design in which animals are exposed to the test agent for the majority of their natural life span (2 years), followed by a complete microscopic evaluation of approximately 50 tissues from every animal to identify induced cancers and other lesions. This study design has been used widely to evaluate the potential carcinogenicity of new drugs, chemicals, and environmental agents; the IARC and the United States National Toxicology Program (NTP) have both performed statistical analyses demonstrating the utility of the chronic rodent bioassay as a predictor of human carcinogenicity. As a result, it is generally accepted among toxicologists that the chronic bioassay in rodents currently provides the best available experimental

approach to identify agents that may be carcinogenic in humans.

In all studies conducted using this study design, chronic exposure to power frequency EMF had no effect on the incidence of neoplasia in any of the three putative targets for EMF action (brain, breast, and hematopoietic system) that had been identified by epidemiology. Furthermore, chronic exposure to EMF did not induce any pattern of biologically significant increases in cancer incidence in other tissues. The very close comparability of the results of chronic rodent oncogenicity bioassays conducted independently in three laboratories strengthens the conclusion that exposure to magnetic fields does not induce cancer in rodents. On the basis of the demonstrated predictive nature of the rodent 2-year bioassay, these findings do not support the hypothesis that EMF is a significant risk factor in the etiology of human neoplasia.

6.2.2 Site-Specific Rodent Oncogenicity Studies

It is generally accepted that exposure to power frequency EMF does not induce mutations or other genetic damage that is identifiable using standard genetic toxicology model systems. Because EMF is apparently not genotoxic, it is logical to conclude that any oncogenic effects of exposure are mediated through co-carcinogenic or tumor promotion mechanisms. To address this possibility, a relatively large number of *in vivo* studies have been conducted to identify possible co-carcinogenic or tumor promoting effects of EMF in various target tissues. The design of these studies involves simultaneous or sequential exposure to EMF in combination with another agent (generally a chemical carcinogen or ionizing radiation) and is focused on neoplastic development in a specific organ. Most multistage tumorigenesis studies of EMF have been conducted using animal models that are designed as research tools to study site-specific carcinogenesis. As a result, the utility of these assays to predict human oncogenicity is less completely understood than are the results of the chronic oncogenicity bioassay.

Studies of the effects of EMF on cancer induction in multistage models for cancer of the brain, hematopoietic system, and liver have been uniformly negative: in all cases, exposure to an inducing agent + EMF induced no more neoplasms than were induced by exposure to the inducing agent alone. Conflicting data have been presented for studies of the effects of EMF exposure on the induction of skin and breast cancers in multistage animal models: in each case, positive data have been presented by one laboratory, but independent studies conducted in one or more additional laboratories have failed to confirm the original finding.

Overall, the peer-reviewed literature provides little compelling evidence that exposure to EMF has co-carcinogenic or tumor promoting activity in any organ site in experimental animals. Completely negative results were found in studies conducted using models for cancer in two of the three target organs (brain and hematopoietic system) identified in epidemiology studies as possible targets for EMF action; data in the third putative target tissue (breast) are conflicting. These data generally support the conclusions from the 2-year oncogenicity bioassays and do not support the hypothesis that EMF exposure is a key risk factor for cancer induction in these target tissues.

6.2.3 Oncogenicity Studies in Genetically Engineered Animals

Insights into the molecular mechanisms of disease have provided the scientific basis for the development and use of genetically modified animals to study disease processes and the application of these models in hazard identification. The science supporting the use of genetically engineered animals in safety assessment stems from initial observations that the incidence of malignancy is increased or its latency is decreased in transgenic animal strains into whose germ line a tumor-associated gene (oncogene) has been inserted and in knockout animal strains from whose germ line a tumor suppressor gene has been deleted. Genetically engineered animals demonstrate a predisposition to specific diseases and thereby provide an approach to hazard identification that may identify effects that occur in sensitive subpopulations but rarely or not at all in the general population. As a result, genetically modified models may demonstrate sensitivity to EMF bioeffects that do not occur in standard animal strains.

Although the total number of completed oncogenicity evaluations of EMF in genetically engineered animals is small, the results of published studies are consistent. In three studies conducted in the United States and in Australia, EMF exposure had no effect on the induction of hematopoietic neoplasia in one transgenic mouse strain (two independent studies) and in one knockout mouse strain. Because EMF exposure did not increase the incidence of hematopoietic neoplasia in any experimental group, the data from these genetically engineered mouse models can be considered to confirm and extend the negative

oncogenicity data generated in the 2-year rodent oncogenicity bioasssays of EMF.

6.3 Possible Mechanisms of EMF Action in Tumorigenesis

Over the past two decades, researchers have proposed a number of possible mechanisms though which exposure to EMF may act to induce or stimulate carcinogenesis; these proposed mechanisms include a wide range of potential effects at the molecular, cellular, and whole organism levels. Review of the published scientific literature provides no clear support for any specific mechanism of EMF action in carcinogenesis. Furthermore, no reproducible body of scientific evidence exists to link EMF exposure to alterations in any biological end point that is mechanistically related to neoplastic development in any tissue.

The majority of hypothesized mechanisms of EMF action in carcinogenesis can be grouped into five general types of effects:

1. Genetic toxicity (DNA damage, clastogenesis or mutagenesis)
2. Alterations in gene expression
3. Biochemical changes associated with regulation of cell proliferation
4. Alterations in immune function
5. Alterations in melatonin levels or action

These general classifications are necessarily arbitrary and were developed to simplify the purposes of this review. It is clear that several of these mechanisms overlap and that not all possible mechanisms of EMF action are included in these five groups. However, these groups do encompass the vast majority of mechanisms proposed for EMF bioeffects and do include mechanisms that have received the most extensive study in order to identify possible linkages between EMF exposure and carcinogenesis.

6.3.1 Genetic Toxicity

The possible genotoxicity of EMF exposure was reviewed in Section 5. As indicated in that section, numerous well-designed, complete, reproducible, and apparently well-conducted studies have failed to demonstrate any genotoxic effects of EMF.

It is generally agreed that ELF magnetic fields do not possess sufficient energy to damage DNA via direct interaction. Although it is possible that power frequency EMF could damage DNA through an indirect mechanism (i.e., via generation of free radicals), an overwhelming majority of genetic toxicology studies conducted in standard safety assessment models have failed to identify any significant mutagenic or clastogenic effects of EMF exposure. As such, a consensus has emerged in the scientific community that exposure to power frequency EMF presents little to no risk of genetic toxicity.

6.3.2 Alterations in Gene Expression

The possible influence of EMF exposure on the expression of cancer-related genes is one of the most controversial areas of research in bioelectromagnetics. Over the past decade, several investigators have reported increases in the expression of one or more protooncogenes (generally c-*myc* or c-*fos*) in cell cultures exposed to 60 Hz EMF. However, replication studies conducted by numerous other investigators have not confirmed these findings, and other, more broadly based screening efforts to identify genes that are up- or down-regulated by EMF exposure have generally yielded negative results. On this basis, the robustness of the reports of altered gene expression, as well as the generality of those findings, must be questioned.

Given the huge universe of genetic targets in the mammalian cell, it is considered likely that exposure to 60 Hz EMF may alter the expression of one or more genes. It is important to note, however, that a finding of enhanced expression of an oncogene or any other gene is not, by itself, sufficient evidence to suggest physiologic or pathophysiologic activity. Because many cellular pathways exhibit biological redundancy, alterations in one pathway may be compensated for by an antagonistic change in another pathway. For this reason, although findings of altered gene expression may be considered to suggest a biologically important effect, demonstration of that effect is necessary to establish the biological relevance of the observed alteration in gene expression. Lacking the demonstration of any physiological/pathophysiological effect, an isolated finding of altered gene expression cannot be construed to be biologically significant. Restated with emphasis on the process of carcinogenesis, a finding of altered expression of an oncogene that is associated with EMF exposure can by no means be equated with any activity of EMF as a carcinogen or tumor promoter.

6.3.3 Biochemical Changes Associated with Regulation of Cell Proliferation

Changes in the expression or activity of enzymes and protein products involved in cell proliferation, cell

cycle regulation, and apoptosis would be expected if EMF exposure was significantly associated with either complete carcinogenesis or tumor promotion. Several reports of this type of EMF bioeffect (e.g., alterations in the activity of ornithine decarboxylase) have been presented in the literature. However, these reports generally demonstrate little consistency across investigators or experimental model systems; as such, the results of individual studies do not appear to be supportable as a general mechanism for EMF activity.

As discussed earlier with regard to possible alterations in gene expression, an isolated finding of changes in enzyme activity or other pathway in cells that are exposed to EMF can be considered to be no more than suggestive of a possible adverse outcome. Linkage of these biochemical or cell-based effects to the physiological or pathophysiological effect is essential to demonstrate their biological significance.

6.3.4 Alterations in Immune Function

Down-regulation of the host immune response by EMF is a tempting hypothesis through which EMF exposure could be associated with risk of carcinogenesis. However, as reviewed in Section 4, this hypothesis is supported by little experimental evidence: with the exception of an apparently biologically insignificant effect on NK cell function, the results of all studies of EMF effects using standardized immunotoxicology test systems and end points have failed to demonstrate effects of EMF on any arm of the host immune response. Although the hypothesis that EMF exposure stimulates tumorigenesis through an indirect mechanism involving suppression of host immunity is intellectually appealing, it is unsupported by any substantial body of experimental evidence.

6.3.5 Alterations in Melatonin Levels or Action

The "melatonin hypothesis" is perhaps the most widely accepted potential mechanism for the biological effects of EMF exposure. A simplified version of this hypothesis states that EMF bioeffects are mediated through alterations in the function of the pineal gland; these changes in pineal function are then responsible for alterations in patterns of melatonin synthesis, kinetics, or action. Ultimately, reductions in melatonin synthesis may have a number of potential adverse effects on the host, including reduced activity as an endogenous free radical scavenger, and influences on the hypothalamic-pituitary-gonadal axis.

A considerable body of evidence to support the melatonin hypothesis was generated in bioelectromagnetics studies performed during the 1980s and early 1990s; in these studies, reductions in circulating melatonin levels or time shifts in the circadian rhythm of melatonin biosynthesis were reported in both experimental animals and in humans. However, several leading investigators who previously reported significant effects of EMF exposure on pineal function have been unable to replicate their own data. This failure of replication is often associated with the acquisition of new, more sophisticated EMF exposure and monitoring equipment. Furthermore, the majority of papers from other laboratories have failed to demonstrate any consistent pattern of effects of EMF exposure on melatonin synthesis or kinetics in humans or in rodent model systems.

One notable exception to this trend is a series of studies that have been conducted using the Siberian hamster as a model system; EMF effects on melatonin secretion in this species appear to be a reproducible finding. However, this animal demonstrates a seasonal circadian rhythm that is considerably different from that seen in either humans or rodent species that are commonly used for safety assessments; as such, a relationship between this finding and possible human health effects is difficult to establish.

Concomitant with the weakening of the data set relating EMF exposure to alterations in pineal function, the melatonin hypothesis has been revised to suggest that EMF influences on melatonin may be effected through alteration in melatonin effects at the level of the target cell, rather than through effects on its synthesis or secretion. The database supporting this hypothesis is very limited and is considered insufficient to provide strong support for this potential mechanism of EMF action.

7. CONCLUSION

With one possibly notable exception, the large body of epidemiologic and experimental data generated over the past 20-plus years generally fails to support the hypothesis that exposure to power frequency EMF is associated with adverse health effects in either humans or experimental animals. No substantive evidence of generalized toxicity resulting from acute, subchronic, or chronic exposure to EMF has been reported in either humans or animal model systems. EMF exposure appears to have no biological significant effects on host immunity and does not impair fertility in either sex. Although some

conflicting data have been generated, EMF exposure does not appear to be a significant risk factor for the developing fetus.

Those data notwithstanding, however, the primary consideration in most hazard assessments is whether the agent being evaluated causes cancer. EMF exposure is not genotoxic, and the results of oncogenicity evaluations conducted using standard animal models, multistage animal models, and genetically engineered animal models are overwhelmingly negative. Similarly, the results of epidemiology studies provide no clear evidence of EMF oncogenicity in any organ site in adults. However, a small, but consistent increase in the risk of childhood leukemia has been observed in a substantial number of EMF epidemiology studies; the consistent nature of this finding was considered to be sufficient for the IARC Working Group to conclude that "limited evidence" of activity exists for EMF in the induction of childhood leukemia.

In summary, epidemiologic evidence provides limited evidence that EMF exposure is associated with an increased risk of childhood leukemia; by contrast, epidemiology studies have not identified increases in cancer risk for any other site in children or for any tissue in adults. No compelling body of epidemiologic or experimental evidence exists to demonstrate any other toxicologic effect of exposure to power frequency EMF, and no substantive biological mechanism has been identified for EMF action. Further epidemiology studies will be required to characterize the relationship between EMF and childhood leukemia more completely.

electric charge A property of the elementary particles of matter that gives rise to electric and magnetic interactions; electrons have negative charge and protons have positive charge.
electric current Net flow of electric charge due to the motion of charged particles in a conducting material.
electric field Lines of force produced by an electric charge and exerting a force on other electric charges.
electromagnetic induction Phenomena in which a change of magnetic field induces an electric field or electromotive force (EMF); the basis of the electric generator.
magnetic field Lines of force produced by an electric current or ferromagnet and exerting a force on other electric currents or on the poles of a magnet.
Maxwell's equations A set of four equations that describe the electric and magnetic fields as functions of position and time.

Electromagnetism is the science of electric and magnetic fields and of the interactions of these fields with electric charges and currents, and as such it is one of the fundamental interactions of nature. Its physical origin lies in a property possessed by elementary particles of matter—electrons and protons—called electric charge. The electromagnetic interaction also governs light and other forms of radiation. Electricity and magnetism appear in many natural phenomena and are applied in many inventions of technology and everyday life. This article describes the basic science and applications of electromagnetism.

1. INTRODUCTION

The earliest discoveries of electric and magnetic forces were made by philosophers of ancient Greece. They observed that when amber is rubbed with animal fur, it acquires the ability to attract small bits of reed or feathers. This small effect was the first observation of static electricity. (The Greek word for amber, $\varepsilon\lambda\varepsilon\kappa\tau\rho o\nu$, is the origin of our word "electric.") They also observed that a lodestone exerts a force on iron—the first example of magnetism. (The Greek province of Magnesia, where the iron ore magnetite occurs naturally, is the origin of our word "magnetic.") These discoveries of weak and mysterious forces were the first steps toward our scientific understanding of electromagnetism. Today science has dispelled much of the mystery of electricity and magnetism, and created technological power beyond the dreams of the ancient philosophers.

2. ELECTRIC CHARGE AND CURRENT

2.1 Electrostatics and Electric Charge

Electric charge is a property of matter. At the most basic level, the constituents of atoms are charged particles—electrons with negative charge ($-e$) and protons with positive charge ($+e$). An atom has equal numbers of electrons and protons so it is electrically neutral. However, a sample of matter becomes electrically charged if the balance between electrons and protons is broken. For example, when amber is rubbed with fur, electrons are transferred from the fur to the amber; the amber then has net negative charge.

Like charges repel and unlike charges attract. That is, if two samples of matter have net positive charge (or both have net negative charge), they exert equal but opposite repulsive forces on one another. If the samples have unlike charges, one positive and the other negative, then each exerts an attractive force on the other. The strength F of the electric force **F** was measured accurately by Charles Augustin de Coulomb (Vectors are indicated in boldface, scalars in plain face). The force is proportional to the product of the charges, q_1 and q_2 and inversely proportional to the square of the distance of separation r,

$$F = \frac{kq_1q_2}{r^2} \quad \text{where} \quad k = 8.99 \times 10^9\ \mathrm{Nm^2/C^2}.$$

This simple mathematical formula has been tested to extreme precision. The dimensional units for the constant k are $\mathrm{Nm^2/C^2}$, where N = newton = unit of force, m = meter = unit of length, and C = coulomb = unit of charge. The proton charge is $e = 1.602 \times 10^{-19}$ C. It forms part of the foundation for the theory of electromagnetism.

2.2 Magnetostatics and Electric Current

Everyone has observed magnets and their forces, which can be quite strong even in small magnets. Every magnet has polarity—north and south poles. Two magnets repel if their north poles approach one another and repel if the south poles approach; but they attract if north approaches south. Magnets have a special attraction to iron; if either pole is placed near an iron object, a magnetic force pulls the magnet and the object toward one another. Science has identified the origins of magnetic forces. Technologies based on magnetic forces are used every day throughout the world.

Magnetism is very closely connected to the electric charge of subatomic particles. The most familiar example of a magnet is a ferromagnet—a piece of magnetized iron. However, a ferromagnet is not the only source of magnetism nor even the most basic. Electric currents also produce magnetic forces, and in some ways the magnetic field associated with electric current is the most basic form of magnetism. The term magnetic field used in this section refers to any magnetic effect. The more technical meaning of the term is explained in Section 3.

2.2.1 Electric Current as a Source of Magnetic Field

An electric current is a stream of electrically charged particles (of one sign) moving in the same direction. The current may be constant in time (DC, or direct current), oscillating in time with a constant frequency (AC, or alternating current), or varying in time. Currents can exist in metals and in several other forms of conducting matter. In a metal, some electrons occupy states that extend over large distances (i.e., not bound to a single atomic core). If an electric force is applied, then these conduction electrons will move in response, creating an electric current. (Ohm's law, $V = IR$ where V = potential difference in volts, I = current in amps, and R = resistance in ohms, expresses quantitatively the relation between the electric force and the current.) In metals, the positively charged atomic nuclei are fixed in a crystalline lattice, so the electric current is due to motion of electrons.

The first observation of the magnetic field associated with an electric current was an accidental discovery by Hans Christian Oersted during a public lecture in 1819. The current existed in a metal wire connected across a battery. Oersted noticed that a nearby compass needle deflected while the current was flowing. The strength of the magnetic field at a distance of 1 centimeter from a 1 ampere current is 2×10^{-5} tesla, comparable to the earth's magnetic field of approximately 5×10^{-5} tesla.

Oersted's discovery was studied in detail by Jean Marie Ampère. The magnetic field can be determined quantitatively by measuring the force on a pole of a magnet or the torque on a compass needle. A compass needle in equilibrium points in the direction of the field vector at the position of the compass. Therefore, a compass can be used to map the field directions. Ampère found that the field direction "curls around" the current. Figure 1 shows a segment of current-carrying wire and the associated magnetic field encircling the wire. The field directions follow the right-hand rule: with the thumb of your right hand pointing along the wire in the direction of the current, the fingers naturally curl in the direction of the magnetic field around the wire. The theory of the magnetic field created by an electric current is called Ampère's law.

Electric currents can also exist in materials other than metals, such as plasmas and ionic solutions. The associated magnetic fields may be measured for scientific purposes. For example, the current in a neuron in the brain creates a magnetic field that is measured in magnetoencephalography. Or a lightning strike (current in an ionized path through the atmosphere) creates a magnetic field that may be measured to study the properties of lightning. The magnetic field of the earth is another natural example

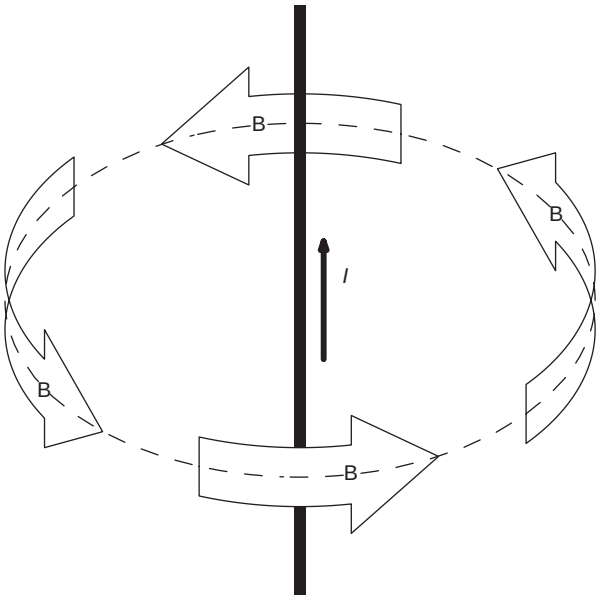

FIGURE 1 The magnetic field **B** curls around the current *I*. The dashed curve indicates an imaginary circle around the wire segment. A compass needle placed near the wire will point in the direction of the field.

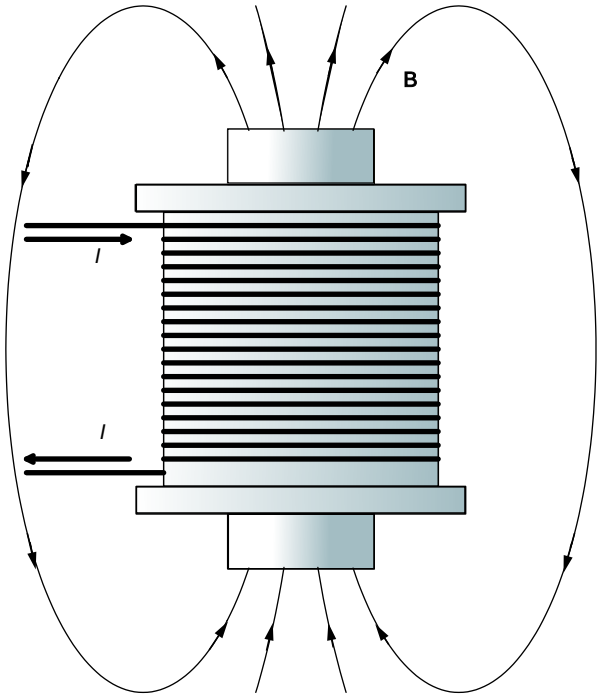

FIGURE 2 An electromagnet.

of a field produced by an electric current. The core of the earth is highly metallic and at high temperature and pressure. Electric currents in this metal core create the earth's magnetism, which we observe at the surface of the earth.

2.2.1.1 Electromagnets Ampère's law is applied in electromagnets. The magnetic field due to a straight length of current-carrying wire is weak. However, if the wire is wound around a cylinder, making a coil with many turns as illustrated in Fig. 2, then the field inside and near the ends of the cylinder can be strong for a practical current. The cylindrical coil is called a solenoid. The field strength can be increased by putting an iron core in the cylinder. Unlike a permanent ferromagnet, the field of an electromagnet can be turned on and off by an electric switch. Electromagnets are commonly used in electric motors and relay switches.

2.2.2 The Magnetic Force on an Electric Current A magnetic field, whether produced by a ferromagnet or by an electric current, exerts a force on any electric current placed in the field. Indeed, there exists a magnetic force on any moving charged particle that moves across the magnetic field vectors. So the interaction between electric charges in motion and a magnetic field has two aspects: (1) an electric current creates a magnetic field (Ampère's law); (2) a magnetic field exerts a force on an electric current.

2.2.2.1 The Electric Motor The magnetic force on an electric current is the basis for all electric motors. The magnetic field may be produced by a permanent magnet (in small DC motors) or by an electromagnet (in large DC and AC motors). The current flows in a rotating coil of wire and may be produced by a battery or some other source of electromotive force. Many practical designs have been invented, with the common feature that a magnetic force acts on the current-carrying coil, in opposite directions on opposite sides of the coil, creating a torque that drives the rotation of the coil. A co-rotating shaft attached to the coil is then connected to a mechanical system to do useful work.

3. THE FIELD CONCEPT

In field theory, electric and magnetic forces are described as the effects of electric and magnetic fields. The theory of electromagnetic phenomena is entirely based on the field concept.

Any electrically charged particle q creates an associated electric field **E**. The field extends throughout the space around q and varies with the position

x in space. If the particle is at rest (in some frame of reference), then its field is independent of time. In a system with many charges, the full electric field is the sum of the electric fields of the individual charges. Thus, the electric field in an electrostatic system, denoted mathematically by $\mathbf{E}(\mathbf{x})$, is a function of position **x** and depends on the locations and charge strengths of all the charged particles.

The electric field extends throughout a volume of space. It exerts a force on any charge in the space. To consider the field concept, suppose two charged particles, q_1 and q_2, are located at positions $\mathbf{x}_1$ and $\mathbf{x}_2$, respectively (see Fig. 3). The electric field at an arbitrary point **x** is

$$\mathbf{E}(\mathbf{x}) = \frac{kq_1}{r_1^2}\,\mathbf{e}_1 + \frac{kq_2}{r_2^2}\,\mathbf{e}_2,$$

where r_1 is the distance from q_1 to **x**, $\mathbf{e}_1$ is the unit vector in the direction from q_1 to **x**, and q_2 and $\mathbf{e}_2$ are the analogous quantities for q_2. A small test charge q placed at **x** will experience a force $\mathbf{F} = q\mathbf{E}(\mathbf{x})$. Since $\mathbf{E}(\mathbf{x})$ is the sum of the fields due to q_1 and q_2, the force **F** on the test charge is the sum of the two forces exerted on q. The charges q_1 and q_2 also experience forces due to the presence of each other. For example, the force on q_2 due to q_1 is $q_2\mathbf{E}_1(\mathbf{x}_2)$, where $\mathbf{E}_1$ is the field due to q_1 alone. The field due to a charged particle is inversely proportional to the square of the distance from the particle, so the force between charges obeys the inverse-square law observed by Coulomb.

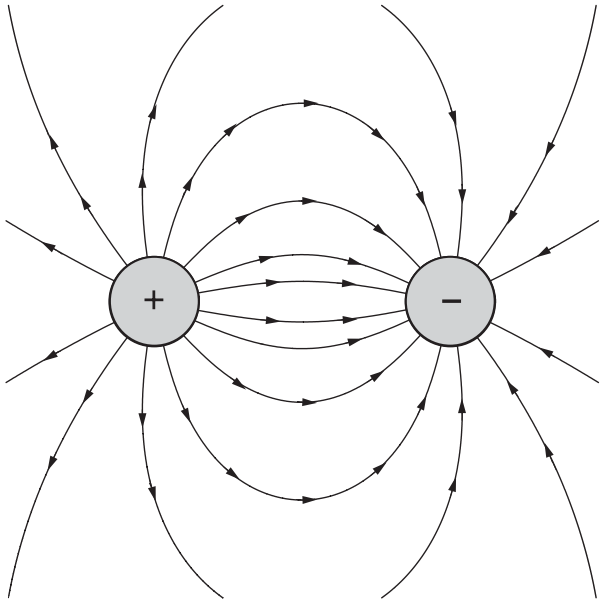

FIGURE 3 The electric field lines of a system of two charges with equal but opposite charge.

In field theory, the force on a charged particle q is attributed to the field $\mathbf{E}(\mathbf{x})$ created by the other charges. Thus, the field concept is significantly different from "action at a distance." The force on the particle, equal to $q\mathbf{E}(\mathbf{x})$, is exerted by the field at the position of q, rather than by direct actions of the distant charges. In other words, an electrostatic system consists of two physical entities: a set of charged particles and an electric field $\mathbf{E}(\mathbf{x})$. The field is just as real as the particles.

Figure 3 illustrates the electric field for a system of two charged particles with equal but opposite charges. The curves in Fig. 3, called the electric field lines, represent the field. The electric field is a vector at each point throughout the space around the charges. A positive test charge q in the field would experience a force in the direction of the field vector at its position. We visualize the field by drawing the field lines, which are curves that are everywhere tangent to the field vector directions.

Electric charges at rest create an electric field $\mathbf{E}(\mathbf{x})$. Ferromagnets and electric currents create another field—the magnetic field $\mathbf{B}(\mathbf{x})$. Figure 4 illustrates the magnetic fields for two elementary current sources: (1) a small current loop and (2) a long current-carrying wire. In a ferromagnet the atoms behave as small current loops with a uniform orientation. The combined atomic fields make up the field of the magnet.

Both **E** and **B** are force fields, which extend throughout a volume of space. But they exert distinct and different forces. The electric field **E** exerts a force on a charge q in the direction of the field vector. The magnetic field **B** exerts a force on moving charges or current-carrying wires. The direction of the magnetic force is perpendicular to both the current and the field, as illustrated in Fig. 5. The magnetic field also exerts forces on the poles of a ferromagnet. The direction of the force is parallel (for a north pole) or antiparallel (for a south pole) to the vector **B**. A compass needle aligns with the magnetic field because the equal but opposite forces on the two poles of the needle compose a torque that twists the needle toward alignment with the field. The magnetic forces on the current elements around a small current loop also compose a torque; in equilibrium, the plane of the loop is oriented perpendicular to the **B** vector. The combined torques on the atoms in a ferromagnet make up the net torque on the magnet.

The field concept was first stated by Michael Faraday. From years of experimental studies on electricity and magnetism, Faraday had formed the idea that a physical entity extends throughout

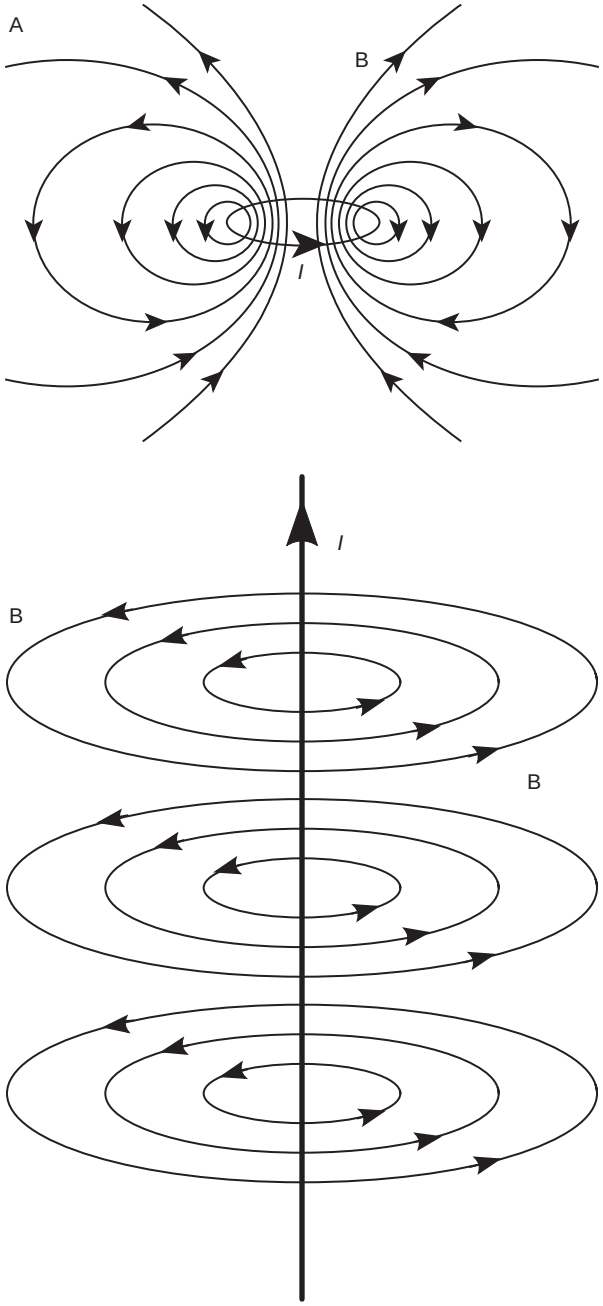

FIGURE 4 Magnetic field of (A) a small current loop and (B) a long straight wire segment.

the space outside charges or magnets and exerts forces on other charges or magnets in the space. He referred to this extended entity as the "lines of force." The term "electromagnetic field" was coined by James Clerk Maxwell, the renowned theoretical physicist who developed a mathematical theory of electromagnetism based on the field concept.

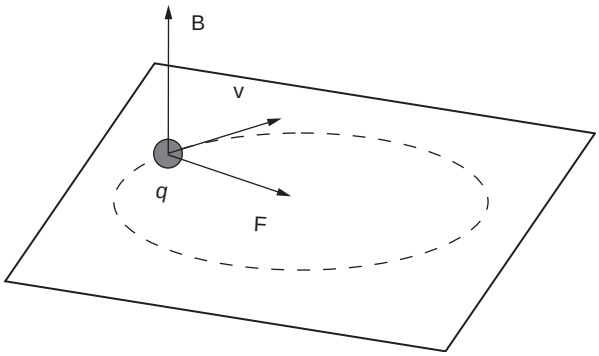

FIGURE 5 The magnetic force on a moving charged particle (or current segment). The direction of the force is perpendicular to both the particle velocity **v** (or current) and the magnetic field: $\mathbf{F} = q\mathbf{v} \times \mathbf{B}$. A charged particle moving on a plane perpendicular to a uniform magnetic field moves along a circle.

4. ELECTROMAGNETIC INDUCTION

The previous sections were concerned with static systems of electric charge or current—that is, in which the fields $\mathbf{E}(\mathbf{x})$ and $\mathbf{B}(\mathbf{x})$ do not change in time. Some relationships between electricity and magnetism were discussed: a steady electric current produces a magnetic field (Ampère's law); a magnetic field exerts a force on any electric charge moving across the field lines. However, for static fields electric and magnetic phenomena appear to be rather distinct.

Time-dependent fields will be described next. The electric field $\mathbf{E}(\mathbf{x}, t)$ and magnetic field $\mathbf{B}(\mathbf{x}, t)$ are functions of time t as well as position $\mathbf{x}$. In dynamic systems, the two fields affect each other significantly. Therefore electric and magnetic phenomena are connected and must be described by a unified theory. Electricity and magnetism are then combined into electromagnetism.

The phenomenon of electromagnetic induction was discovered in 1831 by Michael Faraday in England and independently by Joseph Henry in the United States. The effect is that when a magnetic field changes in time, an electric field is induced in directions that curl around the change of the magnetic field. This phenomenon has important technological applications.

Electromagnetic induction may be observed directly in simple physical demonstrations. Figure 6 shows schematically a coil of conducting wire C connected to a galvanometer G. The galvanometer acts as a current indicator: When no current flows around C the galvanometer needle points toward the

central (zero current) position; when current flows, the needle is deflected. No current source (such as a battery) is connected to the wire coil. In Fig. 6, M is a magnet that can be moved toward or away from the coil C. When the magnet is at rest, no current flows in C and the galvanometer needle points in the central direction.

If the magnet in Fig. 6 moves toward the coil, the galvanometer needle will be deflected in one direction, indicating that a current is flowing in C. The current exists while M is moving. When the motion of M ceases, the needle will return to the central position indicating that the current has stopped. If the demonstration is repeated with the magnet moving away from the coil, the galvanometer needle will be deflected in the opposite direction while M moves. These demonstrations show directly that a change in the magnetic field through the coil induces a current around the coil.

The magnetic field in the demonstration might be varied in a different way. Suppose the bar magnet M in Fig. 6 is replaced by an electromagnet that does not move. Electric current $I(t)$ in the electromagnet solenoid produces a magnetic field $\mathbf{B}(\mathbf{x}, t)$ according to Ampère's law. If the solenoid current is constant, then $\mathbf{B}$ is constant in time and there is no current in the coil C. But if the solenoid current changes, the magnetic field changes. A deflection of the galvanometer needle will be observed while the magnetic field is varying in time. A current around the sensing coil C is again induced when the magnetic field through the coil is changing.

These demonstrations show that when a magnetic field $\mathbf{B}(\mathbf{x}, t)$ changes in time, a current is induced in a conductor that is present in the field. However, the induced current is actually a secondary effect. The current in C is created by an induced electric field $\mathbf{E}(\mathbf{x}, t)$, and $\mathbf{E}$ is the primary effect. Electromagnetic induction is fundamentally a phenomenon of the fields, $\mathbf{B}(\mathbf{x}, t)$ and $\mathbf{E}(\mathbf{x}, t)$. A magnetic field that changes in time induces an electric field in directions curling around the change of the magnetic field. If there happens to be a conducting coil present—as, for example, C in Fig. 6—then the induced electric field drives an electric current around C. But the primary effect is induction of the electric field. The induced electric field $\mathbf{E}(\mathbf{x}, t)$ exists while the magnetic field $\mathbf{B}(\mathbf{x}, t)$ is varying in time.

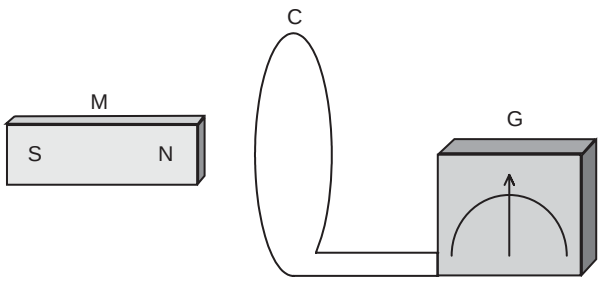

FIGURE 6 Schematic apparatus for demonstrations of electromagnetic induction.

The apparatus shown in Fig. 6 is only schematic. The induced current in C would be very small for an ordinary bar magnet M moving at reasonable velocities. A practical demonstration would require a sensing coil with many turns of wire and a sensitive galvanometer. The effect might be increased by putting an iron core inside the coil to enhance the magnetic field.

Faraday and Henry performed laboratory experiments similar to the demonstrations illustrated in Fig. 6 in their discoveries of electromagnetic induction. Faraday described the results of his detailed studies in terms of the lines of force—his concept of a magnetic field filling space around a magnet. In modern language, a statement summarizing his observations is

> **Faraday's law:** *When the flux of magnetic field through a loop changes in time, an electromotive force (EMF) is induced around the loop.*

This statement is Faraday's law of electromagnetic induction. In equation form, $d\Phi/dt = -\varepsilon$, where Φ is the magnetic flux through the loop, $d\Phi/dt$ is the rate of change of the flux, and ε is the electromotive force around the loop. The "flux" is a quantitative measure of the field lines passing through the loop, defined by the product of the component of the magnetic field vector perpendicular to a surface bounded by the loop and the area of the surface.

The "loop" in Faraday's law is a closed curve (e.g., a circle). The loop may be a conducting loop, in which case the induced EMF drives a current, or it may just be an imaginary curve in space. In either case, the EMF is an induced electric field curling around the change of the magnetic field.

Another, related demonstration may be carried out with the simple apparatus of Fig. 6. Instead of moving the magnet M and holding the coil C fixed, suppose the coil is moved while the magnet is held fixed. Again, a current will be observed around C. The phenomenon in this case is called "motional EMF"; an electromotive force is induced in a conductor that moves relative to a nonuniform magnetic field. In the language of Faraday, when a conducting wire moves through magnetic lines of

force, an induced current flows in the wire. Evidently, any change of the magnetic flux through a conducting loop will induce a current in the loop.

Yet another way to change the magnetic flux through the coil C in Fig. 6 is to change the orientation of the coil. In Fig. 6 the plane of the coil is shown perpendicular to the bar magnet. In this orientation the magnetic field lines pass straight through C; the flux is the product of the magnetic field strength B and the area A of the loop, $\Phi = BA$. Now suppose the coil rotates about a vertical axis, with M fixed. Then the flux of magnetic field through the coil changes as the plane of the loop is at a varying angle to the field vector. When the plane of the loop is parallel to the field lines, the flux is zero because no field lines pass through the coil. While the coil is rotating, a deflection of the galvanometer needle will be observed, consistent with Faraday's law, because of the changing flux. This is another example of motional EMF: The conducting wire moves through the magnetic field lines, and there is an induced current in the wire.

5. APPLICATIONS OF ELECTROMAGNETIC INDUCTION

A number of important inventions are based on the phenomenon of electromagnetic induction. Two that have great technological significance will be described here.

5.1 The Electric Generator

An electric generator (or dynamo) is a machine that generates an electromotive force (EMF) by electromagnetic induction. One or more coils of wire rotate in a magnetic field. The magnetic flux through a coil changes as the coil rotates, inducing an EMF around the coil by Faraday's law, $\varepsilon = -d\Phi/dt$.

Figure 7 shows schematically the design principle of an electric generator. In the model, the square coil rotates about the vertical axis that bisects the coil. The model field **B** is the constant field between north and south poles of ferromagnets. As the coil rotates, the flux through it varies sinusoidally as a function of time. Then there is an induced alternating EMF around the coil.

The model generator in Fig. 7 has the ends of the coil in contact with two slip rings. The voltage difference between the rings is equal to the EMF ε around the coil. Thus the device generates an alternating voltage V (shown in the inset graph) with constant frequency equal to the rotational frequency of the coil. If the rings are connected by a wire with resistance R, an alternating current (AC) I will occur in the wire with $V = IR$ by Ohm's law.

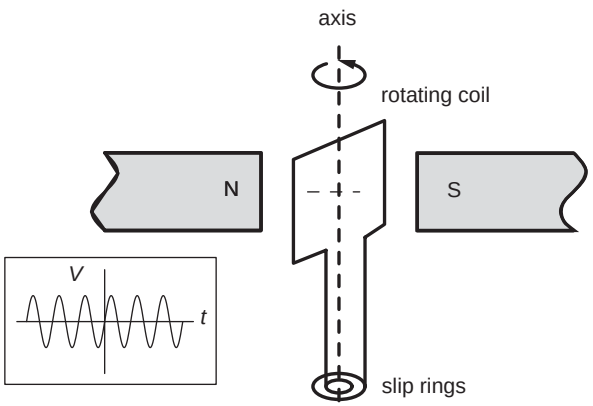

FIGURE 7 The design principle of an electric generator. The magnetic flux through the coil varies as the coil rotates and an EMF is induced in accord with Faraday's law. The voltage difference V between the slip rings varies sinusoidally in time (inset graph).

An external torque must be applied to the coil of the generator to maintain the constant rotation. If the slip rings are connected to an electric appliance, then energy is supplied by the generator because the induced EMF drives an alternating current in the appliance. But energy cannot be created—only converted from one form to another. If no external torque is applied, the generator coil will slow down and stop as its rotational kinetic energy is converted to the work done by the appliance. The slowing of the rotation is an example of magnetic braking: a conductor moving in a magnetic field experiences a force opposite to the motion. To maintain a constant rotation of the generator coil (and hence AC power to the appliance), the coil must be driven by a torque exerted by an external device. In a portable generator, the external torque is produced by a gasoline-powered engine. In an electric power plant, the external torque is produced by a turbine driven by a flow of hot steam; the steam is produced in a boiler (e.g., from burning coal in a coal-fired power plant or from the heat of nuclear reactions in a nuclear reactor).

The electric generators producing electric power around the world are large and complex machines; but the fundamental physics in these devices is simple: Faraday's law and the design principle in Fig. 7.

5.2 The Transformer

A transformer takes an input alternating EMF V_1 (e.g., from an electric generator) and makes an output EMF V_2 that might be supplied to an electric appliance (see Fig. 8). The frequencies of V_1 and V_2 are equal, but the amplitudes are different. A step-down transformer has $V_2 < V_1$; for example, a transformer might take in 110 volts (alternating) from a wall socket and put out 10 volts to a small electric motor in an appliance. A step-up transformer has $V_2 > V_1$; high-voltage applications require such a transformer.

The physical phenomenon acting in a transformer is electromagnetic induction. Figure 8 shows a simple transformer: two coils of conducting wire are wrapped around a toroidal ferromagnetic core. The alternating current driven in the primary coil by the input EMF $V_1(t)$ creates a strong alternating magnetic field $\mathbf{B}(t)$, according to Ampère's law. Because of the ferromagnetism, $\mathbf{B}$ extends around the toroid. Then the changing magnetic flux through the secondary coil induces an EMF by Faraday's law, $\varepsilon = -d\Phi/dt$; this EMF is the output voltage V_2. If N_1 is the number of turns of wire in the primary coil and N_2 is the number of turns in the secondary coil, then the ratio of the voltages is $V_2/V_1 = N_2/N_1$.

Transformers are a crucial part of the electric power grid. An electric power plant creates a three-phase alternating EMF supplied to the grid. But the electric appliances that will use the power are located far from the power plant. Therefore a current must occur over very long transmission lines. The amount of lost power P_{lost}, dissipated in resistance of the transmission wires, is given by the formula $P_{\text{lost}} = I^2R$ where $I =$ current and $R =$ resistance of the line. The power supplied to users is $P_{\text{used}} = IV$, where V is the transmitted EMF. The ratio of power lost to power used is

$$\frac{P_{\text{lost}}}{P_{\text{used}}} = \frac{(P_{\text{used}}/V)^2 R}{P_{\text{used}}} = \frac{P_{\text{used}} R}{V^2},$$

that is, it is inversely proportional to the square of the line voltage. Therefore the transmission of electric power is most efficient if the voltage V is high.

A typical power-plant generator might produce an alternating EMF with amplitude 168 kV (i.e., root mean square EMF 120 kV). But that voltage would be changed in a step-up transformer at the power plant to a very high voltage (e.g., 345 kV). High-voltage transmission lines carry the electric power across large distances. Then step-down transformers are required at the end of a transmission line to reduce the voltage for applications. A transformer substation might reduce the voltage to 4.8 kV for overhead lines into residential areas. A final transformer mounted on the utility pole reduces the voltage to 110 V for the wires to a single house.

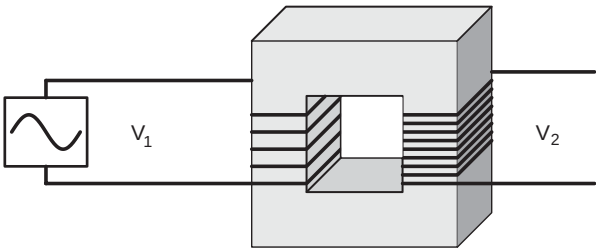

FIGURE 8 The design principle of a transformer. Two coils of conducting wire are wrapped around an iron core. The number of turns is different in the two coils, so the output EMF V_2 is different from the input EMF V_1.

6. THE MAXWELL EQUATIONS OF THE ELECTROMAGNETIC FIELD

The mathematical theory of electromagnetism was developed and published in 1864 by James Clerk Maxwell. He described the known electric and magnetic effects in terms of four equations relating the electric and magnetic fields and their sources—charged particles and electric currents. The development of this theory was a supreme achievement in the history of science. Maxwell's theory is still used today by physicists and electrical engineers. The theory was further developed in the 20th century to account for the quantum theory of light. But even in quantum electrodynamics, Maxwell's equations remain valid although their interpretation is somewhat different from the classical theory. In any case, Maxwell's theory continues today to be an essential part of theoretical physics.

A knowledge of calculus and vectors is necessary for a full understanding of the Maxwell equations. However, the essential structure of the theory can be understood without going into the mathematical details. Each equation is expressed most powerfully as a partial differential equation relating variations of the electric and magnetic fields, with respect to variations of position or time, and the charge and current densities in space.

Gauss's Law. Gauss's law, written as a field equation, is $\nabla \cdot \mathbf{E} = \rho/\varepsilon_0$. (The symbol $\nabla\cdot$ denotes the divergence operator.) Here $\rho(\mathbf{x}, t)$ is the charge per unit volume in the neighborhood of $\mathbf{x}$ at time t; ε_0

is a constant of nature equal to $8.85 \times 10^{-12}\,C^2/Nm^2$. Gauss's law relates the electric field $\mathbf{E}(\mathbf{x}, t)$ and the charge density. The solution for a charged particle q at rest is $\mathbf{E}(\mathbf{x}) = kq\mathbf{e}/r^2$, where r is the distance from the charge to $\mathbf{x}$, $\mathbf{e}$ is the direction vector, and $k = 1/(4\pi\varepsilon_0)$; this is the familiar inverse square law of electrostatics. Electric field lines diverge at a point charge.

Gauss's Law for Magnetism. The analogous equation for the magnetic field is $\nabla \cdot \mathbf{B} = 0$. There are no magnetic monopoles, particles that act as a point source of $\mathbf{B}(\mathbf{x}, t)$. Unlike the electric field lines, which may terminate on charges, the magnetic field lines always form closed curves because magnetic charges do not exist. There is no divergence of magnetic field lines.

Faraday's Law. The field equation that describes Faraday's law of electromagnetic induction is $\nabla \times \mathbf{E} = -\partial\mathbf{B}/\partial t$. The quantity $\nabla \times \mathbf{E}$, called the curl of $\mathbf{E}(\mathbf{x}, t)$, determines the way that the vector field $\mathbf{E}$ curls around each direction in space. Also, $\partial\mathbf{B}/\partial t$ is the rate of change of the magnetic field. This field equation expresses the fact that a magnetic field that varies in time implies an electric field that curls around the change of the magnetic field. It is equivalent to Faraday's statement that the rate of change of magnetic field flux through a surface S is equal to an electromotive force (EMF) around the boundary curve of S.

The Ampère-Maxwell Law. In a system of steady electric currents, the magnetic field is constant in time and curls around the current in directions defined by the right-hand rule. The field equation that expresses this field $\mathbf{B}$ (Ampère's law) is $\nabla \times \mathbf{B} = \mu_0\mathbf{J}$, where $\mathbf{J}(\mathbf{x})$ is the current per unit area at $\mathbf{x}$ and μ_0 is a constant equal to $4\pi \times 10^{-7}\,Tm/A$. (The units are T = tesla for magnetic field and A = ampere for electric current). But Ampère's law is incomplete, because it does not apply to systems in which the currents and fields vary in time. Maxwell deduced from mathematical considerations a generalization of Ampère's law,

$$\nabla \times \mathbf{B} = \mu_0\mathbf{J} + \mu_0\varepsilon_0\frac{\partial \mathbf{E}}{\partial t},$$

in which the second term on the right side is called the displacement current. The displacement current is a necessary term in order for the system of four partial differential equations to be self-consistent. The Ampère-Maxwell law implies that $\mathbf{B}$ curls around either electric current ($\mathbf{J}$) or changing electric field ($\partial\mathbf{E}/\partial t$). The latter case is analogous to electromagnetic induction but with $\mathbf{E}$ and $\mathbf{B}$ reversed; a rate of change in one field induces circulation in the other field.

Maxwell's introduction of the displacement current was a daring theoretical prediction. At that time there was no experimental evidence for the existence of displacement current. Laboratory effects predicted by the displacement current are very small, and their observation was not possible with the apparatus available at that time. However, the Maxwell equations, including the displacement current, make a striking prediction—that light consists of electromagnetic waves. The fact that Maxwell's theory explains the properties of light, and other forms of electromagnetic radiation, provides the evidence for the existence of the displacement current.

7. ELECTROMAGNETIC WAVES

Electromagnetism includes phenomena involving charges, currents, magnets, and the fields $\mathbf{E}$ and $\mathbf{B}$. Light is also an electromagnetic phenomenon. Light and other forms of radiation are described by field theory as electromagnetic waves. Therefore optics—the science of light—is a part of electromagnetism.

The Maxwell equations describe the behavior of the electric field $\mathbf{E}(\mathbf{x}, t)$ and magnetic field $\mathbf{B}(\mathbf{x}, t)$. The time-dependent fields influence each other, even in a vacuum where no charge or current is present, through Faraday's law ($\nabla \times \mathbf{E} = -\partial\mathbf{B}/\partial t$) and the displacement current ($\nabla \times \mathbf{B} = \mu_0\varepsilon_0\partial\mathbf{E}/\partial t$). The four field equations are all satisfied in vacuum if both $\mathbf{E}(\mathbf{x}, t)$ and $\mathbf{B}(\mathbf{x}, t)$ are waves traveling in space. However, the electric and magnetic waves are codependent (i.e., intricately related in several ways).

Figure 9 shows a snapshot in time of the fields for a section of an electromagnetic wave in vacuum. The field vectors are shown at points along a line parallel to the direction of propagation of the wave (z axis). The wavelength is constant (at least for the section of wave shown). The field vectors $\mathbf{E}$ and $\mathbf{B}$ vary in magnitude as a function of position along the line of propagation. The magnitudes are related by $B = E/c$, where c is the wave speed. The directions of $\mathbf{E}$ and $\mathbf{B}$ are orthogonal, in the x and y directions, respectively. The field components oscillate sinusoidally with z. An electromagnetic wave is a transverse wave because the fields oscillate in directions orthogonal to the direction of propagation.

Figure 9 shows the field vectors along only a single line parallel to the direction of propagation $\hat{\mathbf{z}}$. The full wave fills a three-dimensional volume. In a

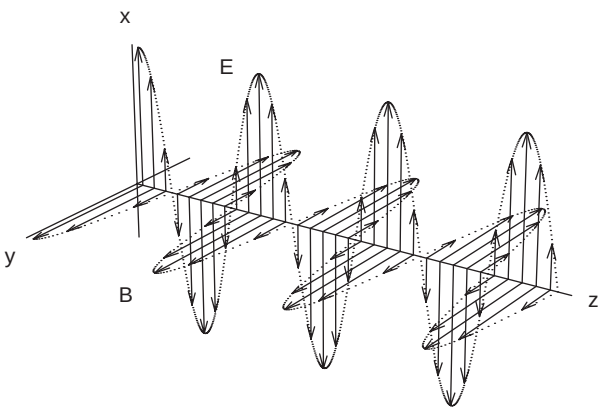

FIGURE 9 Electric and magnetic field vectors in a section of a linearly polarized electromagnetic wave.

linearly polarized plane wave the field vectors are constant on planar wave fronts orthogonal to $\hat{\mathbf{z}}$—that is, with **E** and **B** pointing in the $\hat{\mathbf{x}}$ and $\hat{\mathbf{y}}$ directions, respectively, uniformly over the wave front. All properties of polarized light are then described by the wave theory. As another 3D example, a short radio antenna radiates a spherical wave; far from the antenna **E** and **B** are orthogonal to one another on spherical wave fronts.

A wave is a structure that is extended in space. The parts of the wave also vary in time. Figure 9 is a snapshot showing the wave as a function of position at an instant of time. As time passes, the fields at any fixed position **x** will change. For a linearly polarized plane wave, **E** at **x** oscillates in time between orientations parallel and antiparallel to a fixed polarization direction ($\hat{\mathbf{x}}$), which is orthogonal to the line of propagation ($\hat{\mathbf{z}}$); **B** varies similarly in a direction ($\hat{\mathbf{y}}$) orthogonal to both **E** and the line of propagation. The combined variations in space and time imply that the wave structure moves as a whole in the direction of propagation. So a snapshot at a later time would look just the same as Fig. 9 except translated by some distance in the direction of propagation. In other words, the shape is constant but the positions of the nodes (points where $\mathbf{E} = 0$ and $\mathbf{B} = 0$) move in space.

7.1 The Electromagnetic Spectrum

Electromagnetic waves have an infinite range of wavelength λ. Visible light has λ from 400 nm (violet) to 700 nm (red). Ultraviolet and infrared light have shorter and longer wavelengths, respectively. Microwaves have λ from 1 mm to 1 m, with important technological uses (e.g., communications and radar). X-rays have very short wavelengths, $\lambda < 1$ nm. All these forms of electromagnetic radiation have the same wave speed in vacuum, which can be evaluated from the field theory, $c = 1/\sqrt{\mu_0 \varepsilon_0} = 2.998 \times 10^8$ m/s.

8. SUMMARY

Our scientific understanding of electricity and magnetism has developed over a period of centuries. Phenomena that we understand today as examples of electricity, magnetism, or electromagnetism have been observed since ancient times: For example, lightning is an electric discharge in the atmosphere; a lodestone attracts iron; light consists of electromagnetic waves. Such common phenomena, while easily observed, were unexplained until the scientific revolution. Today we are able to accurately describe and explain all variety of electromagnetic phenomena, based on the mathematical theory of fields. With this knowledge has come the ability to create technologies, such as the distribution of electric power, that affect our daily lives.

emdollar (or EM$) A measure of the money that circulates in an economy as the result of some process. In practice, to obtain the emdollar value of an emergy flow or storage, the emergy is multiplied by the ratio of total emergy to gross domestic product for the national economy.

emergy An expression of all the energy used in the work processes that generate a product or service in units of one type of energy. Solar emergy of a product is the emergy of the product expressed in the equivalent solar energy required to generate it. Sometimes it is referred to as energy memory.

emjoule The unit of measure of emergy, "emergy joule." It is expressed in the units of energy previously used to generate the product; for instance, the solar emergy of wood is expressed as joules of solar energy that were required to produce the wood.

empower Emergy per unit time (sej/time)

energy Sometimes referred to as the ability to do work. Energy is a property of all things that can be turned into heat and is measured in heat units (BTUs, calories, or joules)

nonrenewable emergy The emergy of energy and material storages like fossil fuels, mineral ores, and soils that are consumed at rates that far exceed the rates at which they are produced by geologic processes.

production Production measured in emergy is the sum of all emergy inputs to a process.

renewable emergy The emergy of energy flows of the biosphere that are more or less constant and reoccurring, and that ultimately drive the biological and chemical processes of the earth and contribute to geologic processes.

transformity The ratio obtained by dividing the total emergy that was used in a process by the energy yielded by the process. Transformities have the dimensions of emergy/energy (sej/J). A transformity for a product is calculated by summing all of the emergy inflows to the process and dividing by the energy of the product. Transformities are used to convert energies of different forms to emergy of the same form.

This article presents a brief review of the concepts of energy hierarchy and definitions of emergy and related quantities. Tables of data are given on global emergy flows from which emergy and transformities of most products and processes of the biosphere are calculated. Then tables of transformities for many products are provided. Finally, several case studies of evaluations of energy technologies are given. In a summary discussion emergy analysis (EMA) and embodied energy analysis (EEA) are compared describing the strengths and weaknesses of each approach related to the evaluation of energy systems.

1. INTRODUCTION

1.1 Energy and the Emergy Hierarchy

Emergy is a universal measure of the work of nature and society made on a common basis. The work of nature and society results in energy transformations

that when viewed in totality are interconnected in webs of energy flow. All energy transformations of the geobiosphere can be arranged in an ordered series to form an energy hierarchy. For example, many joules of sunlight are required to make a joule of organic matter, many joules of organic matter to make a joule of fuel, several joules of fuel are required to make a joule of electric power, and so on. Since different kinds of energy are not equal in their contribution to processes, work is made comparable by expressing each form of energy in units of one form. To accomplish this, the available energy of different forms of energy is evaluated by means of the energy of one type previously required to produce it. This quantity of one type of energy previously used is called emergy (spelled with an "m").

1.2 Definitions

The following paragraphs contain definitions and a brief explanation of emergy concepts. A more complete introduction can be found in H. T. Odum's 1996 text, *Environmental Accounting: Emergy and Environmental Decision Making*.

Emergy is the availability of energy (exergy) of one kind that is used up in transformations directly and indirectly to make a product or service. The unit of emergy is the emjoule, a unit referring to the available energy of one kind consumed in transformations. For example, sunlight, fuel, electricity, and human service can be put on a common basis by expressing them all in the emjoules of solar energy that is required to produce each. In this case, the value is a unit of solar emergy expressed in solar emjoules (abbreviated sej). Although other units have been used, such as coal emjoules or electrical emjoules, in most cases, all emergy data are given in solar emjoules.

Unit emergy values are calculated based on the emergy required to produce them. There are three main types of unit emergy values as follows:

- Transformity is one example of a unit emergy value and is defined as the emergy per unit of available energy (exergy). For example, if 4000 solar emjoules are required to generate a joule of wood, then the solar transformity of that wood is 4000 solar emjoules per joule (abbreviated sej/J). Solar energy is the largest but most dispersed energy input to the earth. The solar transformity of the sunlight absorbed by the earth is 1.0 by definition.
- Specific emergy is the unit emergy value of matter defined as the emergy per mass, usually expressed as solar emergy per gram (sej/g). Solids may be evaluated best with data on emergy per unit mass for its concentration. Because energy is required to concentrate materials, the unit emergy value of any substance increases with concentration. Elements and compounds not abundant in nature therefore have higher emergy/mass ratios when found in concentrated form since more work was required to concentrate them, both spatially and chemically.
- Emergy per unit money is a unit emergy value used to convert money payments into emergy units. Since money is paid to people for their services and not to the environment, the contribution to a process represented by monetary payments is the emergy that people purchase with the money. The amount of resources that money buys depends on the amount of emergy supporting the economy and the amount of money circulating. An average emergy/money ratio in solar emjoules/$ can be calculated by dividing the total emergy use of a state or nation by its gross economic product. It varies by country and has been shown to decrease each year. This emergy/money ratio is useful for evaluating service inputs given in money units where an average wage rate is appropriate.

Emergy accompanying a flow of something (energy, matter, information, etc.) is easily calculated if the unit emergy value is known. The flow expressed in its usual units is multiplied by the emergy per unit of that flow. For example, the flow of fuels in joules per time can be multiplied by the transformity of that fuel (emergy per unit energy in solar emjoules/joule), or the mass of a material input can be multiplied by its specific emergy (emergy per unit mass in solar emjoules/gram). The emergy of a storage is readily calculated by multiplying the storage quantity in its usual units by the emergy per unit.

Unit emergy values are a kind of efficiency measure, since they relate all the inputs to an output. The lower the transformity or specific emergy, the more efficient the conversion. It follows from the second law that there are some minimum unit emergy values for processes, which are consistent with maximum power operations. While there is no way to calculate them directly, the lowest transformity found in long-operating systems is used as an approximation. When estimating a theoretical potential of some system, it is appropriate to use the best (lowest) transformity known.

Empower is a flow of emergy (i.e., emergy per time). Emergy flows are usually expressed in units of solar empower (solar emjoules per time).

1.3 Emergy Evaluation Procedure

Emergy accounting uses the thermodynamic basis of all forms of energy, materials, and human services but converts them into equivalents of one form of energy. Emergy accounting is organized as a top-down approach where first a system diagram of the process is drawn to organize the evaluation and account for all inputs and outflows. Tables of the actual flows of materials, labor, and energy are constructed from the diagram and all flows are evaluated. The final step of an emergy evaluation involves interpreting the quantitative results. In some cases, the evaluation is done to determine fitness of a development proposal. In others, it may be a question of comparing different alternatives. The evaluation may be seeking the best use of resources to maximize economic vitality. So the final step in the evaluation is to calculate several emergy indices that relate emergy flows of the system being evaluated with those of the environment and larger economy within which it is embedded and that allow the prediction of economic viability, carrying capacity, or fitness.

This evaluation process has been termed emergy synthesis. Synthesis is the act of combining elements into coherent wholes. Rather than dissect and break apart systems and build understanding from the pieces upward, emergy synthesis strives for understanding by grasping the wholeness of systems. Emergy is a systems concept, context driven, and cannot be fully understood or utilized outside of systems. By evaluating complex systems using emergy methods, the major inputs from the human economy and those coming "free" from the environment can be integrated to analyze questions of public policy and environmental management holistically.

1.3.1 Left-Right Energy Systems Diagram

Systems diagrams are used to show the inputs that are evaluated and summed to obtain the emergy of a resulting flow or storage. The purpose of the system diagram is to conduct a critical inventory of processes, storages, and flows that are important to the system under consideration and are therefore necessary to evaluate. Components and flows within diagrams are arranged from left to right reflecting more available energy flow on the left, decreasing to the right with each successive energy transformation. For example, abundant solar energy is utilized in successive transformations in ecological, agricultural, and technoeconomic subsystems to support a small amount of high-quality energy of humans, their government, and information. A simple diagram of the global system including humans is shown in Fig. 1. The left-to-right organization also corresponds to increasing scale of territory and turnover time. As illustrated in Fig. 1, every energy transformation box has more than one input, including larger energy flows from the left, lesser amounts from units in parallel, and small but important controlling energies feeding back from the right.

1.3.2 Preparation of an Emergy Evaluation Table

Tables of the actual flows of materials, labor, and energy are constructed from the diagram. Raw data on flows and storage reserves are converted into emergy units and then summed for a total emergy flow to the system. Inputs that come from the same source are not added, to avoid double counting. Only the larger input is accounted for. If the table is for the evaluation of a process, it represents flows per unit time (usually per year). If the table is for the evaluation of reserve storages, it includes those storages with a turnover time longer than a year.

Separate tables are constructed for evaluations of flows and storage. Tables are usually constructed in the same format, as given by the column headings and format shown in Table I.

- Column 1 is the line item number, which is also the number of the footnote found below the table where raw data sources are cited and calculations are shown.
- Column 2 is the name of the item, which is also shown on the aggregated diagram.
- Column 3 is the raw data in joules, grams, dollars or other units. The units for each raw data item are shown in column 4.
- Column 5 is the emergy per unit used for calculations, expressed in solar emergy joules per unit. Sometimes, inputs are expressed in grams, hours, or dollars, therefore an appropriate conversion ratio is used (sej/hr; sej/g; sej/$).
- Column 6 is the solar emergy of a given flow, calculated as raw input times the transformity (column 3 times column 5).
- Column 7 is the emdollar value of a given item for a given year. This is obtained by dividing the emergy in Column 6 by the emergy-to-money ratio (EMR) for the country and selected year of the evaluation (units are sej/$). The EMR is calculated independently. The resulting values in this column express the amount of economic activity that can be supported by a given emergy flow or storage.

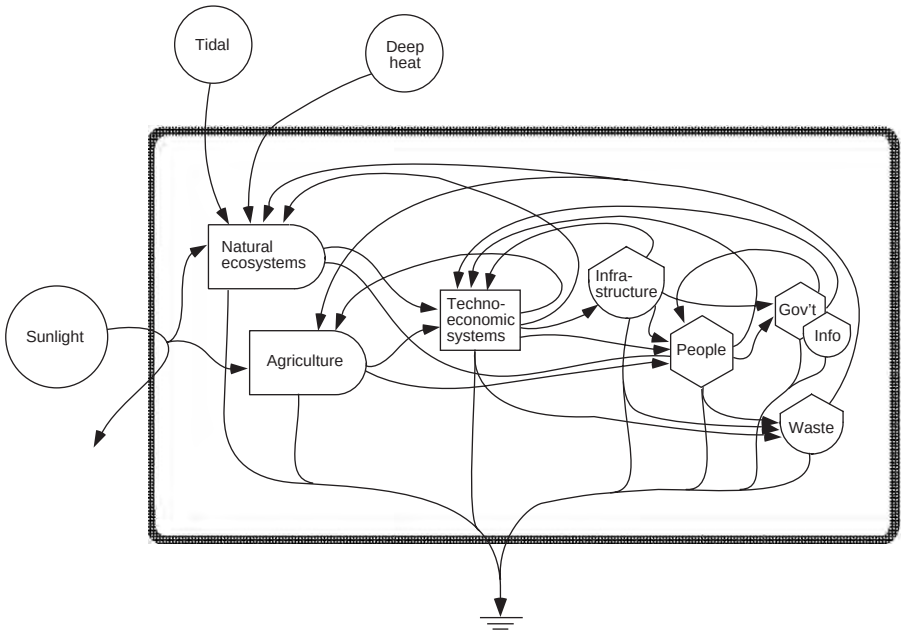

FIGURE 1 Successive energy transformations supporting human civilization. Large energy flows from the right support smaller and smaller amounts of high-quality energy. With each succeeding energy transformation, some energy is degraded some is passed on to the next level (to the left) and some is fed back in control actions. Explanations of symbols may be found in Odum (1996).

1.3.3 Emergy of Storages

When calculating the emergy of stored quantities (storages)—for instance, wood biomass in a forest ecosystem or buildings in a city—it is necessary to sum the emergy of each of the inputs for the time of its contribution. Input emergy inflows are multiplied by the time it takes to accumulate the storage and exported yield, if any.

1.3.4 Evaluations Based on Averaged Inputs

Apparently all systems pulse with time intervals and pulse strength that increase with scale. To evaluate a process on one scale of time and space usually means using averages for each of the inputs from smaller scales where pulses are of high frequency. For example, for an evaluation of phenomena on the scale of human economy, yearly averages are often appropriate. On this scale average solar energy and average tidal energy are used. For calculations of global processes over a longer scale of time, an average of inputs from the deep earth may be used. Thus, for many purposes emergy evaluations are made with averaged inputs. The result is emergy evaluation as if the system was in a steady state. If the table is an evaluation of a storage, the result is in solar emjoules. If the table is an evaluation of a

product flow, the result is in solar emjoules per time (or empower).

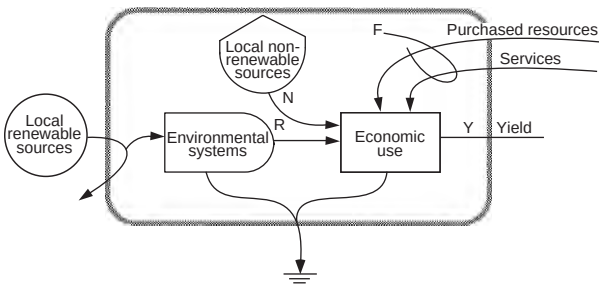
Dynamic emergy evaluations of storages and flows are also used. When a storage is growing, decreasing, or oscillating, its stored emergy contents and transformity are changing as well. Where a system is adequately represented by a dynamic model, an algorithm can be added to the model which calculates a time sequence of emergy and transformity. A simulation model of this type produces a running calculation according to the emergy definition, summing the inputs to storages, multiplying these by their unit emergy, and subtracting emergy removals.

1.3.5 Calculating Unit Emergy Values

After a table is prepared that evaluates all the inputs, unit emergy values of products can be calculated. The output or product (row "O" in Table I) is evaluated first in units of energy, exergy, or mass. Then the input emergy is summed and unit emergy value for the product calculated by dividing the emergy by the units of the output. The unit values that result are useful for other emergy evaluations. Thus, any emergy evaluation generates new emergy unit values.

1.3.6 Performance Indicators

The systems diagram in Fig. 2 shows nonrenewable environmental contributions (N) as an emergy storage of materials, renewable environmental inputs (R), and inputs from the economy as purchased (F) goods and services. Purchased inputs are needed for the process to take place and include human service and purchased nonrenewable energy and material brought in from elsewhere (fuels, minerals, electricity, machinery, fertilizer, etc.). Several ratios, or indices are given in Fig. 1 that are used to evaluate



Yield (Y) = R + N + F
Emergy yield ratio = Y/F
Emergy investment ratio = F/(R + N)
Environmental loading ratio = (F + N)/R
Empower density = (R + N + F)/area

FIGURE 2 Emergy indices used as performance indicators.

the global performance of a process as follows:

Emergy yield ratio. The ratio of the total emergy (local and imported) driving a process or system to the emergy imported. The ratio is a measure of the potential contribution of the process to the main economy, due to the exploitation of local resources.

Environmental loading ratio. The ratio of nonrenewable and imported emergy use to renewable emergy use. It is an indicator of the pressure of a transformation process on the environment and can be considered a measure of ecosystem stress due to a production (transformation activity).

Emergy sustainability index. The ratio of the emergy yield ratio to the environmental loading ratio. It measures the potential contribution of a resource or process to the economy per unit of environmental loading.

Emergy investment ratio. The ratio of emergy fed back from outside a system to the indigenous emergy inputs (both renewable and nonrenewable). It evaluates if a process is a good user of the emergy that is invested, in comparison with alternatives.

Empower density. The ratio of total emergy use in the economy of a region or nation to the total area of the region or nation. Renewable and nonrenewable emergy density are also calculated separately by dividing the total renewable emergy by area and the total nonrenewable emergy by area, respectively.

Several other ratios are sometimes calculated depending on the type and scale of the systems being evaluated.

Percent renewable emergy (%Ren). The ratio of renewable emergy to total emergy use. In the long run, only processes with high %Ren are sustainable.

Emprice. The emprice of a commodity is the emergy one receives for the money spent. Its units are sej/$.

Emergy exchange ratio. The ratio of emergy exchanged in a trade or purchase (what is received to what is given). The ratio is always expressed relative to one or the other trading partners and is a measure of the relative trade advantage of one partner over the other.

Emergy per capita. The ratio of total emergy use in the economy of a region or nation to the total population. Emergy per capita can be used as a measure of potential, average standard of living of the population.

1.3.7 Understanding Emergy Indicators: What They Indicate

Lengthy discussion of the performance indicators were given in a previous publication by the authors titled "Emergy Based Indices and Ratios to Evaluate Sustainability—Monitoring Economies and Technology towards Environmentally Sound Innovation." Additional background and further discussion follows.

Transformity only measures how much emergy it takes to generate one unit of output, regardless of whether or not the input is renewable. It is a measure of efficiency on the global spatial and timescale of the biosphere. It indicates the hierarchical position of an item in the thermodynamic scale of the biosphere and can be regarded as a quality factor from the point of view of biosphere dynamics.

The ELR = (N + F)/R is designed to compare the amount of nonrenewable and purchased emergy (N + F) to the amount of locally renewable emergy (R). In the absence of investments from outside, the renewable emergy that is locally available would have driven the growth of a mature ecosystem consistent with the constraints imposed by the environment and would be characterized by an ELR = 0. Instead, the nonrenewable imported emergy drives a different site development, whose distance from the natural ecosystem can be indicated by the ratio (N + F)/R. The higher this ratio, the bigger the distance of the development from the natural process that could have developed locally. In some ways, the ELR is a measure of the disturbance to the local environmental dynamics, generated by the development driven from outside. The ELR is clearly able to make a difference between nonrenewable and renewable resources, thus complementing the information that is provided by the transformity (Brown and Ulgiati, 1997). From past experience gained in previous case studies investigated, it appears that low ELRs (around two or less) are indicative of relatively low environmental impacts (or processes that can use large areas of a local environment to "dilute impacts"). ELRs between three and ten are indicative of moderate environmental impacts, while ELRs ranging from ten up to extremely high values indicate much higher environmental impacts due to large flows of concentrated nonrenewable emergy in a relatively small local environment.

The emergy yield ratio, EYR = (R + N + F)/F, is a measure of the ability of a process to exploit and make available local resources by investing outside resources. It provides a look at the process from a different perspective, its openness. It provides a measure of the appropriation of local resources by a process, which can be read as a potential additional contribution to the economy, gained by investing resources already available. The lowest possible value of the EYR is 1, which indicates that a process delivers the same amount of emergy that was provided to drive it, and that it is unable to usefully exploit any local resource. Therefore, processes whose EYR is 1 or only slightly higher do not provide significant net emergy to the economy and only transform resources that are already available from previous processes. In so doing, they act as consumer processes more than creating new opportunities for system's growth. Primary energy sources (crude oil, coal, natural gas, uranium) usually show EYRs greater than 5, since they are exploited by means of a small input from the economy and return much greater emergy flows, which have been generated by previous geologic and ecological activities that accumulated these resources over past millennia. Secondary energy sources and primary materials like cement and steel show EYRs in the range from 2 to 5, indicating moderate contribution to the economy.

If the ELR (nonrenewable versus renewable emergy flows) and EYR (outside versus local emergy flows) are combined, a sustainability index is created—that is, an aggregated measure of the potential contribution to the larger system (EYR) per unit of loading imposed on the local system (ELR). This indicator, called emergy index of sustainability (EIS) is usefully applicable to measure openness and loading changes occurring over time in both technological processes and economies. In principle, the lowest possible value of the EIS is zero (when EYR = 0 and ELR $< \infty$ or when EYR $\neq 0$ and ELR $\rightarrow \infty$), while the theoretical upper limit ($\rightarrow \infty$) is only possible for untouched, mature ecosystems. According to the results of several case studies investigated, EIS's lower than 1 appear to be indicative of consumer products or processes and those greater than 1 indicative of products that have net contributions to society without heavily affecting its environmental equilibrium. As it relates to economies, an EIS lower than 1 is indicative of highly developed consumer-oriented systems, EISs between 1 and 10 have been calculated for what have been termed "developing economies," while EISs greater than 10 indicate economies that have not yet significantly started any industrial development.

Finally, the emergy density, ED, measures the amount of emergy invested on one unit of land and suggest land be a limiting factor to any kind of development or process. Higher EDs characterize

city centers, information centers such as governmental buildings, universities, and research institutions, and industrial clusters, while lower EDs are calculated for rural areas and natural environments.

2. EMERGY EVALUATION OF THE BIOSPHERE AND ITS PROCESSES

Figure 3 shows an aggregated system diagram of the energy transformation network of the biosphere arranged with decreasing energy from left to right. In Fig. 3, all the components interact and are required by the others. As a result, the total emergy driving the biosphere (the sum of solar, tidal, and deep heat) is required by all processes within, and thus the emergy assigned to each of the internal pathways is the same. After millions of years of self-organization, the transformations of the driving energies by the atmosphere, ocean, and land are organized simultaneously to interact and contribute mutual reinforcements. Therefore, the energy flow of each jointly necessary process is the sum of the emergy from the three sources.

2.1 Annual Budget of Emergy Flow (Empower) Supporting the Geobiosphere

An emergy evaluation table of the main inputs to the geobiosphere of the earth (omitting, for the moment, the emergy use from nonrenewable resources) is given in Table II. The annual budget of emergy flow (empower) supporting the geobiosphere (atmosphere, ocean, and earth crust) includes solar energy, tidal energy, and heat energy from the deep earth. Other inputs from space, such as the high-energy radiation of solar flares, cosmic rays, meteorites, and stellar dust, are not evaluated. All of these vary with oscillations and pulses, and their emergy values vary with their intensities.

Total emergy contributions to the geobiosphere are about 15.83 E24 sej/year based on a reevaluation

and subsequent recalculation of energy contributions done in the year 2000. Prior to that date, the total emergy contribution to the geobiosphere that was used in calculating unit emergy values was 9.44 E24 sej/year. The increase in global emergy reference base to 15.83 E24 sej/year changes all the unit emergy values that directly and indirectly were derived from the value of global annual empower. Thus, unit emergy values calculated prior to that year are multiplied by 1.68 (the ratio of 15.83/9.44).

2.2 Average Emergy Unit Values for Main Global Processes

Table III calculates unit emergy values for some main flows of the earth. The total emergy input to the geobiosphere in solar emergy (15.83 E24 sej/yr from Table II) is divided by each of the global product's ordinary measure (number of joules or grams). The unit values that result are useful for other emergy evaluations where global averages can be used.

2.3 Temporary Emergy Inputs to the Geobiosphere

In the 19th and 20th centuries, the production and consumption processes of human civilization using the large emergy in the geologic stores of fuels and minerals reached a scale with global impact. Because these storages are being used much faster than they are being generated in geologic cycles, they are often called nonrenewable resources. They are actually very slowly renewed resources. Table IV summarizes these additional components of the global emergy budget.

At present, the emergy contribution through the human civilization to the geobiosphere from the slowly renewed resources is greater than the inputs from renewable sources. A symptom of this surge of temporary emergy inflow is the carbon-dioxide accumulation in the atmosphere that causes greenhouse effects that change the pattern and intensity of weather.

It is important to note that the unit emergy values given in Table III are average values for global processes. It is well understood that there is no single

unit emergy value for any given product, since no two processes are alike. This also holds for the processes of the biosphere. For instance, there are many transformities for rain depending on location and even time of year. Precipitation varies with altitude, is affected by mountains, and depends on the weather systems in complex ways. The evaluations in Table III are for the whole earth with 70% ocean. If the land is regarded as a higher level in the hierarchical organization of the geobiosphere, then rain over the land represents a convergence of oceanic resources as well as those of the continents, and calculation of continental rain transformity includes all geobiosphere driving energy (see rows 3 and 4 in Table III). As a result, continental rainfall has a higher transformity compared to the global average. To carry this idea even farther, the rainfall in any particular location may have a higher or lower transformity depending on the source area and intensity of the solar energy driving the cycles that produce it.

3. UNIT EMERGY VALUES FOR FUELS AND SOME COMMON PRODUCTS

Unit emergy values result from emergy evaluations. Several tables of unit emergy values for some common materials and energy sources follow. In Table V, unit emergy values are given for primary nonrenewable energy sources along with the emergy yield ratio (EYR). In some cases, the EYR is based on only one

evaluation for instance plantation pine. In other cases, several evaluations have been done of the same primary energy but from different sources and presumably different technology, so a range of values are given. For instance, the range of values for natural gas (6.8 to 10.3) represent the difference between offshore natural gas (6.8) and on natural gas produce in the Texas field on shore (10.3). Obviously each primary energy source has a range of values depending on source and technology. By using data from typical production facilities (and actually operating facilities), the unit emergy values represent average conditions and can be used for evaluations when actual unit values are not known. If it is known that conditions where an evaluation is being conducted are quite different than the averages suggested here, then detailed evaluations of sources should be conducted.

Table VI lists the unit emergy values for some common products in the order of their transformity. Only a few products are given here, while many more evaluations leading to unit emergy values have been conducted and are presented in a set of emergy folios, published by the Center for Environmental Policy at the University of Florida (www.ees.ufl.edu/cep).

Calculations of emergy production and storage provide a quantitative basis for making choices about environment and economy. The unit energy values done previously aid new evaluations, since they may save time and energy of authors attempting other evaluations because they do not need to reevaluate all inputs from scratch. In light of this, a series of emergy folios have been published, and others planned, that provide data on emergy contents, the computations on which they were based, and comparisons (www.ees.ufl.edu/cep/emergydownloads.asp). To date there are five folios by as many authors, who take the initiative to make new calculations or assemble results from the extensive but dispersed literature in published papers, books, reports, theses, dissertations, and unpublished manuscripts. The tabulating of unit emergy values and their basis is the main purpose of the handbooks.

4. CASE STUDIES: EVALUATION OF ENERGY CONVERSION SYSTEMS

Several case studies of conversion systems are evaluated using embodied energy analysis and emergy analyses (hereafter EEA and EMA, respectively). The results from case studies are discussed jointly in the following sections of this article. Comparisons are made to highlight synergisms that support each other and differences that require EMA be used for a deeper understanding of energy systems performance. Evaluations of the case studies resulted from a joint research project between the authors with funding from the Italian Energy Agency (ENEA).

4.1 Description of the Power Systems

4.1.1 Oil-Powered Thermal Plant

A conventional oil-powered thermal plant (Fig. 4) mainly consists of a fuel storage area, boilers for

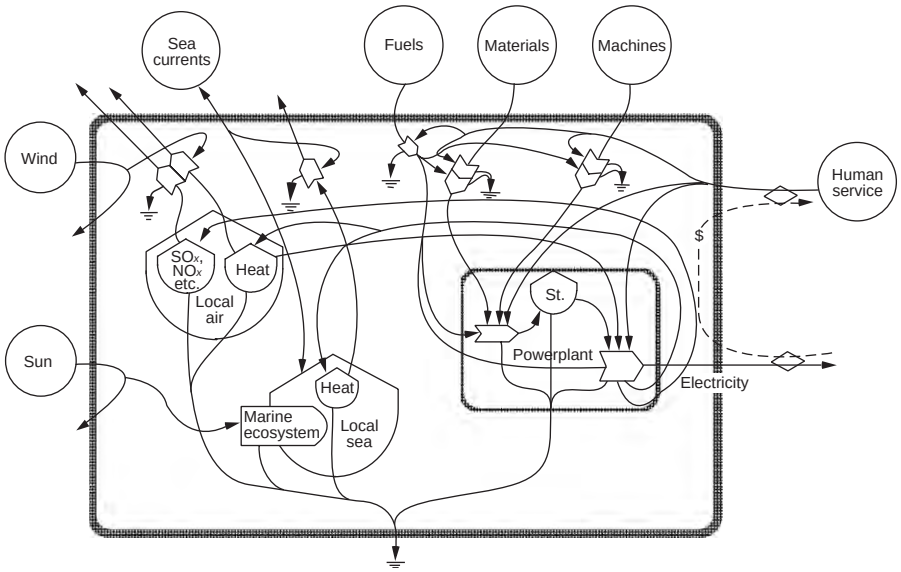

FIGURE 4 System diagram of a thermal power plant an its environment showing the use of nonrenewable energy as well as the use of the environment for cooling.

steam generation, steam turbines, electric generators, a set of electricity transformers from low to high voltage for easier transport to final users, one or more chimneys for the release of combustion gases to the atmosphere, and finally a set of heat exchangers and pumps to cool the plant off by means of river or sea water (44 m^3/s) and condense the steam. Filters and scrubbers for partial uptake of pollutants at the chimney mouth as well as fuel desulfurization devices are also used. The data for the evaluation were provided by the Italian National Electric Company (ENEL) and relate to the actual average performance of the Piombino 1280 MWe power plant (Tuscany, Italy). The plant consists of four 320 Mwe boiler-turbine-generator groups, cooled by the seawater from the nearby Mediterranean Sea. All inputs were listed and grouped according to their material components (steel, copper, etc.), then suitable energy and emergy intensity coefficients were used, according to previous studies available in the scientific literature. Labor and services are also accounted for in the emergy analysis only. Waste heat and chemicals released to the environment (seawater and atmosphere) were quantified and the amount of environmental services (cooling water, wind, etc.) needed for dispersal, dilution and abatement is calculated by means of the emergy accounting procedure. Fig. 4 shows the direct and indirect annual environmental flows supporting the construction of the plant structure (assuming a lifetime of 25 years) as well as its daily operation. The plant started to be fully operative in the year 1979, which means that it is not far from the end of its life cycle and may require a significant upgrade investment or final decommissioning and replacement by a more modern technology.

4.1.2 Wind Turbine

The investigated case study (Fig. 5) consists of a 2.5 MW wind powered field, composed with 10 single-blade, 250 kW, wind turbines M30-A, sited in southern Italy (Casone Romano). The wind field, installed in the year 1995 by the Riva Calzoni Company, is presently operated by ENEL. The distance between two generators is 150 m. Each turbine is located on the top of a 33 m support tower. Operating wind speeds are between 4 and 25 m/s. For wind speeds outside of these extremes, the turbine automatically stops. The wind field does not require any local labor for its daily activity and is directly managed from the operating company by means of remote control. The energy systems diagram of a wind power plant is shown in Fig. 5.

4.1.3 Geothermal Plant

To optimize the exploitation of the rich geothermal fields available in central Italy (Tuscany), the National Electric Company designed a 20 MW power module to be efficiently and cost-effectively installed in several sites of the geothermal area (Fig. 6). The main reason supporting the development of such a module is the need for the reduction of the time between the discovery of a new geothermal site and

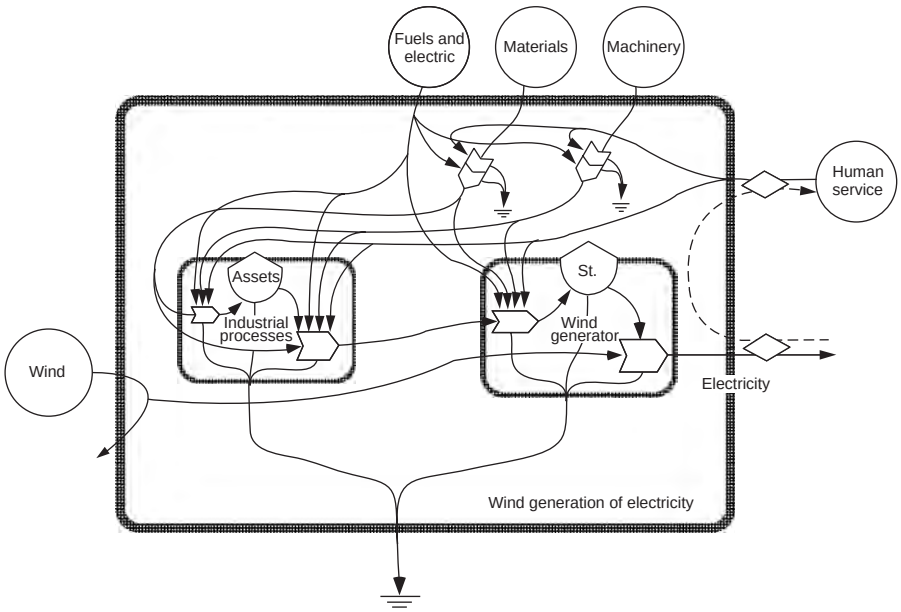

FIGURE 5 System diagram of wind power plant showing the industrial processes required to produce the generator and associated structure and the use of wind energy in the production of electricity.

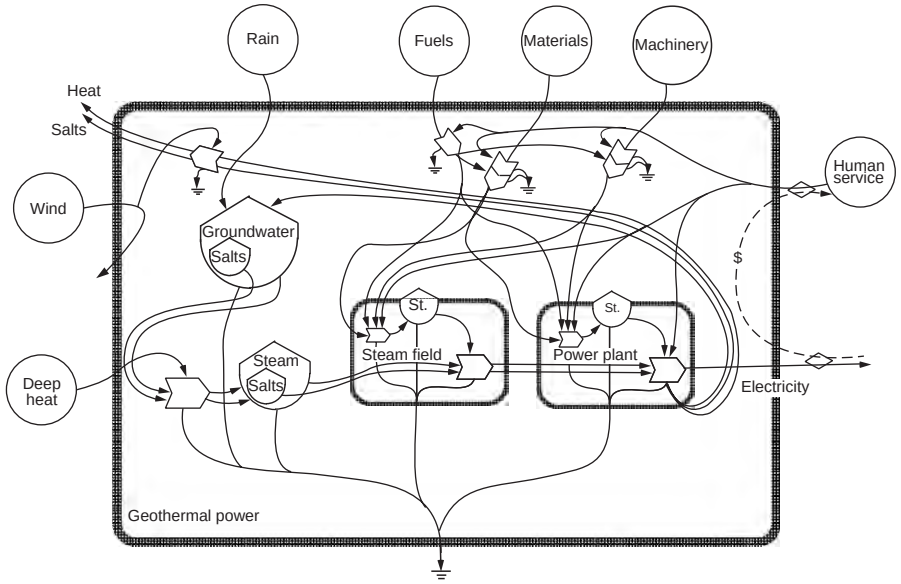

FIGURE 6 System diagram of a geothermal power plant showing the use of nonrenewable energies in developing the steam field and power plant, the use of geothermal steam, and release of heat and salts to the larger environment.

its actual exploitation. The module essentially consists of a turbine-generator group, receiving high-enthalpy fluids from nearby wells. A fraction of the extracted steam is then released to the atmosphere, through three cooling towers. The remaining fraction is, instead, condensed and reinjected into the underground reservoir to avoid their water depletion. The steam pipelines are made with steel and are insulated with rockwool and aluminum. Instead, the reinjection lines are made with glass fiber. The data used for the case study were provided by ENEL and relate the Cornia 2 power plant, sited close to Pisa and installed in the year 1994. No local labor is required. The plant is 24 hours per day distance-operated by the

company's operative station sited in Larderello, the site where the first electric plant running on geothermal heat was installed in 1904.

Geothermal fluids carry and release significant amounts of hydrogen sulphide, carbon dioxide, radioactive radon, arsenic, mercury, nitrogen, and boron. This involves plant corrosion problems as well as pollution problems in the area. For this reason, several devices have been designed for the uptake and abatement of the most dangerous chemicals. The plant as well as the environmental and technological flows supporting its activity are described by the systems diagram drawn in Fig. 6.

4.1.4 Hydroelectric Plant

The case study (systems diagram shown in Fig. 7) concerns the reservoir-dam electric plant Pollino Nord, sited in southern Italy. Its activity started in the year 1973. The reservoir has a capacity of 1000 m^3 and is located at about 600 m above sea level. Water flows out of the dam through an iron pipeline reaching the turbines located downstream, at about 50 m above sea level. Two 51 MW turbines with vertical axis convert the water energy into electricity, generating a total actual electric power of about 85 MW. The plant started its activity in 1973. No labor is required for plant operation. It is distance-operated from the ENEL headquarters in Catanzaro (southern Italy).

4.1.5 Bioethanol Production

Figure 8 describes the main steps of the process: corn production, harvesting and transport to plant, and industrial processing. Corn is processed to ethanol and distillers dried grains with solubles (DDGS), to be used as animal feed. Agricultural residues were considered as a partial source of process heat (to substitute for some of the coal), so that a lower fossil energy input can be charged to the industrial phase. However, harvesting agricultural residues depletes the amount of nutrients in soil and requires significant energy expenditure for their replacement. Soil erosion is also accelerated, with significant consequences on soil fertility. Therefore, the fraction of agricultural residues that can be actually harvested is small and depends on a variety of parameters that are not easy to determine. The evaluation was conducted assuming that approximately 70% of agricultural residues were harvested, taking some of the above mentioned consequences (loss and replacement of nutrients in soil) into account. Corn production data refer to Italian agricultural standards, while corn-to-ethanol industrial conversion refers to average available conversion technologies.

4.1.6 Hydrogen from Steam Reforming of Natural Gas

Steam reforming of hydrocarbons (mainly natural gas) has been the most efficient, economical, and

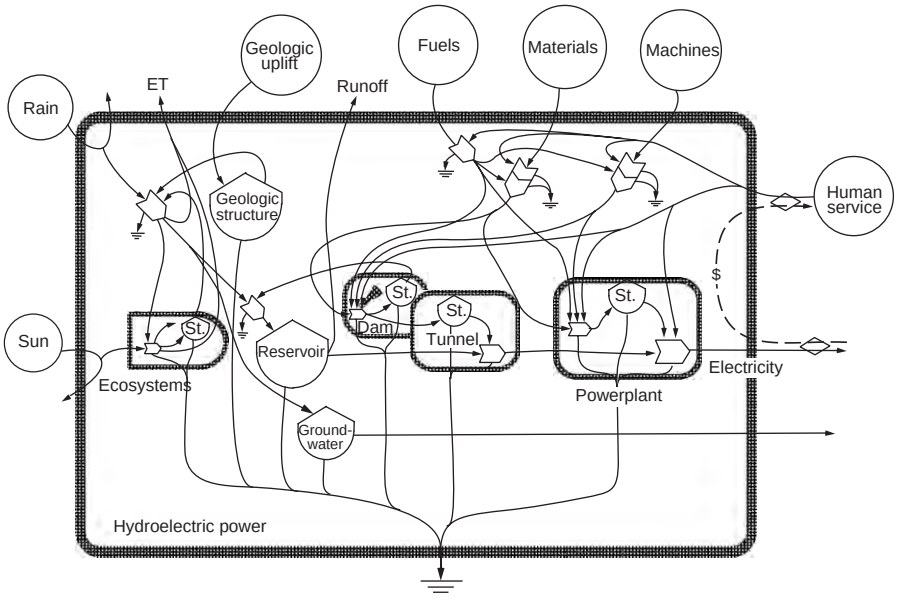

FIGURE 7 Systems diagram of a hydroelectric power plant showing the use of nonrenewable energy materials machines and human service in the construction operation and maintenance of the plant as well as the reliance of the system on geologic formation of the watershed and input of rain.

widely used process for hydrogen production. An aggregated energy systems diagram of a conventional steam reforming process is shown in Fig. 9A. The feedstock (i.e. natural gas) is mixed with process steam and reacts over a nickel-based catalyst contained inside a system of alloyed steel tubes. To protect the catalyst, natural gas has to be desulfurized before being fed to the reformer. The following reactions take place in the reformer:

$$CH_4 + H_2O \rightarrow CO + 3H_2$$
$$CO + H_2O \rightarrow CO_2 + H_2.$$

The output of the reformer is fed to a series of shift reactors and a pressure swing adsorption unit, where hydrogen is separated and purified to over 99% purity. The reforming reaction is strongly endothermic and energy is supplied by combustion of natural gas or fuel oil. The reaction temperature is usually in the range 700 to 900°C.

4.1.7 Hydrogen from Water Electrolysis

Figure 9B shows an aggregated view of the hydrogen/water electrolysis process. Alkaline water electrolysis is a well-established industrial process in which electricity is used to split water into its component elements, generating hydrogen in a 1:1 molar ratio, with cell efficiencies in the order of 80 to 90%. The following reactions take place at the electrodes of an electrolysis cell (called an electrolyzer) filled with a suitable electrolyte (aqueous solution of KOH, NaOH, or NaCl) upon the application of a potential:

Cathode reaction: $2H_2O\ (l) + 2e^- \rightarrow H_2(g) + 2OH^-\ (aq)$

Anode reaction: $2OH^-(aq) \rightarrow \frac{1}{2}O_2(g) + H_2O(l)$

Overall cell reaction: $H_2O\ (l) \rightarrow H_2(g) + O_2\ (g)$

An electrolysis plant can operate over a wide range of capacity factors and is convenient for a wide range of operating capacities, which makes this process interesting for coupling with both renewable and nonrenewable energy sources. The needed electricity can be purchased from the grid (an interesting option in the case of excess electricity production from hydroelectric plants, for example) or produced on site. In this article, the electrolysis is assumed driven by the electricity generated by the oil-powered and wind-powered plants described earlier.

4.1.8 Ocean Thermal Energy Conversion (OTEC)

OTEC is an energy technology that converts indirect solar radiation to electric power (Fig. 10). OTEC systems use the ocean's natural thermal gradient—the fact that the ocean's layers of water have different temperatures—to drive a power-producing cycle. Commercial ocean thermal energy conversion plants must be located in an environment that is stable enough for efficient system operation. The temperature of the warm surface seawater must differ about 20°C (36°F) from that of the cold deep water that is no more than about 1000 meters (3280 feet) below the surface. The natural ocean thermal gradient necessary for OTEC operation is generally

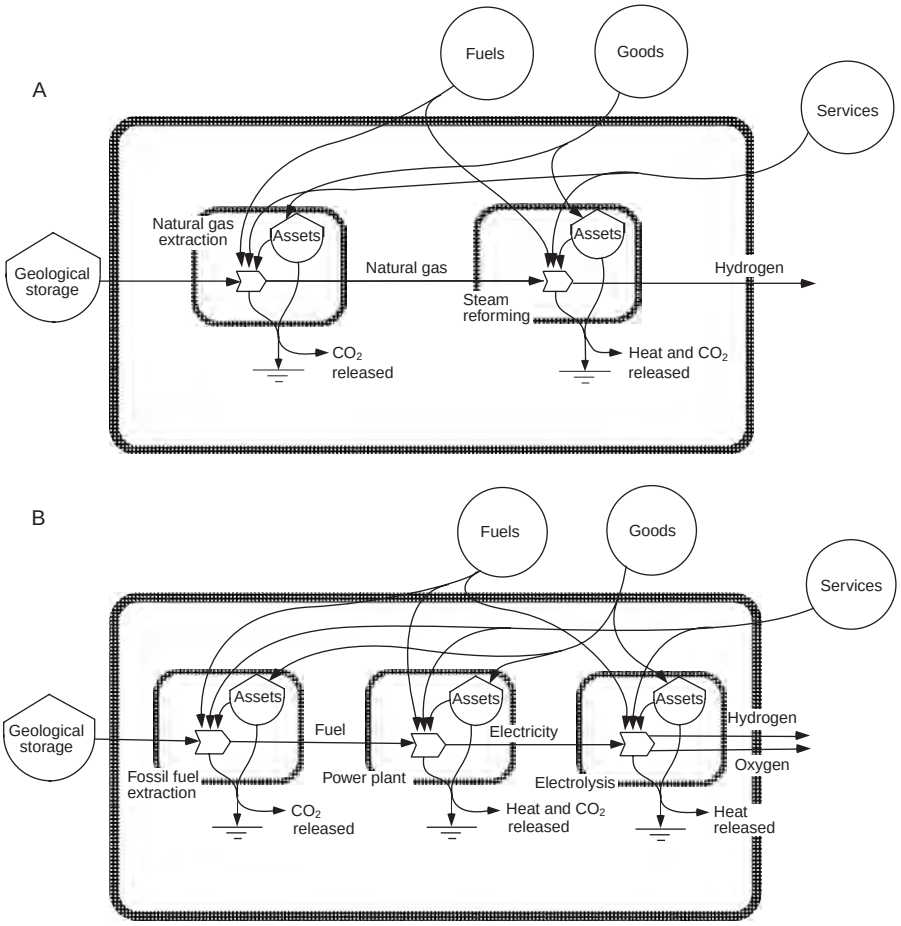

FIGURE 9 (A) Aggregated systems diagram of hydrogen production from steam reforming and (B) electrolysis.

found between latitudes 20 °N and 20° S. Within this tropical zone are portions of two industrial nations—the United States and Australia—as well as 29 territories and 66 developing nations. Of all these possible sites, tropical islands with growing power requirements and a dependence on expensive imported oil are the most likely areas for OTEC development. Electricity generated by plants fixed in one place can be delivered directly to a utility grid. A submersed cable would be required to transmit electricity from an anchored floating platform to land. Moving ships could manufacture transportable products such as methanol, hydrogen, or ammonia on board. The OTEC data for the evaluation are from Odum. He investigated the OTEC technology, performing both an energy and emergy assessment. His conclusions, based on emergy accounting, were that although OTEC shows a small net emergy yield it is unlikely to be competitive with fossil powered technologies for electricity, due to the excessive dilution of solar energy resulting into a very small heat gradient of marine water.

4.2 Methods

Apart from the OTEC plant, the case studies represent real plants, evaluated on the basis of the electricity actually generated and the fuel actually used. Therefore, calculated performance indicators may appear worse than those theoretically obtainable on the basis of nameplate power and efficiency, although the order of magnitude does not change significantly.

4.2.1 Data and Calculations

Unless specified differently, a lifetime of 25 years is assumed for each of the investigated plants or assets. Data used include construction materials, source energy, and labor in construction, as well as operation and maintenance, environmental inputs,

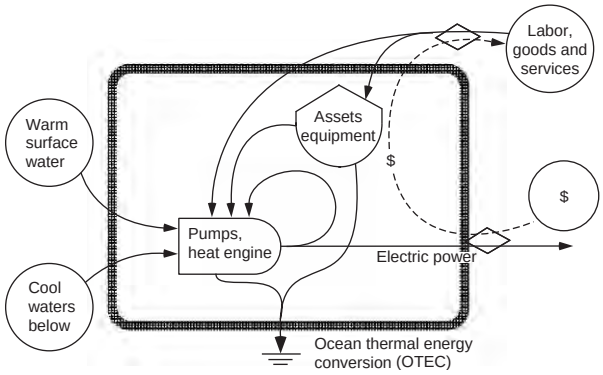

FIGURE 10 Aggregated systems diagram of ocean thermal energy conversion showing the use of labor, goods, and services (nonrenewable) and differential in surface and deep ocean water temperature.

and process outputs including electricity and pollutants. Input data for main plant components were kindly supplied by the companies producing and operating them.

All plants are analyzed using the same procedures as outlined earlier. Input data for each item (row) in the evaluation tables are the actual operational data of each plant and are converted into appropriate units using specific calculation procedures, most of which are described by Odum in his text *Environmental Accounting*. Input data to each investigated process are multiplied by suitable conversion coefficients (unit oil equivalents, g_{oil}/unit of item, for energy evaluation; transformities, sej/unit of item, for emergy evaluation), to yield energy and emergy values associated with each input item. Energy values (expressed as grams of oil equivalent) are then converted into grams of released carbon dioxide, by means of an average oil-to-carbon dioxide conversion coefficient derived from typical reaction stoichiometry. Energy, emergy, and CO_2 flows are then summed, yielding a total that is divided by the amount of the product of each plant to yield its energy cost, its transformity, and its associated carbon emissions. Finally, data are used to calculate several other energy-, emergy-, and carbon-flow indicators to obtain an overall picture of plant performance. All inputs to the electric production systems are expressed on a yearly basis. Fixed capital equipment, machinery, buildings, and so on are divided by their estimated useful life (10 to 30 years, depending on the case). Outputs are also expressed on an annual basis. CO_2 production is calculated for direct fuel combustion in thermal plants and estimated for goods and human services using multipliers of indirect energy consumption for their production. These multipliers are derived from a standardized comparison of literature in this field.

4.2.2 Performance Indicators

EEA typically evaluates energy sources and the outputs from process in their heat equivalents. Two indicators commonly used in EEA are calculated for all the investigated case studies. The first one is related to CO_2 production and global warming potential and is the amount of CO_2 released per megawatt of energy delivered. The second indicator is the output/input energy ratio (also called energy return on investment, EROI, according to Hall *et al.*). It is calculated as the ratio of heat equivalent energies of outputs and input flows and is considered as a measure of the first law energy efficiency of a process. The total input energy in this study is derived by multiplying all goods and materials consumed in the construction (divided by the average life span of the structure and equipment) and the annual maintenance of plants by energy equivalent multipliers, and adding the annual energy consumed directly and indirectly.

The output as electricity is converted to joules using the standard conversion of 3.6×10^6 J/kWh, while the masses of bioethanol and hydrogen are multiplied by their higher heating value (J/g). CO_2 releases are evaluated by multiplying the total input energy (sum of energy used directly and indirectly) by a standard stoichiometric conversion, 3.2 g CO_2/g oil equivalent. Renewable energy plants (wind, hydro, and geothermal) obviously do not burn fossil fuels directly, so their direct CO_2 emissions are lower (zero for the hydro and wind plants, but not negligible for the geothermal power plant due to underground CO_2 contained in the geothermal fluid extracted).

EMA indices are calculated in a similar way. Each item in Table VII (bioethanol) and Table VIII (wind turbine) as well as in all the other tables related to the investigated case studies is multiplied by an appropriate transformity to get the emergy input from the item to the process. The total emergy (a measure of the total environmental support or ecological footprint to the process) is then calculated by summing all inputs according to the previously described emergy algebra. Finally, a new transformity for the process output is calculated by dividing the total emergy by the exergy (sometimes the mass) of the product. Further emergy-based indicators (emergy yield ratio, environmental loading ratio, emergy index of sustainability, emergy density) are also calculated.

4.3 Results and Discussion

Comparing EEA- and EMA-based performance indicators for each kind of energy conversion device makes it possible to ascertain what pieces of information can be obtained from each one of the two approaches and to better understand the space-time scale difference between them.

A careful reading of Tables VII to X provides a rich set of information. Tables VII and VIII are given as examples of how emergy calculations are performed. Table VII refers to bioethanol production from corn (Fig. 8), while Table VIII refers to a 2.5 MW wind electricity production field (Fig. 5). Tables IX and X provide a comparison among energy-, carbon-, and emergy- based indicators in all the conversion patterns investigated. Table IX refers to electricity generation, while Table X refers to selected energy carriers other than electricity. Conversion factors used and references are clearly listed in each table.

4.3.1 Energy and Emergy Evaluations

Emergy evaluations of bioethanol production from corn (Table VII) and electricity generation from wind (Table VIII) are given as examples for a clear description of the emergy approach. These two case studies do not focus on the best available technologies and it is possible that other wind turbines or biomass-to-ethanol processes exist showing better performances. These two cases are used as more or less average-technology case studies. The same rationale applies to the other case studies summarized in Tables IX and X but not shown in detail here.

Renewable flows to bioethanol production from corn (Table VII) account for about 15.3% of the total emergy driving the process. They can be identified as the rain driving the agricultural phase and the wind dispersing the pollutants that come out of the industrial step. Electricity and fuels (including coal) account for about 17.4%, goods and machinery for 42.6%, while labor and services represent 24.7% of the total emergy input. Goods and machinery are therefore the main emergy input to the process, due to the environmental support embodied in their manufacture from raw materials.

Environmental flows as well as labor and services are not included in the conventional energy accounting, therefore a comparison between EEA and EMA requires the percentages be calculated taking these flows out of the total emergy. In so doing, fuels and electricity come out to be respectively the 29% of total emergy and the 45% of total energy, while goods and machinery account for 71% of total emergy and 55% of total energy. This means that EEA overestimates the role of direct energy inputs and underestimates the role of energy flows embodied in goods and machinery. A similar calculation can be performed for the wind turbine by using data presented in Table VIII. As far as wind plant is concerned, it can be noted that wind emergy accounts for about 82% of the total emergy input, while labor and services (4%) and goods and machinery (14%) play a much smaller role. A comparison with energy data is less significant here, since no direct energy inputs are required. It is crystal clear that EMA offers a more comprehensive picture of the whole process by taking into account the hidden environmental flows that support a given process and by evaluating their role on the scale of the biosphere, where they are compared by means of a common measure of environmental quality.

4.3.2 Embodied Energy Performance Indicators

The EEA results are synoptically shown in Tables IX and X. The EROIs of electricity generation range from a low 0.30 of the oil-powered plant to a high 23.7 of the hydroelectric plant. The geothermal and wind conversions also show high energy returns (respectively 20.7 and 7.7), while the OTEC plant only shows an energy return equal to 3.8, due to the low thermal gradient between deep and surface water temperatures. Similarly, Table X shows EROIs in the range 0.24 to 6.1 for energy carriers different than electricity (bioethanol and hydrogen). As expected, the lower value refers to hydrogen production via electrolysis with electricity generated by an oil-powered, thermal plant similar to the one described in Table IX. Instead, the highest EROI is shown by hydrogen generated via electrolysis by means of wind-powered electricity.

The net CO_2 release shows similar patterns, with higher values when direct fossil fuel combustion is involved and lower values when renewable sources drive the process, as expected. In the latter case, only indirect emissions can be calculated, linked to fuel use for the production of components and for machinery construction and operation. The surprising high emission from geothermal electricity is due to the CO_2 content of geothermal fluids.

The better performance of processes driven by renewables is clearly due to the fact that the EROI compares only commercial energies (i.e., calculates the ratio of the thermal energy delivered to the fossil or fossil equivalent energy that is provided to the

process). Energies that are not purchased, but instead are provided for free by nature (e.g., the solar energy driving the wind or the solar energy that drives the photosynthesis for corn production) are not accounted for by EEA and therefore are not reflected in the EROI or in the CO_2 release.

4.3.3 Emergy-Based Performance Indicators

A series of emergy performance indicators are given in Tables IX and X for selected energy conversion devices. Some of these processes, driven by intensive use of primary nonrenewable resources, are secondary energy conversions, while others (wind, hydro and geothermal) should be considered primary energy exploitation patterns. Their values can be usefully compared to those of the primary fuels (oil, coal, natural gas) shown in Table X. Electricity generation in Table IX shows transformities that are, as expected, process specific and range from the low value of about 1.1×10^5 seJ/J for hydro- and wind-electricity up to much higher values around 3.5×10^5 seJ/J for geothermal and oil-powered electricity. The role of labor and services in these processes can be quantified as about 5 to 10% of the transformity. This means that the main contributions to any electricity generation process are the driving forces of fuels or renewable sources, followed by the emergy associated with plant components. As a consequence, a significant lowering of the total emergy demand cannot be expected by simply moving the plant to countries with lower cost of labor, as has become very common with goods production. The OTEC plant combines very small inputs in the form of solar energy via the temperature gradient of the oceans and technological equipment and, instead, a significant input in the form of financial investment, labor, and services, to which a huge emergy is associated. This makes this plant too dependent on nonrenewable, purchased emergy inputs, very high compared to the locally available renewable flow. The transformity of OTEC electricity is around 1.7×10^5 seJ/J, but declines by more than one order of magnitude when labor and services are not accounted for.

Transformities of energy delivered in the form of energy carriers other than electricity (Table X) show similar orders of magnitude. Hydrogen from water electrolysis shows higher or lower transformities depending respectively on oil- or wind-generated electricity. Hydrogen from steam reforming of

natural gas shows a relatively low transformity. Unfortunately, only the value without services was calculated in the steam-reforming case study. However, since steam-reforming is a well-known technology, not particularly labor intensive, a dramatic increase of its transformity should not be expected when adding the emergy value of labor and services. The comparison with the transformities of primary sources in Table IV clearly shows that transformities depend on the length of the manufacturing chain. More process steps require more emergy inputs and may decrease the actual energy delivered at the end of the chain. Oil, coal, natural gas, hydro- and wind-electricity, and hydrogen from steam reforming all show transformities on the order of 10^4 seJ/J. However, when technologically heavy steps are added to further process the primary energy source, transformities grow by an order of magnitude to 10^5 seJ/J. It can be clearly understood that if bioethanol were used to generate electricity or if electricity from oil were used to refine metals, transformities would become even greater.

The other emergy indicators complement this picture, by showing low EYRs for oil-powered and OTEC electricity as well as for bioethanol and hydrogen from thermal electricity. Not surprisingly, all the other energy conversions have EYRs around 5. Similarly, high ELRs characterize oil-based patterns, as well as bioethanol and OTEC electricity, while very low ELRs (below 1) are shown by the processes relying to a larger degree on renewables. As a consequence, the aggregated sustainability measure expressed by the EIS ranges from a low 0.06 for oil-based processes up to a significantly high 25 for wind-based ones. Again, the OTEC plant shows a very low performance, quantified by an EIS lower than 0.01. However, let's recall that the evaluation of OTEC is based on a feasibility study and not on an actually existing plant.

calculate bad performance indicators for oil-based energy systems. EEA simply indicates that the ability of the investigated devices to operate the conversion chemical energy to work is low, as expected for any engine subject to the second law and the Carnot factor. EMA adds an indication of poor sustainability in both the global dynamics of the economy and the biosphere. The same consideration applies to the investigated bioethanol from corn. In this case, however, EEA indicates a small thermal energy return, which supports several claims of bioenergy supporters in favor of increased use of photosynthesis for energy. On the other hand, EMA jointly evaluates the environmental work diverted from its natural pattern in order to provide free renewable inputs, to replace fertile soil eroded by the intensive tilling, to supply fuels, goods and machinery, to support labor and services, and concludes that the global sustainability of this product is so low that it cannot be usefully pursued as an alternative energy source.

Much lower environmental work is required to deliver energy via hydro- and wind-powered turbines, which simply means that less environmental activity is diverted from its original patterns to provide electricity to the economy. This ensures that these technologies are not withdrawing too many resources from the global biosphere dynamics. Renewable energies (sun, wind, rain and deep heat) already have a role in nature's self-organization processes, so that diverting to much of them to support an economic process reduces their input to other natural processes. EEA assigns a more favorable energy return to hydro- than to wind-electricity, while EMA-based sustainability is much greater for wind conversion, due to equal EYRs and much lower ELR of wind compared to hydro.

Geothermal energy return is surprisingly high according to EEA, since the huge amount of deep heat (high-quality flow) is not accounted for as an input. EMA indicators still suggest a good performance for geothermal electricity, but the fact that a large fraction of high-quality deep heat is dispersed increases the transformity of the output. In addition, the load on the environment due to the release of chemicals extracted with the underground fluid increases the ELR and decreases the global EIS of the process. None of these considerations could be obtained by the traditional energy analysis.

A final remark about OTEC is also illuminating. The process was evaluated as a net energy supplier according to EEA, due to an energy return equal to 3.8. However, this favorable result cannot be obtained without supplying a significant amount of resources in the form of capital, labor, and services. These resources, generated by previous investment of primary emergy sources, decrease the global sustainability of the process to values that make its viability very unlikely, more than its actual feasibility.

4.3.5 EEA and EMA: Scale and Energy Quality

Emergy analysis and embodied energy analysis treat the conceptual issues of scale and quality of energy very differently. From these differences, significant discussion has arisen over the years (see, for instance, the article in *Ecological Economics* titled "Embodied Energy Analysis and Emergy Analysis: A Comparative View" by Brown and Herendeen). In the following discussion, two important issues are elucidated: temporal and spatial scale, and energy quality.

4.3.5.1 Issues of Scale It should be kept in mind that EEA and EMA have different windows of interest (although they also share several common features) and therefore are used to investigate different questions about a given process.

In particular, EEA provides a measure of the overall commercial (oil equivalent) energy invested to support a production process. Its outcome is the amount of oil equivalent energy required to drive a process or to generate a product. Its spatial scale is the actual scale of the process, although it may in principle include the spatial scale of the previous commercial processes from which the input flows came from (for instance, if a mineral from a faraway country is fed to the process, transport must also be accounted for). Its timescale is the time required to extract the raw materials and to actually make the product. In principle, time is only accounted for in order to calculate the fraction of embodied energy of assets and machinery that are used up in the process and that therefore should be assigned to the product. Since machinery and assets have little embodied energy relevance, this time and the related amount of assets are often disregarded by EEA analysts.

Instead, the outcome of EMA is a quantification of the environmental support provided by nature to a process, which may be or may be not under human control. The spatial scale of EMA is larger than the actual scale of the process, since the evaluation also includes free environmental flows from - the larger scale of the biosphere that are not accounted for in energy analysis. In a similar way, the EMA timescale is the total time it took to make a resource via all natural processes involved (generation of minerals, fossil fuels, topsoil, water storages, etc.):

embodied in the transformity of a resource is the global environmental input required over space and time to drive the geological and biosphere processes, which converge to build a resource storage or to support a resource flow. Emergy-based indicators therefore have a built-in memory of the process history—that is, the real "trial and error" pathway that was followed by environment and humans to generate the product, including those pathways discarded by natural selection for maximum power output. The latter sentence may not completely apply to short timescale of technological processes and human economies, but results can be managed in such a way as to take into account the further uncertainty related to patterns that are not yet optimized.

4.3.5.2 Issues of Quality Energy has been defined as the ability to do work, based on the physical principle that work requires energy input. Energy is measured in units of heat, or molecular motion, the degree of motion resulting in expansion and quantified in degrees of temperature. All energies can be converted to heat at 100% efficiency; thus, it is relatively easy and accurate to express energies in their heat equivalents. The basic units of energy are the amount of heat required to raise a given amount of water a given number of degrees of temperature. Thus, the calorie is the amount of heat required to raise 1 cm^3 of water 1°Celsius. A joule is equal to 4.187 calories.

Heat-equivalent energy is a good measure of the ability to raise water temperature. However, it is not a good measure of more complex work processes. Processes outside of the window defined by heat engine technology do not use energies that lend themselves to thermodynamic heat transfers. As a result, converting all energies of the biosphere to their heat equivalents reduces all work process of the biosphere to heat engines. Human beings, then, become heat engines and the value of their services and information is nothing more than a few thousand calories per day. Obviously, not all energies are the same and methods of analysis need reflect this fact.

Different forms of energy have different abilities to do work, not only in terms of amounts of work but also in terms of kind of work. It is therefore necessary to account for these different abilities if energies are to be evaluated correctly. A joule of sunlight is not the same as a joule of fossil fuel or a joule of food, unless it is being used to power a steam engine. Sunlight drives photosynthesis. A system organized to use concentrated energies like fossil fuels cannot process a more dilute energy form like sunlight, joule for joule. Evaluation of energy sources is system dependent. The processes of the biosphere are infinitely varied and are more than just thermodynamic heat engines. As a result, the use of heat measures of energy that can only recognize one aspect of energy, its ability to raise the temperature of things, cannot adequately quantify the work potential of energies used in more complex processes of the biosphere. As in thermodynamic systems where energies are converted to heat to express their relative values, in the larger biosphere system as a whole energies should be converted to units that span this greater realm, accounting for multiple levels of system processes, ranging from the smallest scale to the largest scales of the biosphere, and accounting for processes other than heat engine technology. The ability of driving processes other than engine-like ones is a new quality aspect of resource flows, which is accounted for by emergy analysis.

Net energy evaluations of energy sources and transformation processes are designed to provide information concerning efficiency and potential yield under the engine-like point of view cited previously. This is something that energy analysis does appropriately. It is able to offer at least two different results:

1. As embodied energy analysis, it provides a measure of the commercial energy cost of a product (MJ or grams of oil equivalent per unit of product). When the product is energy, this measure is better expressed as EROI (joules of energy delivered per unit of energy provided to the process).

2. As exergy analysis at the process scale, it provides a measure of thermodynamic efficiency, indicates possible optimization patterns, and finally ranks the quality of the product from the user-side point of view.

Neither of these two energy analysis patterns is able to provide any significant insight into the quality of each input and output flow in the larger scale of the biosphere, as pointed out earlier. Neither of them takes into account the role of the environmental work supporting both ecosystems and human societies, in particular the role of unmonied inputs provided by nature to human economies. This is something that requires a scale expansion and a change of perspective, from local to global, i.e., the emergy approach.

5. SUMMARY

This article is a brief synopsis of the emergy accounting methodology. Emergy-based case studies of energy conversion systems are presented to allow both an increased understanding of how the method is applied as well as a critical comparisons with embodied energy analysis. Much like a short intensive course given in a limited time frame, this article has touched on what is most important. There is much literature explaining the theory and concepts of the emergy approach as well as applications of the method to a large number of case studies, ranging from ecosystems to socioeconomic systems, to evaluations of the biosphere, including energy processing, agriculture, industry, tourism, wastewater management, recycling patterns, generation and storage of culture and information, development of cities as emergy attractors, and scenarios for future societal development. References to emergy literature are given throughout. Starting on 1999, an international emergy conference takes place every other year. The books of proceedings of the first two emergy conferences provide a significant set of theoretical and applied papers for further reading. In all cases, the common thread is the ability to evaluate all forms of energy, materials, and human services on a common basis by converting them into equivalents of one form of energy, solar emergy, a measure of the past and present environmental support to any process occurring in the biosphere.

Glossary

application for permit to drill (APD) An application to drill a well; submitted by a lessee or operator to the Bureau of Land Management.
Bureau of Land Management (BLM) The Department of the Interior agency responsible for managing most federal onshore subsurface minerals.
environmental impact statement (EIS) A written analysis of the impacts on the natural, social, and economic environment of a proposed project or resource management plan.
lease An authorization to possess and use public land for a period of time sufficient to amortize capital investments in the land.
public lands The lands owned by the federal government, including parks, monuments, wilderness areas, refuges, underground mineral reserves, marine sanctuaries, historic parks, forests, and seashores.
withdrawal An action that restricts the disposition of public lands and that holds them for specific public purposes.

Public lands in the United States have provided supplies of raw energy resources for over a century. The story of the harvest and administration of energy from natural resources reveals the public debate and contest that often results when resources are owned in common. Recent developments suggest that future use of these resources will continue to be hotly debated.

1. INTRODUCTION

When Woody Guthrie wrote the song *This Land Is Your Land*, his rough-toned voice instructed Americans to recall that "this land was made for you and me." Nowhere is this American ideal more obvious than in the nation's publicly owned lands—or so it would seem. Yet the spirit of Guthrie's idealism has rarely penetrated the administration of the more than 600 million acres of land that belong to each citizen. One-third of all national land is administered by the federal government and is owned collectively by the people of the nation. For a variety of reasons, including climate and the late entry of Euro-American settlers, most of the federal land can be found in the American West.

Public lands include parks, monuments, wilderness areas, refuges, underground mineral reserves, marine sanctuaries, historic parks, forests, and seashores. Throughout American history, the administration of this great national resource has been tied to politics and the powerful elements of economic development. The use of public land sites and particularly the harvest of natural resources existing on them have been consistently debated in recent years. Should these lands be viewed as vast storehouses of resources on which our nation depends? Or are federal lands intended more for preservation, regardless of valuable resources that might be found within their borders? And, of course, when development takes place, who should gain the financial benefit?

As a matter of existing law, mineral resources on public lands exist as national property, primarily due to specific strategies to foster development in the western United States. Outside variables, including the needs of war or domestic crisis or even presidential preference, influence the perceptions of mineral resources, particularly those resources related to energy production. Although the use and availability of such resources vary with the philosophy of each presidential administration, each American leader has viewed these energy sources as an important tool for economic development of communities in the western United States. The harvest of resources on public lands carries economic benefits locally and nationally (see Table I).

Although wood must be included as an energy resource that has been harvested from federal lands, the major sources in the 20th century have included: coal, oil, natural gas, shale, uranium, and geothermal. In recent years, there has additionally been a concerted effort to develop alternative energy resources (such as solar and wind) on public lands. By the end of the 20th century, the energy industry estimated that Americans received 30% of their fuels for energy production from public lands.

[a] Data estimated from available records.

[b] Chiefly public, private, and preemption sales, but includes mineral entries, scrip locations, and sales of town sites and town lots.

[c] The homestead laws generally provided for the granting of lands to homesteaders who settled on and improved vacant agricultural public lands. Payment for the lands was sometimes permitted, or required, under certain conditions.

[d] Universities, hospitals, asylums, etc.

[e] For construction of various public improvements (individual items not specified in the granting acts), reclamation of desert lands, construction of water reservoirs, etc.

[f] The government has confirmed title to lands claimed under valid grants made by foreign governments prior to the acquisition of the public domain by the United States.

[g] The timber and stone laws provided for the sale of lands valuable for timber or stone and unfit for cultivation.

[h] The timber culture laws provided for the granting of public lands to settlers on condition that they planted and cultivated trees on the lands granted. Payments for the lands were permitted under certain conditions.

[i] The desert land laws provided for the sale of arid agricultural public lands to settlers who irrigated them and brought them under cultivation.

2. ENERGY FOR ALL?

The remaining oil, natural gas, and mineral deposits in the continental United States are concentrated in the American West, where they were created between 40 million and a few hundred million years ago. The abundance of such resources on public lands is a historical confluence of variables: lands that were unsettled and therefore taken by the federal government happen to have been the site, thousands of years ago, of ecosystems that today result in abundant energy resources. Western sites such as Fossil Butte National Monument (Wyoming) and Dinosaur National Monument (Utah) contain the fossilized remains that demonstrate abundant life many yeas ago, both in and out of the sea. Of course, as these ancient plants and animals decomposed over millions of years, extreme heat and pressure transformed them into resources that can be mined and burned to provide energy.

Such nonrenewable sources are just a fraction of the available energy resources. Today, the open space available on much of the federal lands has also become a resource for the development of another type of energy: renewable, including wind, solar, and water power. The U.S. Department of the Interior (USDI) oversees the leasing of lands for this development, including mining. Within USDI, the Bureau of Land Management (BLM) manages the development of all fossil fuels and minerals on nearly all of the lands, excluding areas of special jurisdiction such as the Naval Petroleum Reserves

[a] Lands under the exclusive jurisdiction of the Bureau of Land Management (BLM) (and resources) managed solely by the BLM. The table includes all Uperfected entries except for those involving reclamation and forest homesteads. Differences in fiscal year 1997 acreage from the previous year are due to land acreage acquired by the BLM; exchange land acreage received by the BLM; exchange BLM acreage (surface estate only) patented out by the BLM; withdrawn land acreage restored to BLM's jurisdiction; withdrawals, rights-of-way, acreage adjustments in carryover data.

[b] The following types of surveyed and unsurveyed public and ceded Native American lands are included: areas withdrawn under the executive orders of November 26, 1934, and February 5, 1935 (43 CFR 2400.0-3 *et seq.*); areas embraced in mineral withdrawals and classifications; area withdrawn for survey; and areas restored to entry within national forests (Act of June 11, 1906, 34 Stat. 233, 16 U.S.C.,§§ 506–509), within reclamation projects (Act of June 17, 1902, 32 Stat. 388) and within power site reserves (Act of June 10, 1920, 41 Stat. 1063; 16 U.S.C.,§§ 791). These lands are not covered by any nonfederal right or claim other than permits, leases, rights-of-way, and unreported mining claims.

[c] Land Utilization project lands, purchased by the federal government under Title III of the Bankhead–Jones Farm Tenant Act and subsequently transferred by various executive orders between 1941 and 1958 from jurisdiction of the U.S. Department of Agriculture to the U.S. Department of the Interior, now administered by the Bureau of Land Management. Acreages are within grazing districts unless otherwise noted.

and hydroelectric watershed development areas that are administered by the Army Corps of Engineers (see Table II).

The sheer amount of energy resources on federal lands is staggering. Of the 75.6 million acres of coal-bearing public lands, only 1% is currently being

mined. As for oil and gas, energy companies are actively working between 18,000 and 25,000 wells on public lands, with tens of thousands more sites held in reserve. A rarer mineral, uranium, is processed to create nuclear energy, which provides electricity to millions of homes, schools, and businesses. About one-third of all oil and gas comes from public lands. In addition, public lands are estimated to contain about 68% of all undiscovered oil reserves and 74% of all undiscovered gas reserves in our country. Nearly all reserves of uranium are found on federal land. Public lands are also used for harvesting hydroelectric power, although these areas are administered by the Army Corps of Engineers.

Regardless of the resource, the story of the harvest and administration of this energy supply reveals a theme that recurs in many publicly owned areas: public debate and contest. If studied over time, the use and management of the energy resources on public lands demonstrate important changes in the ethics guiding the management of federal lands. In addition, though, a survey of public land use demonstrates a public controversy that promises to rage deep into the 21st century.

3. GENERAL PHASES OF PUBLIC LAND ADMINISTRATION

Broader philosophical ideas, called ethics, toward land-use inform the administration of public lands. For the purposes of this discussion, the administration of public lands can be separated into four distinct eras or shifts in these larger, governing ethics. Such ethics, of course, are formed by a complex set of cultural, social, and political variables. As a publicly administered entity, public lands are subject to the influence of larger patterns within American society. In the case of energy development on public lands, the predominant cultural variable has been the ideological shifts caused by the evolution of the modern environmental movement in the 20th century. The ethic of the environmental movement has provided a nonutilitarian impulse toward the administration of the public domain.

Although the overall progression of public land use has moved toward incorporating an environmental ethic into the general management of the land, there have been a few crucial junctures in which the overall trajectory of this policy shift has been interrupted by a backlash of regressive efforts at development. After introducing the overall phases of public land administration, the focus here will be to trace the general chronology of legal restrictions on public land policy, to explore how the harvest of specific resources has been affected by these laws, and, finally, to shed light on a few of these interruptions in the overall evolution of public lands policy. The data in Table III detail how public lands were allocated in 1996.

3.1 Settlement Phase

The settlement phase of land use grew out of the nation's emphasis on settling or reclaiming nearly 1.8 billion acres of original public domain. Hundreds of laws were passed between 1785 and 1878 that were designed to encourage settlement and development of the timber, mineral, and forage supplies. Typically, such policies said little about the native peoples who were being displaced by this disposal of land or about the fashion in which the lands were to be developed. This phase of land use had little to do with energy development, because it predominantly concerned an era in which there was little use of fossil fuels. Growing out of this approach to land use, however, Congress created the General Mining Law of 1872, which remains in effect to govern mining on public lands. The General Mining Law grants free access to individuals and corporations to prospect for minerals in public domain lands. Once anyone discovers a location, they can stake a claim on the mineral deposit. This claim provides the holder the right to develop the minerals and may be "patented" to convey full title to the claimant. In this stage of land use, the federal government clearly prioritized the stimulation of new use over any other consideration.

3.2 Resource Conservation Phase

Growing out of the American conservation movement of the late 1800s, the resource conservation era in public land use emphasized progressive ideals, particularly those expressed during the administration of President Theodore Roosevelt (1901–1909) by the president and his chief advisor on land management, Gifford Pinchot. This era marked the beginning of the nation's first period of public land stewardship. President William Henry Harrison previously began the forest reserve system with land appropriations before solidifying it the Organic Act of 1897.

Roosevelt and Pinchot emphasized forest management, expanding the reserves to 148 million acres. Energy resources, other than wood, attracted the attention of progressives with the Coal Lands

[a] Purchase money includes all revenues collected during the reporting fiscal year at allowed and approved stages from all ongoing cases leading to patent; however, this money is not always received in the same year that the application is allowed or approved, or in the same year that the patent is issued. Purchase money enters into the land exchange process because exchanges must result in equal value given and received by both parties; this means that cash payments are sometimes made or received by the Bureau of Land Mangement to ensure an equitable exchange.

[b] FLPMA, Federal Land Policy and Management Act of 1976.

[c] Patents issued under Sections 203 and 209 of the Federal Land Policy and Management Act of 1976 (43 U.S.C. §§ 1713, 1719).

[d] Includes two Certificate of Transfer/Change of Use patents.

[e] Public land sale (2.5 acres), Santini–Burton Act of December 23, 1980 (94 Stat. 3881; Public Law 96-586).

[f] Public land sale patent under the Act of September 19, 1964 (78 Stat. 988; Public Law 88-608).

withdrawal in 1906 that allowed the government to reserve mineral rights on 66 million acres. Initially, this reservation included oil and gas, though it would be further expanded to include many other minerals. Roosevelt also withdrew other public lands from settlement, using them to create national parks, monuments, wildlife refuges, and military bases. Within such sites, this era saw an increase in control over the use of the resources on public lands, including legislation such as the Mineral Leasing Act of 1920 and the Taylor Grazing Act of 1934. Pinchot's conservation ethic was reflected in laws that promoted sustainable use of natural resources. These ideas were also of interest to President Franklin Delano Roosevelt, who used the Civilian Conservation Corps (CCC) during the 1930s to carry out many of these ideas on public lands.

3.3 Post-World War II Phase

During World War II and for most of two decades following it, the federal management of public lands went along with nationwide initiatives to stimulate national growth and international security. In 1946, the Grazing Service merged with General Land Office to form the BLM, the entity that oversees

the majority of the public lands in the western United States. The pressure to harvest resources from these lands intensified with the need for materials for war and the expansion of American consumption with the massive growth of its middle class.

With the beginnings of environmentalism in the late 1950s, many Americans grew more concerned that public lands were not subject to environmental assessment prior to use. This shift in overall ethics is generally accepted to have grown from the effort to prevent the damming of the Green River in Dinosaur National Park in 1954. Although the environmental movement influenced land use in national parks to a much greater degree, the public lands shifted more toward a compromise philosophy of "multiple use."

3.4 Environmental Protection Phase

Although the era of environmental protection has met with significant interruptions, the overall pattern from 1960 to the present has been toward a more environmentally sustainable pattern of use on public lands. The Multiple Use Sustained Yield Act in 1960 was followed by the public outcry related to Rachel Carson's publication of *Silent Spring* in 1962. The ensuing flurry of environmental legislation culminated in 1969 with the National Environmental Policy Act (NEPA), which created the Environmental Protection Agency (EPA) and required that any development on federally owned lands needed to be preceded by an environmental impact statement. Ecological concepts, such as ecosystems and watersheds, provided administrators with a new way of viewing public lands. No longer simply a storehouse of potential resources, each of these sites could now be seen as part of larger, complex natural systems. This awareness crystallized during a serious period of contestation over the use of public lands in the late 20th century.

4. ESTABLISHING THE LEGAL FRAMEWORK

The basic tool for defining each of the eras in public land use has been laws or regulations. Throughout the history of public lands, the primary rationale for their administration was their usefulness. If settlers had found reasons to build communities in certain areas, it is likely that those areas would not have become public lands in the first place. Vast tracts of the territories that became states in the late 1800s were simply unwanted by settlers and developers. Similar to the Homestead Act, the General Mining Law of 1872 provided incentives to settlement and development (see Table IV). Typical of legislation of this era, the General Mining Law emphasizes individual rights with minimal government management. The law prioritizes free and open access to the land and relatively unlimited opportunity to explore and develop resources. Developers were offered access to permanent, exclusive resource rights and were exempted from paying royalties to the federal government. Clearly, the law is based on the simple motive to spur development.

The success of the effort of the General Mining Law to stimulate western development relied on allowing open exploration. During the late 19th century, little was done to stop exploration from growing rapidly into mine development and full-blown extraction. In these early years, miners were not required to share production, to create joint ventures, or to pay taxes or royalties. Many mining expeditions proceeded largely unnoticed on public lands. Today, the Mining Law continues to provide the structure for much of the western United States mineral development on public domain lands. The unfettered basis of use and ownership established by the 1872 law continues to fuel the debate over how to harvest energy and mineral resources from public lands. The basis for such law was the assumption that there were no alternative criteria for land valuation than the resources that it held. The basis for much of the debate at the end of the 20th century revolved around the simple question of what would happen when, for a variety of reasons, this land became desirable.

These debates in the 20th century slowed the unlimited development of the earlier years. Many of the public lands had acquired additional importance, independent of energy and mineral resources. Additionally, such development now rarely proceeded unnoticed. Some Americans began calling for energy companies to share revenues with the land's owner through royalties. Other observers reflected a growing call for more stringent oversight of the extraction process. This call resulted in the 1920 Minerals Leasing Act. For the first time, this act closed some federal lands to open access. Most often, such lands then became available for leasing. The 1920 act established a broad framework for leasing and for the payment of royalties. Lands were to be designated as "known mineral areas" (KMAs) and then administered by one of two methods: (1) preference right leasing, which provided exploration permits that would expire if the search was unsuccessful, or

(2) competitive bidding for designated tracts, which used lotteries, oral auctions, sealed bids, or other formats to disperse the rights to KMAs and transfer them into known leasing areas (KLAs).

Eventually, the Competitive Bidding Act would be made even more specific. For coal, the law differentiated between new or maintenance tracts, but still required bids for existing operators to continue mining an existing site. Oil and gas development used reservoir studies to determine the pattern of leasing and lottery systems. In 1987, lottery systems were discontinued for oil and gas and development and were replaced by a familiar pattern in which industry representatives nominated tracts, which were then assessed for their environmental acceptability.

Neither the 1872 Mining Law nor the 1920 Mineral Leasing Act contained any direct environmental controls, but mining claims are subject to all general environmental laws as a precondition for development. These restrictions and requirements grew out of additional legislation, particularly the seminal environmental policies of the 1960s and 1970s, including the Multiple Use Sustained Yield Act, Wilderness Act, National Forest Management Act, National Environmental Policy Act (NEPA), and Federal Land Policy and Management Act. To varying degrees, each of these policies addressed environmental protection, multiple use, and management of federal land generally. By imposing new requirements on agency actions, and by withdrawing some federal lands from development, these acts have significantly influenced mineral development on public lands.

By far, the most critical policies relating to the administration related to the formation and structure of the BLM. When it was formed by merging two portions of the U.S. Department of the Interior (the General Land Office and the Grazing Service) in 1946, the BLM became entrusted primarily with the management of the remaining public domain and railroad/wagon road grant lands. The BLM also has the primary responsibility for the management oversight of the mineral domain that underlies the public lands. As with the sister agencies, the BLM is heavily involved in forest and rangeland planning, as well as keeping the official land status records of all public federal lands. Over time, the BLM followed the lead of the U.S. Department of Agriculture (USDA) Forest Service and adopted policies of multiple use and, eventually, of ecosystem management. In many cases, BLM lands are adjacent to or intermingled with other public lands, particularly National Forest land. The BLM essentially operated under these previously existing acts until congressional discussion over forest management in the Forest Service came to a head in the mid-1970s. This debate resulted in the passage of the Federal Land Policy and Management Act of 1976 (FLPMA), which provided the BLM with its "organic act"—albeit three decades after its founding.

FLPMA brought the greatest change to the administration of public lands in American history. Through FLPMA, BLM acquired an unequivocal

statutory basis for its public land management policy; however, debate continued over what exactly this meant. The 1934 Taylor Act had provided for management of natural resources on public land "pending its final disposal." To some observers, the phrase spoke to the old policy of transfer of public lands into private ownership; to others, it provided an argument against federal investment in land administration or rehabilitation. FLPMA, however, clearly prescribed retention of public lands in federal ownership as the rule and made transfer a carefully circumscribed exception. FLPMA established or amended many land and resource management authorities, including provisions on federal land withdrawals, land acquisitions and exchanges, rights-of-way, advisory groups, range management, and the general organization and administration of BLM and the public lands. FLPMA also called for public lands and their resources to be periodically and systematically inventoried. The BLM was empowered to use the data to create a plan for each site's present and future. Additionally, after many years of debate, FLPMA also specified that the United States must receive fair market value for the use of public lands and their resources.

Finally, BLM was required to administer public lands in a manner that protected the quality of scientific, scenic, historical, ecological, environmental, air and atmospheric, water resource, and archeological values. Where appropriate, BLM was also empowered to preserve and protect certain public lands in their natural condition, particularly when such preservation would provide food and habitat for fish and wildlife. Of course, BLM also remained responsible for providing sites for outdoor recreation and human occupancy and use of such sites. In short, FLPMA proclaimed multiple use, sustained yield, and environmental protection as the guiding principles for public land management. Thanks to FLPMA, BLM took on the responsibility of administering public lands so that they are utilized in the combination that will best meet the present and future needs of the American people for renewable and nonrenewable natural resources. Although this remains the role of BLM today, there have been many exceptions to this jurisdiction.

5. MAKING LEGAL EXCEPTION: NATIVE AMERICAN COMMUNITIES

There remain areas of federal lands that do not cohere to these legal regulations. For instance, it is reported that 80% of the nation's uranium reserves, 33% of the nation's low-sulfur coal, and 3–10% of the recoverable oil and gas are located on Native American reservation land. Problems of jurisdiction and ownership have highlighted the history of resource extraction on native lands. More important, though, are the health, social, and environmental impacts that have been noted where such development has been allowed to take place.

Outside sources approached Native American reservations for energy resources as early as 1920. For instance, the Navajo's prolonged involvement with oil development began with the influence of New Mexico's own Secretary of the Interior Albert B. Fall (who will be discussed later for his pivotal role in the management of energy resources on federal land). With one of Interior's charges being to administer Native American reservations, Fall soon looked toward reservation land as a vast, untapped (and unprotected) resource. Native peoples, Fall wrote, were "not qualified to make the most of their natural resources." Using the General Leasing Act of 1920, Fall attempted to clarify the status of treaty lands for leasing so that the government could do the leasing for the Native Americans. Although Fall's perspective grew from a desire to battle waste, public sentiment after World War I held that the United States would run out of oil within 10 years. Fall saw to it that oil companies won leases on reservation land, particularly that of the Navajos in New Mexico. In addition, he conspired with oil companies to provide native occupants with ridiculously low royalty rates. Historian Kathleen Chamberlain notes that oil intensified factions within the native community. In sum, she writes, "oil also expedited a shift from subsistence and barter to a wage economy." Although oil generated some jobs for the community, it never neared the promised levels.

Throughout the history of energy development on Native American lands, the development has been found to undermine tribal and family values and identity. For instance, in Hopi and Navajo experiences, wealth from royalties was spread unevenly and the large influx of wealth disturbed traditional hierarchies within the culture. Additionally, the non-Native American workers, who were necessary to energy companies for reservation development of energy resources, represented a persistent threat to tribal sovereignty. Possibly the most invasive change that energy development has wrought on Native American groups is on the traditional political process. In nearly every case, the debate over leasing lands for extraction has bitterly divided tribal leadership,

ultimately resulting in long-term impacts on the political structure of the group. With such breakdown, the reservations become what scholars have called a "colonial reservation economy." Some of the most troubling instances involved negotiations with the U.S. federal government. During World War II and through the Cold War, uranium was mined from Hopi and Navajo reservations in Arizona. The mine remnants as well as the remaining waste have contributed to significant rises in cancer and other health problems. Additionally, many Hopi and Navajo men worked in the mines and have therefore contracted a variety of ailments, particularly lung cancer.

Since the 1970s, Native American groups have attempted to use the courts to acquire fair royalty rates and recompense for health hazards. This has been an uphill battle, with various successes starting in the late 1980s. The Native American community's lessons about the community impact of energy development blossomed into an organization, the Council of Energy Resource Tribes (CERT), which helps each tribe to complete independent management of its energy resources. This has helped many tribes to acquire fair royalty rates as well as to initiate extensive development of alternative sources on western reservation land.

6. HISTORY OF ENERGY DEVELOPMENT ON PUBLIC LAND

The laws and ideas relating to energy development on public lands have changed due to shifts in larger ethics within American society, but also due to the type of resource being extracted. Primarily, the pressure to mine energy resources grew as resources such as petroleum became more and more critical to American life and national security. The most significant change followed the increased use of petroleum for transportation after 1900. For instance, by World War I, the energy reserves on public land had been transformed from an attraction for potential settlement to a matter of national security. In World War I, fossil fuels became directly linked to the nation's ability to protect itself and maintain global security. Petroleum, however, is only one example. In this section, three specific energy resources and the time period that they most influenced are considered.

6.1 The Beginnings with Coal

The first energy resource to be granted unique status on public lands was coal. The Coal Act of 1864 gave the U.S. President authority to sell coal beds or fields for no less than $20/acre. Lands not sold in this fashion could be available to the general public at the minimum price under the general land statutes. In 1873, Congress authorized citizens to take vacant coal lands of not more than 160 acres for a minimum of $10/acre. This law governed the disposal of coal lands until 1920. Precious metals were governed much more freely. In all probability, the rationale behind this distinction lay in the relative ease of locating coal compared to that of most precious metals.

The importance of the coal supply to national development would make it a major political issue in the early 20th century. In rapid succession, the Roosevelt administration proposed controlling the federal grazing lands, increasing the national forests, and withdrawing the coal, oil, and potash lands from sale. In this same period, the administration also reserved potential waterpower sites and set out to reclaim the arid lands of the West. In 1906, Roosevelt faced up to the rumors of random exploitation of coal supplies on federal lands by withdrawing coal-bearing lands from public availability. He responded to industry's complaint that the acreage limitations in the 1873 statute impeded the development of certain types of coal. As a result, many coal and railroad companies evaded these limits by using dummy entries or by entries processed under the agricultural land statutes. To keep certain companies from acquiring a monopoly and to conserve mineral supplies, the withdrawals began in November 1906. Located in Colorado, North Dakota, Montana, Oregon, Washington, Utah, Wyoming, and the Territories of New Mexico, 66 million acres of land with supplies of "workable coal" were withdrawn. In his autobiography, Roosevelt explained his logic as follows:

> *The present coal law limiting the individual to 160 acres puts a premium on fraud by making it impossible to develop certain types of fields….It is a scandal to maintain laws which sound well, but which make fraud the key without which great natural resources must remain closed. The law should give individuals and corporations under proper government regulation and control…the right to work bodies of coal large enough for profitable development. My own belief is that there should be provision for leasing coal, oil and gas rights under proper restrictions.*

Many western congressmen reacted angrily to Roosevelt's withdrawal. They claimed that Congress and not the Chief Executive possessed the right to dispose of the public domain in such a manner. Some

referred to Roosevelt's use of conservation as "state socialism." Roosevelt revised his argument slightly in 1907 to include mineral fuels with forests and navigable streams as "public utilities." Between 1906 and 1909, public coal lands sold for between $75 and $100 per acre. During these same years, over 4 million acres were segregated, though many would be returned to the public domain.

6.2 Contested Development: Petroleum and Teapot Dome

Following the 1859 strike of the first oil well in Pennsylvania, development in the United States moved to the Midwest. As oil exploration moved westward, it became evident that the public lands held great stores of "black gold." By the 1870s, oil fever had swept specifically into the public domain of California. In the early 1890s, oil was discovered near Coalinga, California and in 1892, E. L. Doheny drilled the first successful well in Los Angeles. The Placer Act of 1870 included "all forms of deposit" except veins of quartz. Though the Department of Interior debated whether petroleum qualified, Congress passed an 1897 Placer Act that upheld that oil lands were administered by placer location. In 1909, President Taft temporarily withdrew 3 million acres of potential oil lands in the public domain.

Similar to Roosevelt's coal withdrawals, Taft's act garnered a great amount of debate—particularly in the West. Congress then passed the Pickett Act in 1910 to allow presidents to withdraw public lands for examination and reclassification for various "public purposes." During the 1910s, this act enabled the President to withdraw nearly all of the known oil lands. In order to conserve an adequate supply of oil for the Navy, two naval reserves were established by executive order in 1912; one was in Elk Hills, California and the other was in Buena Vista Hills, California. Similar to a forest reserve, the oil supply, administrators believed, was best preserved if left in the ground. These withdrawals were then followed in 1915 by reserves at Teapot Dome, Wyoming and in 1916 by the naval oil shale reserves in Colorado and Utah. In 1923, a similar reserve was created in Alaska.

Although most of the public debate centered on the right of the executive branch to make such withdrawals, other issues emerged as well, including whether the land should be sold or leased to oil companies, whether land previously patented to railroad companies could be withdrawn by the federal government as well, and whether oil companies had any standing if the federal government wished to withdraw land that they had already leased. These issues, of course, took on greater importance as the United States observed and then participated in World War I at the end of the decade. Petroleum had many military uses, including powering many of the ships of the new Navy.

Historian John Ise was one of the loudest critics of such government policy. His argument, however, differed from those of most of the critics. He wrote in 1926 that "during this time there was always overproduction of oil from privately owned lands and there was never any need or justification for opening any public lands." Although this argument shifted to the fore by the end of the 20th century, there was little public support for the idea of conservation. Western lawmakers focused on ensuring federal supplies of petroleum on public lands when it passed the Mineral Leasing Act of 1920, otherwise known as the Smoot Bill. Congress intended this act to bring relief to some of these issues and to offer more equal treatment to interests of the western United States. In the naval reserves, leases were given only on producing wells, unless the President chose to lease the remainder.

Within 6 months after the passage of the Mineral Leasing Act, the Secretary of the Navy was granted extensive jurisdiction over the naval reserves. In 1921, Albert B. Fall, a senator from New Mexico, was appointed Secretary of the Interior by Warren G. Harding. In short order, Fall convinced Secretary of the Navy Edwin Denby to relinquish control of the reserves and had Harding sign a secret presidential order to this effect. Within a few months, word leaked to the public that Fall had leased reserves in California and Wyoming to his friends in the oil business. The episode that transpired in full view of the public became the primary test of jurisdiction and law regarding energy development and the West.

In the scandal known as Teapot Dome, a congressional committee found that Fall had acted secretly and without competitive bidding to lease the Teapot Dome to Harry Sinclair and the California tract to E. L. Doheny. Allowing a private company to develop naval oil reserves, Fall went outside the boundaries of existing law. As a result, he was one of the first members of a presidential cabinet to serve a jail term; he was convicted of bribery and ordered to serve a year in prison as well as to pay a $100,000 fine.

Fall represented the western interests who felt betrayed by the overly zealous control of the federal government over the development of public lands. Before Warren Harding appointed him as Secretary of the Interior, Fall had earned his spurs in farming and

ranching. In New Mexico, he owned a ranch that spanned more than 55 miles long and 35 miles wide. He had been a judge and a sheriff. Throughout his public life in New Mexico, Fall referred to the territory as "corporation country." He hated government interference in business, and he did not have to struggle with torn loyalties when he became a federal employee. "I have long believed," Fall said in 1918, "that the laws should protect…capital and should be so enforced as to offer an inducement for its investment." In giving business the advantage of governmental favors, Fall had, however, acted as a man of a certain faith. The core of his faith was simple: because nature's resources were unending, there was no need for humanity to restrain its ambitions and desires. "All natural resources should be made as easy of access as possible to the present generation," Fall declared. "Man cannot exhaust the resources of nature and never will." This, of course, included those resources falling within the public domain.

When Americans began to hear about Teapot Dome in news reports in the 1920s, much of the public participated in a growing appreciation of nature. Fall's feelings were well known to many observers. On his appointment in 1921, one newspaper wrote that "To us Fall smells of petroleum and we know what that means among...politicians." Another paper, also prior to the Teapot Dome scandal, described the new administrator of federal lands as a man who found "wise conservation of natural resources...hateful to his every instinct." Although Fall would be held accountable for his abuse of power on the federal lands, his basic idea of unfettered development and unending abundance remains on the table. This has been a major portion of the debate over petroleum development on federal lands. Although Congress would act in 1928 to give the Secretary of the Navy exclusive jurisdiction of the petroleum reserves, the matter would continue to be debated throughout the 20th century.

6.3 Energy and National Security: Uranium

Similar debate followed the post-World-War II search for uranium to be used in nuclear weapons and eventually in nuclear power generation. The demand for fissionable source materials after the war and the urgency of a government monopoly in them prompted the enactment of the Atomic Energy Act of 1946, which reserved all such ores in public domain land to the United States and required that they also be reserved in any mineral patent.

The uranium boom reached its height around 1954, when prospectors flooded western lands in fashion similar to the California gold rush. Private prospectors made millions of dollars leasing and locating uranium supplies through the end of the 1950s. Applicable to both uranium and oil and gas deposits, the Multiple Mineral Development Act of 1954 clarified how lessees were to deal with dormant mining claims that may cloud their own title. The new act provided a procedure in which title examiners may be used. After the lessee filed in the proper county office, he or she then waited for 90 days before filing with the BLM.

7. DEBATING OWNERSHIP: THE SAGEBRUSH REBELLION

Picking up on the ideas of Albert Fall, a group of 11 western states rallied in the 1970s to gain control of the development of the resources on their public lands. In what has become known as the "Sagebrush Rebellion" and the "Wise Use Movement," these groups have gained national attention and have often been able to bypass FLPMA and other government regulations.

In the late 1970's, the movement flared up with the support of Adolph Coors and other westerners. Prominent in this legal effort, the Rocky Mountain Defense Fund employed talented lawyers James Watt and Ann Gorsuch. Prior to his election, Ronald Reagan espoused support for the Sagebrush Rebellion. When he was elected in 1980, Reagan wasted no time in appointing Watt the Secretary of the Interior and Gorsuch to head the Environmental Protection Agency. Watt pressed his ideas forward and was able to open thousands of acres of public land to coal mining. However, with his forced resignation in the 1983, the movement lost a great deal of its support from the Reagan White House.

The same ideas, however, have found new life in the administration of George W. Bush. Guided by leaders such as the Assistant Secretary of the Interior J. Steven Griles, who served under Watt and then spent years as a consultant to the energy industry, the Bush administration pushed to open up vast new tracts of federal land to oil, gas, and coal development.

8. A SYMBOLIC CONTEST: ALASKA

With the growing strength of the environmental movement after 1970, the utilitarian view of public

lands met public debate at nearly every juncture. This has been most evident in an ongoing symbolic fight over federal lands in Alaska.

The energy crisis of the 1970s, which was exacerbated by the 1973 Oil Embargo carried out by members of the Organization of Oil Exporting Countries (OPEC), caused a significant shift in feelings about oil development in federally owned areas of Alaska. The stalled debate over drilling in northern Alaska and constructing a trans-Alaska pipeline (TAP) to Valdez gathered congressional support and was ultimately carried out in the late 1970s. American leaders assured the public that the TAP would be a step toward energy independence. Specifically, the Nixon administration assured Americans that a TAP would cause oil imports from the Middle East to fall from 27% of the U.S. supply to 20% by 1990.

President Jimmy Carter's willingness to allow these developments was predicated on his effort to formalize restrictions on further such activities in undeveloped areas of Alaska. From 1978 to 1980, President Jimmy Carter established the Alaska National Wildlife Refuge (ANWR) and set aside 28% of Alaska as wilderness. Carter announced this watershed legislation as follows: "We have the imagination and the will as a people to both develop our last great natural frontier and also preserve its priceless beauty for our children." With the passage of the Alaska National Interest Lands Conservation Act (ANILCA) in 1980, the BLM was ordered to oversee 11 million acres of Alaska as wilderness. This included the Alaska National Wildlife Refuge.

Debate on further development in these areas of Alaska awaited the administration of George W. Bush. As part of the administration's energy plan, new priority was placed on developing energy resources on federal lands. Secretary of the Interior Gale Norton specifically zeroed in on ANWR in 2000. Congress rebuffed the first effort to open ANWR to oil development, but other efforts are sure to follow. With the Republican victory in the 2002 congressional elections, most environmentalists foresee little to stand in the way of energy developments in ANWR.

9. BATTLE LINES IN THE CURRENT DEBATE

Thanks to FLPMA, most new energy extraction requires an environmental impact statement (EIS), which is a detailed study of the proposed plan and how it will affect wildlife, plant life, and the quality of the water, air, and soil. The EIS also examines how the resource extraction will affect other uses of the public lands, such as recreation, cultural resource conservation, or grazing. If the impacts of the proposed well, dam, or mine seem too great, then alternatives are examined. These range from scrapping the plan entirely to using advanced technology to extract the resource, such as directional drilling, whereby the well is sited in a less vulnerable area but the drill still reaches the underground reserves.

The debate over ANWR crystallizes many of the issues that now make up the larger debate about how energy development should proceed on federal lands. During the administration of President William Clinton, oil and gas leasing increased considerably over previous administrations, but with new environmental restrictions on industries that sought to develop energy resources on public lands (see Table V). President Clinton also designated 21 western national monument areas and 56 million acres of roadless area. Such changes, however, were susceptible to any changes in national politics. That change came in the election of 2000.

"Environmental issues today," instructed Bush's Interior Secretary Gale Norton, "are more complex and subtle than the ones we faced in the 1960s and 70s. With the growth of our population and expansion of our economy, pressures have increased correspondingly on our undeveloped land, water resources, and wildlife." Norton intends to put "collaboration ahead of polarization, markets before mandates…and to transcend political boundaries." In order to do so, she and George Bush coined the phrase "new environmentalism" to meet the U.S. need "for a vibrant economy and energy security—while at the same time protecting the environment." Thus far, environmental organizations have been disappointed by Bush and Norton's "new environmentalism." "We're dismayed that Pres. Bush wants to turn the oil and gas industry loose on virtually all the lands in our national forests, national wildlife refuges, and other public systems," said Wilderness Society representative Bill Meadows. "We're beginning to wonder if James Watt is whispering in his ear," he said.

In addition to ANWR, federal lands along the Rocky Mountain front in northwestern Montana to southern Wyoming's Red Desert and Colorado's Vermillion Basin are being explored for energy development. The BLM collected data on oil and gas deposits and their availability throughout the

public lands in order to support the prodevelopment stance of the Bush administration. Many local landowners and environmentalists have fought these efforts. Norton has requested new financing to streamline permits and study sites to drill on federal lands. The Bush administration has also shown some interest in increasing the development of alternative energy sources on federal lands as well. The future of the public lands is certain to contain open debate over the domain's role in America's energy future.

Large quantities of fossil fuels are burned to meet the world's energy needs. The combustion of these fuels produces carbon dioxide, contributing to increasing concentrations of carbon dioxide in the earth's atmosphere. According to the Intergovernmental Panel on Climate Change, the increasing concentrations of carbon dioxide and other greenhouse gases in the atmosphere due to human activity are causing the average surface temperature of the earth to increase. Such human influences are expected to continue to contribute to rising greenhouse gas emissions and additional global warming through this century.

1. INTRODUCTION

Humans combust these fuels to provide energy for needs such as heating, transportation, refrigeration, and industrial processes. The efficiency with which fossil fuels can be converted to meet these needs determines how much primary energy will be combusted. The greater the end-use efficiency, the less fuel is needed and the less the impact that such human activities will have on global warming, all other factors remaining the same.

Over the past century, the efficiency of energy use has improved. For example, lighting has changed from the burning of candles that produced 1 lumen for every 6 watts of candle or wax burned, to incandescent electric lights that produced 17 lumens with each watt of electric input, to fluorescent lighting that produces 100 lumens per watt. So the energy intensity index, defined as the amount of primary energy needed to produce a unit of gross domestic product, continues to improve. If this index can continue to improve at a rate of 2% per year, the

primary energy needs of the world can be limited even while increasing access to goods and services. Such an improvement in energy intensity also will lead to a reduction in carbon dioxide emissions and limit the extent of global warming.

2. IMPROVING TRENDS IN ENERGY EFFICIENCY

The efficiency of energy use is an important determinant of how much energy will be required to warm a home to a particular temperature or drive a car a certain distance. In our daily lives we often encounter the idea of energy efficiency when figuring how many miles per gallon our automobiles use while driving in town or on a freeway. Clearly, the more miles a car can travel on a gallon of gasoline, the less gasoline will be needed. The same concept applies to all uses of energy.

Since 1973, when the United States first experienced rapid increases in fossil fuel prices, considerable attention has been paid to improving the efficiency of energy use of various appliances and other products. The most effective path toward energy efficiency has been standards for autos, buildings, appliances, and equipment. Figure 1 shows the remarkable gains in refrigerators. Even while increasing in size, refrigeration has improved efficiency 5% every year since the late 1970s.

Figure 2 shows the results of these improvements. With an estimated 150 million refrigerators and freezers in the United States, the difference in consumption at 1974 efficiency levels compared to 2001 levels is the equivalent to avoiding 40 GW of power plants. A typical unit at a nuclear power plant is 1 GW, while the typical natural gas-fired combined cycle plant is 300 MW. This is based on saving 1400 kWh per year with the more efficient appliance and assuming power plant operation of 5000 hours per year.

Significant gains in efficiency also have been achieved with improvements in other appliances. Figure 3 illustrates improvements in three difference appliances (gas furnaces, central air conditioning, and refrigerators) compared to their respective consumption in 1972. This figure is taken from

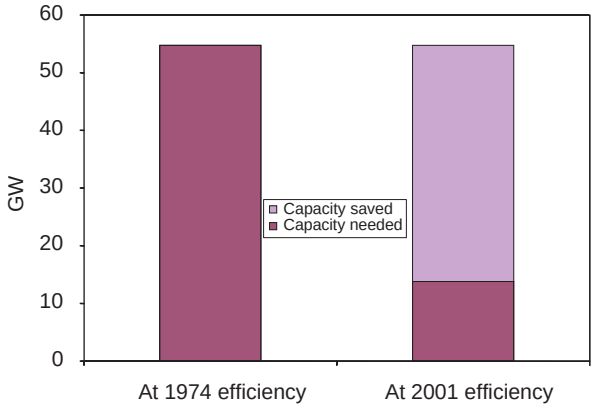

FIGURE 2 Electricity generating capacity for 150 million refrigerators and freezers in the United States.

Steven Nadel in the ECEEE 2003 Summer Study. Compared to consumption in 1972, new gas furnaces use 75%, central air conditioning units use 60%, and refrigerators only 25%. The figure also indicates that early standards were adopted by states. United States' national standards were not adopted until the late 1980s. Although these trends are encouraging, some other uses of energy have shown little improvement in efficiency since the 1980s. For example, average fuel efficiency for cars and truck remains at the same level as in 1985, even though there are no engineering obstacles blocking significant improvements in fleet efficiency. This was after significant improvement in CAFE standards from 18 miles per gallon for model year 1978 cars to 27.5 mpg for 1985 cars. However, even consideration of increasing CAFE standards remains a controversial topic.

3. THE COMBINED IMPACT OF COMPLIMENTARY EFFICIENCY IMPROVEMENTS

Efficiency improvements in appliance and building design and construction can often be combined to result in even larger energy savings. Figure 4 provides an example of this combined impact. Air conditioning operates to cool a home or a portion of a home based on the temperature setting of the

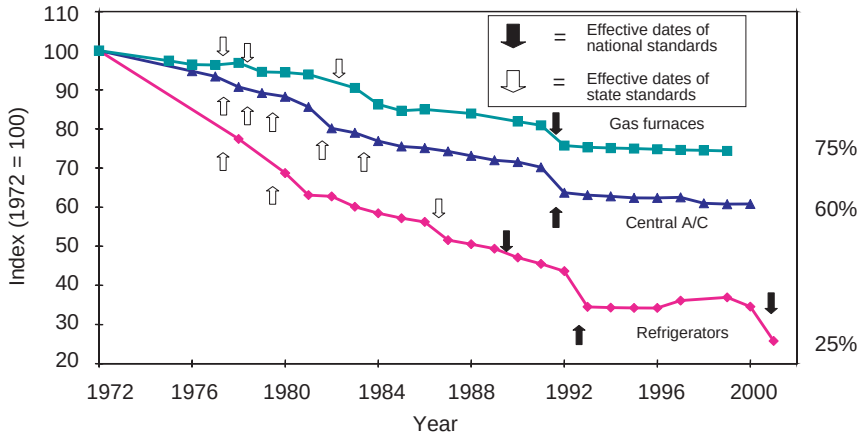

FIGURE 3 Impacts of standards on efficiency of three appliances. From S. Nadel, ACEEE, in ECEEE 2003 Summer Study, www.eceee.org.

thermostat. The efficiency of the air conditioning equipment (for example, the compressor and air handlers) itself is known at the time of purchase and is required to meet a specific federal standard. However, how much it actually runs is also dependent on the characteristics of the building or home where the equipment is located. Prior to the 1970s many homes, especially in milder climates, had little or no insulation and single pane windows. As building standards were introduced, new homes were built to more stringent standards, resulting in lower requirements for heating and cooling to maintain the same temperature within the structure. As indicated in Fig. 4, the effect of combining both air conditioning standards and building standards has been to reduce energy use in a new California home to 40% of the usage in the early 1970s. With the implementation of newer standards in 2006, use is expected to decline to 33% of the 1970s levels.

4. EFFICIENCY IMPROVEMENTS REDUCE GENERATION REQUIREMENTS

Since the early 1970s, efficiency improvements have lowered energy demands and the need for peaking electrical power. To highlight the magnitude of such savings, we now consider how the U.S. demand for peak electrical power has been reduced, compared to what it might have been in the absence of efficiency improvements. The requirement for peaking power to meet air conditioner loads in the United States is about 250 GW. Standards only apply to the 200 GW of residential central systems and commercial rooftops air conditioning systems. By moving to current efficiency standards, equivalent to an energy efficiency ratio (EER) of 11, the United States has avoided about 135 GW of peak electricity load. This is about twice the peak load of the entire state of California and roughly equal to the total nuclear capacity in the United States. In addition, white roofs could save an additional 20 GW.

Enhancements in refrigerator and freezer efficiency save 200 billion kWh per year compared to consumption if refrigerators had remained at 1974 efficiency levels. That amount of electricity is nearly equal to annual electricity consumption in the state of California, about twice the amount of annual generation from existing renewables (not including hydroelectric) in the United States, and about one-third the quantity of electricity generated at nuclear stations in the United States in a year. Since the value of electricity at the point of consumption is worth nearly three times its value at the point of production, the value of improvements in refrigerator and freezer efficiency is worth the same as all the nuclear generation in the United States in a typical year.

Clearly, efficiency improvements have reduced the requirements for all forms of energy, even though some sectors, such as automobile transport, lag in this regard. Emissions of greenhouse gases have been proportionally reduced due to these efficiency gains. Yet it is generally accepted that the earth's surface temperature is on the rise, in great part due to human activity involving the combustion of fossil fuels. We now turn to past and estimated future trends in primary energy requirements.

5. HISTORIC PRIMARY ENERGY TRENDS IN THE UNITED STATES

Even with efficiency gains, energy requirements continue to increase. Figure 5 illustrates this trend. Primary energy use (not just electricity) increased by a factor of three over the time period of 62 years. Carbon dioxide emissions increased at nearly the same rate, as the vast majority of primary energy is provided from fossil fuels with only limited contributions from nuclear, hydroelectric, and other renewable energy sources.

Figure 6 shows a steady increase in per capita energy consumption from 1949 until the early 1970s. The flattening in 1974 is the impact of the OPEC oil embargo and high oil prices until the collapse of OPEC in 1985. Comparing Figures 5 and 6, we can see that much of the increase in primary energy is due to an expanding population, especially during the 1990s when per capita consumption was relatively flat.

6. ENERGY INTENSITY TRENDS IN THE UNITED STATES AND OTHER REGIONS

Another measure of interest to economists and energy analysts is how much energy is used per dollar of gross domestic product (GDP). This measure is referred to as energy intensity. The lower the number, the more efficient in terms of energy per dollar of GDP. Figure 7 shows that the United States improved its energy intensity at a rate of about 1.3% per year through this entire period. However, the rate of improvement is by no means uniform, as can be seen in the figure. Beginning in the early 1970s, the slope of the line changes as the rate of improvement in energy intensity increases.

Figure 8 provides similar data on energy intensities by geographic region. Five regions plus the world are included. Changes in energy intensity are not uniform throughout the world. Western Europe and North America have shown continual improvement over the time period, while other regions have remained flat or increased. China has shown dramatic and sustained improvement.

The next four figures illustrate annual rates of change in energy intensity data available from the United States Energy Information Agency (EIA). The EIA uses market exchange rate to compare gross domestic products across different countries. Market exchange rate is based on trading currency in international monetary markets.

Figures are provided for the United States, Western Europe, China, and the entire World. The

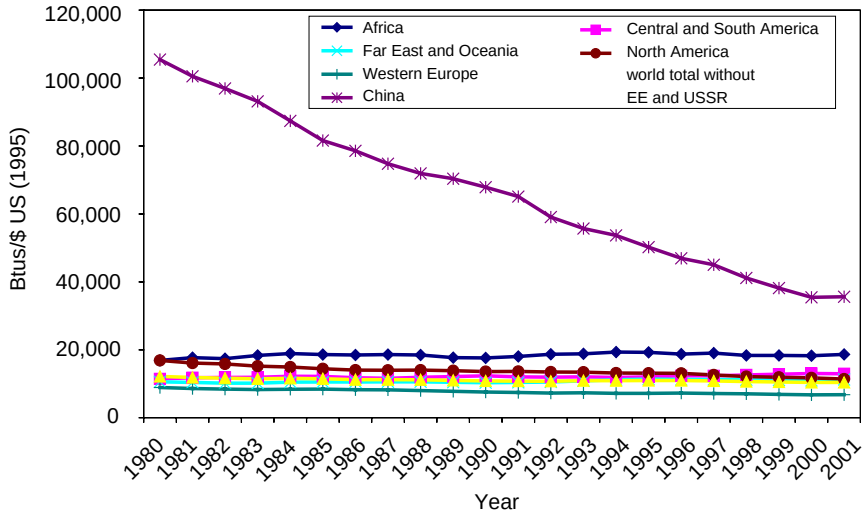

FIGURE 8 Energy intensity by geographic region including China, 1980 to 2001 (Btus/$US 1995). From Energy Information Agency (EIA) data.

vertical lines divide the time period (1981 to 2001) into three eras. Era 1 covers the latter years of high OPEC oil prices. Era 2 starts soon after the collapse of OPEC and the consequent stagnation of corporate automobile fuel economy (CAFE) standards. Era 3 begins with the significant impact of information technologies on business and the economy. The numbers written above each era reflect the average rate of change in E/GDP for that era. We introduce each of these figures and discuss trends of interest as illustrated in the figure.

Figure 9 tracks year to year changes in energy intensity and shows different rates of improvement in E/GDP in each of the three eras discussed earlier. In the early 1980s, the United States experienced improvements averaging −3.4% per year (improvements are indicated as negative numbers on these figures) and only −0.7% between 1986 and 1996. Improvements from 1997 through 2001 averaged −2.7%. Although many factors are at work, a number of analysts argue that the era improvements are the result of structural changes in the economy. The United States has moved away from energy intensive industry, such as steel production, and moved toward service and information-based firms, especially computer and internet firms. Such changes may portend not only less energy use for processes but improvements in scheduling, shipping, and other aspects of business practice due to the additional information availability.

Figure 10 shows a nearly constant improvement in the range of −1.3% per year and much less variability than in the United States. Europe already is considerably more efficient than the United States (see Fig. 8). In Fig. 11, we find nearly constant improvements in E/GDP in the range of −5.0% per year. Such improvement is dramatic. According to IEA's World Energy Outlook 2002, China's GDP has grown at about 8% per year since the 1970s to become the world's second largest consumer of primary energy. Finally, in Fig. 12 we find improvements in energy intensity averaging about −1.0% since the 1970s. Many factors contribute to the energy intensity of a county or a region within a country. As indicated by Figs. 8 to 12, the rate of change of energy intensity varies significantly throughout the world.

For energy intensity (E/GDP) to improve—that is, get smaller—GDP needs to increase more rapidly than primary energy, presuming that both are increasing. For example, primary energy use in the United States grew by 2.4% between 1999 and 2000. GDP grew by 3.7%, resulting in an improvement in energy intensity of 1.3% from 1999 to 2000. This article uses the convention of showing this as −1.3%. From the perspective of using energy better, the United States improved. Yet carbon emission also increased since the majority of primary energy comes in the form of fossil fuel—primarily coal, natural gas, and petroleum. If one is concerned about global warming, it seems that only three options are available to limit carbon emissions: (1) reduce the amount of primary energy requirements or limit the rate of growth in primary energy demand; (2) find

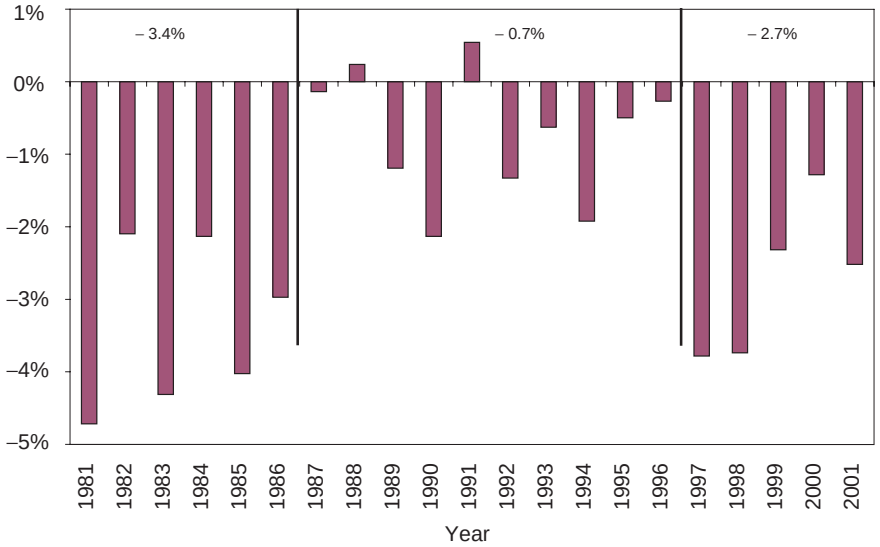

FIGURE 9 Annual rate of change in energy/GDP for the United States.

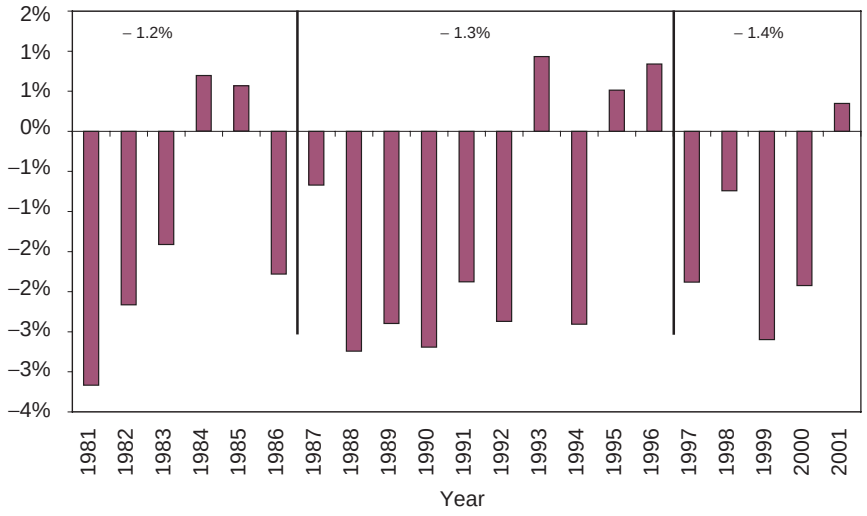

FIGURE 10 Annual rate of change in energy/GDP for Europe.

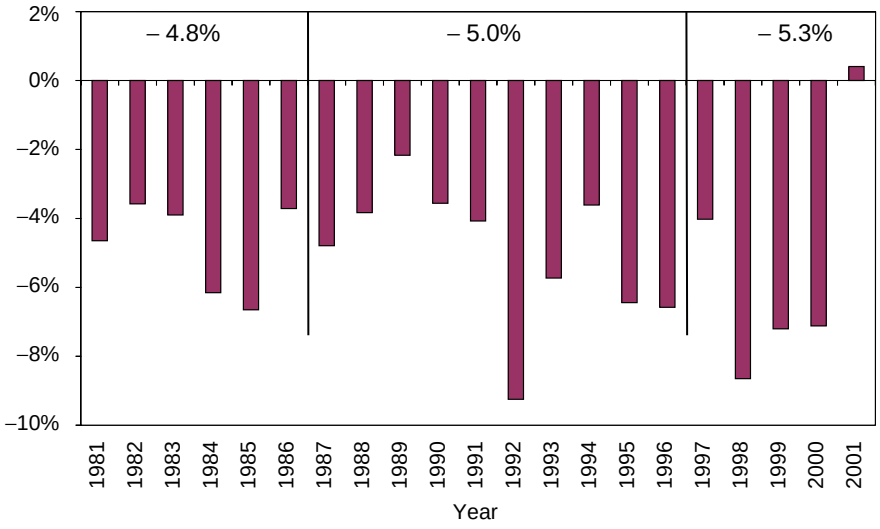

FIGURE 11 Annual rate of change in energy/GDP for China.

primary fuel sources that are not carbon based; and (3) sequester the carbon that is emitted. Not only are these options not mutually exclusive, but we expect all might well be necessary if we are to stem the tide of rising carbon concentrations in the atmosphere and global warming.

Even with improving E/GDP, concerns remain regarding primary energy demands for the world through the coming century and the amount of carbon that may be released into the atmosphere as fossil fuels are burned to meet these needs.

7. FUTURE PRIMARY ENERGY TRENDS FOR THE WORLD

Many different organizations have addressed the issue of how much energy might be needed in the future. Some have tried to forecast this amount; others have developed a host of scenarios to attempt to bound the magnitude of the problem. Estimates of future primary energy requirements vary considerably. Figure 13 illustrates the range of such scenarios. The scenarios all start at current levels on world energy demand, about 400 quads. By 2100, the range of

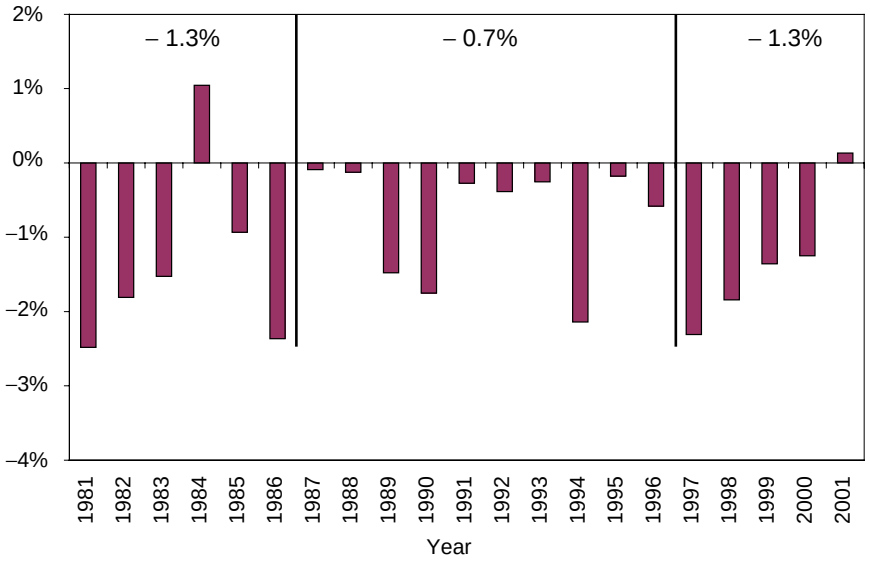

FIGURE 12 Annual rate of change in energy/GDP for the world. Note that Russia not included.

world primary energy demand is from 500 quads all the way to 2600 quads per year. These scenarios are predicated on different estimates of population growth, economic development, and energy intensity.

8. THE EFFECT OF EFFICIENCY IMPROVEMENTS ON PRIMARY ENERGY DEMAND

Efficiency improvements can drastically alter primary energy demand. We now discuss other cases that differ primarily in assumptions regarding the rate of improvement of energy intensity. Using the IPCC's IS 92a as the base case, Fig. 14 compares this case with two alternative trajectories of the world's primary energy consumption. The IS 92a case assumes E/GDP improving at −0.8% per year through 2020 and −1.0% per year thereafter through 2100. The second trajectory is taken from EIA's Annual Energy Outlook 2003. In the third case, energy intensity is assumed to improve at −2.0% annually through 2100. In assuming this improvement, total gross domestic product (or gross world product) is held at the same level as in the IS 92a case, and primary energy is set so that E/GDP improves by −2.0% per year.

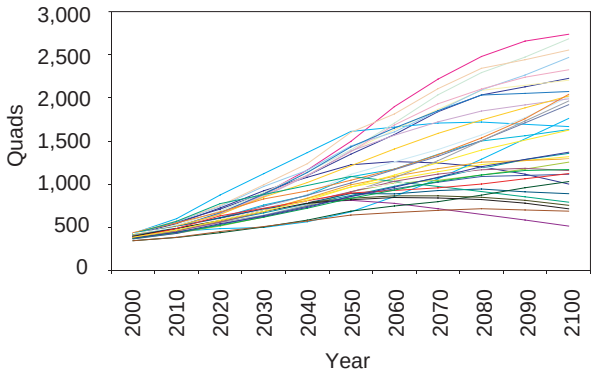

FIGURE 13 Primary energy 2000 to 2100. This figure is taken from data provided in IPCC Special Report on Emissions Scenarios 2001, Appendix VII.

Since the early 1990s when the IS 92a case was developed, primary energy demand has grown more slowly than anticipated. This explains the differences between the base case assumptions and the EIA International Energy Outlook as shown in Fig. 14. These differences result in a reduction of forecasted primary energy demand in 2025 of about 7.5%. However, if we assume that world energy intensity improves at a rate of −2% per year, world energy demand rises to only 510 quads by 2025 and then stays nearly flat through the end of the century. World demand is 400 quads per year.

The impact of improvements in energy intensity is dramatic. Primary energy demand is cut by more than 60% compared to the IS 92a base case. Put more dramatically, IS 92a requires, by 2100, in units of today's energy infrastructure, growth from 1.0 to 3.5, whereas the 2% per year scenario requires growth only from 1.0 to 1.3, at great savings of

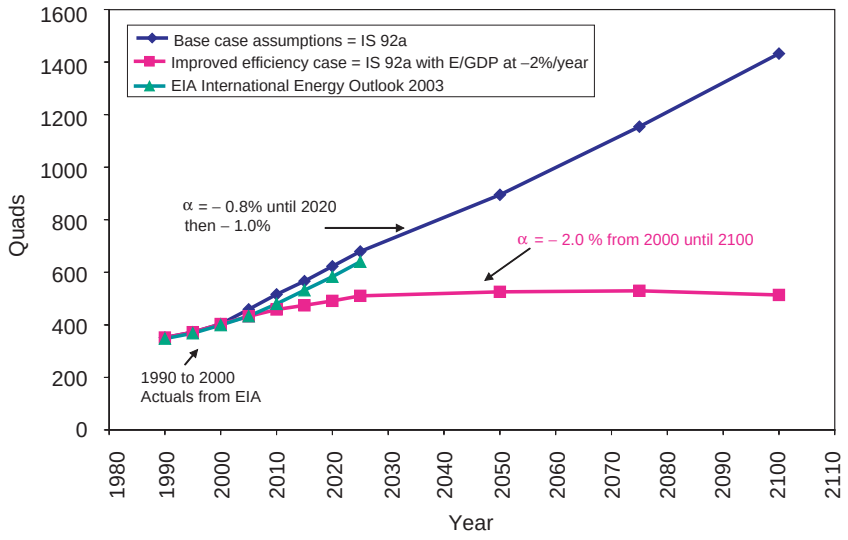

FIGURE 14 Primary energy demand in IPCC base case compared to other cases. α is the annual growth in energy intensity, E/GWP negative α indicates reduced energy intensity.

economic and environmental cost. While all this is occurring, per capita income rises to a worldwide average of nearly 25,000 (in 1995 US$). This is a level consistent with standards in developed European countries and Japan.

9. PATHWAYS TO IMPROVING ENERGY INTENSITY

We have seen that world energy intensity (E/GWP) is spontaneously dropping 1.3% per year, and that gaining another 1% per year for the coming century will cut demand and supply by another factor of 2.7. This extra 1% per year can by achieved by adopting and enforcing building, appliance, and vehicle fuel economy standards, and by ploughing about 1% of utility revenues back into efficiency programs designed to beat the standards. Examples of such programs are rebates for the purchase of super-efficient ("energy star") appliances, buildings, cars and trucks, and technical assistance to industries, architects, building owners and operators, and so on.

Standards are usually designed to reduce utility bills fast enough to repay a slightly higher first cost in 5 to 10 years, which is typically half the service life of the product. We call this a simple payback time (SPT) of 5 to 10 years. Efficiency measures to retrofit existing buildings and industry will also have SPTs that are safely shorter than the service life of the products installed. In contrast, investment in energy supply—power plants, transmission lines, refineries, dams, mines, and wells—typically has an SPT (from sale of energy) of 20 to 40 years, so efficiency is a better investment (although, of course, we need both), and the savings from efficiency, ploughed back into the economy, can stimulate jobs and growth.

Developed countries, which already have low energy intensity, can improve further by tightening and enforcing standards and extending their scope and by expanding efficiency programs. Reductions of CO_2 will then be an attractive by-product.

But later developing countries (LDCs), all of them lacking adequate energy supply, tend to focus on expanding their supply, and indeed rich countries should help them finance new supply. But first, for their own economic development and to reduce CO_2, more developed countries should attach conditions. Before financing supply with a 30-year payback time, developed countries should require that the host country develop standards and programs to capture all measures with a payback time of 3 to 5 years. Also, rich countries can help LDCs with technical assistance and training. These conditions should be adopted worldwide by donor countries, international banks, and host countries and their utilities. This is the cheapest way for the rich countries to delay climate change.

Glossary

conversion efficiency The physical ratio of desired output to total input in an energy conversion process, such as converting fuel to electricity or fuel to heat. Undesired or nonuseful outputs are excluded, making the ratio less than unity for most devices (except in such cases such as heat pumps and heat-powered chillers, where it can exceed unity and is called a coefficient of performance). The definition is thus based partly on what each individual finds useful. Synonymous with the thermodynamic concept of First Law efficiency, but counts only the quantity of energy, not also the quality, and hence differs from Second Law efficiency, which counts both.

customer The ultimate recipient of energy services, regardless of intermediate transactions.

delivered energy Secondary energy provided at the place where it is used to provide the desired energy service (e.g., electricity or fuel entering the end-use device that performs that final conversion). Further losses between that device and the customer may or may not be included. Delivered energy is net of distribution efficiency (1) to the end-use device, but may or may not be net of distribution efficiency (2) between end-use device and customer.

distribution efficiency (1) The fraction of centrally supplied energy shipped out (such as electricity from a power station, petroleum products from a refinery, or natural gas from a treatment plant) that is delivered to the end-use device, net of energy "lost" or "consumed" in its delivery. For electricity, this conversion into unwanted forms, chiefly low-temperature heat, comprises transmission as well as distribution losses, and is conventionally measured from the generator's busbar to the customer's meter. (2) The fraction of energy services produced by the end-use device that reaches the customer (e.g., the fraction of the heat produced by a furnace that provides warmth in a room, net of nonuseful heat escaping from pipes or ducts).

end use (1) The category of desired physical function provided by an energy service, such as heating, cooling, light, mechanical work, electrolysis, or electronic signal processing. (2) The physical quantity of such end use delivered to the customer, whether or not it is useful energy.

end-use device Equipment converting delivered energy into energy service.

end-use efficiency The physical ratio of end use (2) provided to delivered energy converted in the end-use device.

energy conservation An ambiguous term best avoided; considered by some as synonymous with increased energy efficiency but to many others connoting the opposite: privation, curtailment, and discomfort, i.e., getting fewer or lower quality energy services. The degree of confusion between these meanings varies widely by individual, culture, historic period, and language spoken. Some analysts, chiefly outside the United States, embrace energy conservation as an umbrella term for energy efficiency plus changes in personal habits plus changes in system design (such as spatial planning or design for product longevity and materials recovery/reuse).

energy efficiency Broadly, any ratio of function, service, or value provided to the energy converted to provide it. Herein, energy efficiency and its components all use (a) physical rather than economic metrics and (b) engineering, not economic, definitions (this physical convention can, however, become awkward with multiple inputs or outputs). Energy efficiency may or may not count thermodynamic quality of energy (ability to do work); see the distinction between First Law and Second Law efficiency.

energy intensity Energy (primary, delivered, or otherwise defined) "used" per unit of service or value provided.

 © 2004 Rocky Mountain Institute. Published by Elsevier Inc. All rights reserved.

Intensity can be expressed in economic or in physical terms (e.g., the very crude and aggregated metric of primary energy consumption per dollar of real gross domestic product).

energy service The desired function provided by converting energy in an end-use device (e.g., comfort, mobility, fresh air, visibility, electrochemical reaction, or entertainment). These functions, which together contribute to a material standard of living, are generally measured in physical units, not by energy used or money spent. Because diverse services are incommensurable, they cannot be readily added to express a meaningful "total end-use efficiency" for a person, firm, or society. Economic surrogates for such totals are seldom satisfactory.

extractive efficiency The fraction of a fuel deposit that is recovered and sent out for processing and use, net of energy employed to conduct those extractive processes.

hedonic (functional) efficiency How much human happiness or satisfaction (equivalent to economists' welfare metrics) is achieved per unit of energy service delivered. Some analysts similarly distinguish the task (such as delivering heat into a house) from the goal it seeks to achieve (such as the human sensation of indoor comfort in winter).

primary energy (1) Fossil fuel extracted and then converted, typically at a central facility, into a secondary form (e.g., crude oil into refined products or coal into electricity) for delivery to end-use devices. (2) Nuclear, hydroelectric, and renewable energy captured for such delivery; if electric, conventionally expressed as the imputed amount of fossil fuel used to produce that much electricity in a typical thermal power station. (3) The quantity of energy described in (1) or (2). Most analysts exclude from primary energy consumption the metabolic energy in human food, but include the nonsolar energy needed to grow, process, deliver, and prepare it.

secondary energy Any processed, refined, or high-quality form of useful energy converted from primary energy, such as electricity, refined petroleum products, dry natural gas, or district heat. Excludes undesired and nonuseful conversion products.

Second Law efficiency The ratio of First Law thermodynamic efficiency to its maximum theoretically possible value; equivalently, the ratio of the least available work that could have done the job to the actual available work used to do the job. For a device that produces useful work or heat (not both), such as a motor, heat pump, or power plant, Second Law efficiency is the amount of output heat or work usefully transferred, divided by the maximum possible heat or work usefully transferable for the same function by any device or system using the same energy input. This maximum is defined by the task, not the device: to maximize how much heat is delivered from fuel into a building, an ideal fuel cell and an ideal heat pump would be used. Second Law efficiency thus measures the effectiveness of a device in approaching the constraints of the First and Second Laws of thermodynamics. First and Second Law efficiencies are nearly equal for a power plant, but are very different when high-quality energy is converted into a low-energy useful form: a 60%-efficient (First Law) furnace delivering 43°C heat into a house in a 0°C environment has a Second Law efficiency of only 8.2%.

service substitution Providing a desired energy service by a different means (e.g., providing illumination by opening the curtain in the daytime rather than turning on an electric light).

useful energy The portion of an energy service that is actually, not just potentially, desired and used by customers (e.g., lighting an empty room, or overheating an occupied room to the point of discomfort, is seldom useful).

Efficient use of energy is in all countries the most important, economical, prompt, underused, overlooked, and misunderstood way to provide future energy services. It is rapidly becoming even larger, faster, and cheaper as technologies, delivery methods, and integrative design improve. Whole-system design can indeed make very large energy savings cost less than small ones. But capturing energy efficiency's remarkable potential requires careful terminology, prioritization, attention to engineering details and to market failures, and willingness to accept measured physical realities even if they conflict with economic theories. If well done, such energy efficiency can displace costly and disagreeable energy supplies, enhance security and prosperity, speed global development, and protect Earth's climate—not at cost but at a profit.

1. DEFINITION AND IMPORTANCE OF ENERGY EFFICIENCY

Energy efficiency is generally the largest, least expensive, most benign, most quickly deployable, least visible, least understood, and most neglected way to provide energy services. The 39% drop in U.S. energy intensity (primary energy consumption per dollar of real gross domestic product) from 1975 to 2000 represented, by 2000, an effective energy "source" 1.7 times as big as U.S. oil consumption, three times net oil imports, five times domestic oil output, six times net oil imports from Organization of Petroleum Exporting Countries (OPEC) members, and 13 times net imports from Persian Gulf countries. It has lately increased by 3% per year, outpacing the

growth of any source of supply (except minor renewables). Yet energy efficiency has gained little attention or respect for its achievements, let alone its far larger untapped potential. Physical scientists, unlike engineers or economists, find that despite energy efficiency's leading role in providing energy services today, its profitable potential has barely begun to be tapped. In contrast, many engineers tend to be limited by adherence to past practice, and most economists are constrained by their assumption that any profitable savings must already have occurred.

The potential of energy efficiency is increasing faster through innovative designs, technologies, policies, and marketing methods than it is being used up through gradual implementation. The uncaptured "efficiency resource" is becoming bigger and cheaper even faster than oil reserves have lately done through stunning advances in exploration and production. The expansion of the "efficiency resource" is also accelerating, as designers realize that whole-system design integration (see Section 4) can often make very large (one or two order-of-magnitude) energy savings cost less than small or no savings, and as energy-saving technologies evolve discontinuously rather than incrementally. Similarly rapid evolution and enormous potential apply to ways to market and deliver energy-saving technologies and designs; research and development can accelerate both.

1.1 Terminology

Efficiency unfortunately means completely different things to the two professions most engaged in achieving it. To engineers, efficiency means a physical output/input ratio. To economists, efficiency means a monetary output/input ratio, though for practical purposes many economists use a monetary output/physical input ratio. Only physical output/input ratios are used here, but the common use of monetary ratios causes vast confusion, especially to policymakers using economic jargon.

Wringing more work from energy via smarter technologies is often, and sometimes deliberately, confused with a pejorative usage of the ambiguous term energy conservation. Energy efficiency means doing more (and often better) with less—the opposite of simply doing less or worse or without. This confusion unfortunately makes the honorable and traditional concept of energy conservation no longer useful in certain societies, notably the United States, and underlies much of the decades-long neglect or suppression of energy efficiency. However, deliberately reducing the amount or quality of energy services remains a legitimate, though completely separate, option for those who prefer it or are forced by emergency to accept it. For example, the 2000–2001 California electricity crisis ended abruptly when customers, exhorted to curtail their use of electricity, cut their peak load per dollar of weather-adjusted real gross domestic product (GDP) by 14% in the first 6 months of 2001. Most of that dramatic reduction, undoing the previous 5–10 years of demand growth, was temporary and behavioral, but by mid-2002, the permanent and technological fraction was heading for dominance. Even absent crises, some people do not consider an ever-growing volume of energy services to be a worthy end in itself, but seek to live more simply—with elegant frugality rather than involuntary penury—and to meet nonmaterial needs by nonmaterial means. Such choices can save even more energy than can technical improvements alone, though they are often considered beyond the scope of energy efficiency.

Several other terminological distinctions are also important. At least five different kinds of energy efficiency can be measured in at least five different stages of energy conversion chains; these are discussed in Section 1.2. Also, technical improvements in energy efficiency can be broadly classified into those applicable only to new buildings and equipment, those installable in existing ones (retrofitted), those addable during minor or routine maintenance (slipstreamed), and those that can be conveniently added when making major renovations or expansions for other reasons (piggybacked).

Efficiency saves energy whenever an energy service is being delivered, whereas "load management" (sometimes called "demand response" to emphasize reliance on customer choice) changes only the time when that energy is used, either by shifting the timing of the service delivery or by, for example, storing heat or coolth so energy consumption and service delivery can occur at different times. In the context chiefly of electricity, demand-side management, a term coined by the Electric Power Research Institute, comprises both of these options, plus others that may even increase the use of electricity. Most efficiency options yield comparable or greater savings in peak loads; both kinds of savings are valuable, and both kinds of value should be counted. They also have important but nonobvious linkages: for example, because most U.S. peak electric loads are met by extremely inefficient simple-cycle gas-fired combustion turbines, saving 5% of peak electric load in 2000 would have saved 9.5% of total natural gas

consumption, enough to reequilibrate high 2003 gas prices back to ~$2/GJ lower historic levels.

Conflating three different things—technological improvements in energy efficiency (such as thermal insulation), behavioral changes (such as resetting thermostats), and the price or policy tools used to induce or reward those changes—causes endless misunderstanding. Also, consider that the theoretical potential for efficiency gains (up to the maximum permitted by the laws of physics) exceeds the technical potential, which exceeds the economic potential based on social value, which exceeds the economic potential based on private internal value, which exceeds the actual uptake not blocked by market failures, which exceeds what happens spontaneously if no effort is made to accelerate efficiency gains deliberately; yet these six quantities are often not clearly distinguished.

Finally, energy statistics are traditionally organized by the economic sector of apparent consumption, not by the physical end uses provided or services sought. End uses were first seriously analyzed in 1976, rarely appear in official statistics even a quarter-century later, and can be difficult to estimate accurately. But end-use analysis can be valuable because matching energy supplies in quality and scale, as well as in quantity, to end-use needs can save a great deal of energy and money. Supplying energy of superfluous quality, not just quantity, for the task is wasteful and expensive. For example, the United States now provides about twice as much electricity as the fraction of end uses that economically justify this special, costly, high-quality form of energy, yet from 1975 to 2000, 45% of the total growth in primary energy consumption came from increased conversion and grid losses in the expanding, very costly, and heavily subsidized electricity system. Much of the electric growth, in turn, provided low-temperature heat, a physically and economically wasteful use of electricity.

Many subtleties of defining and measuring energy efficiency merit but seldom get rigorous treatment, such as the following losses, services, or metrics:

- Distribution losses downstream of end-use devices (an efficient furnace feeding leaky ducts yields costlier delivered comfort).
- Undesired or useless services, such as leaving equipment on all the time (as many factories do) even when it serves no useful purpose.
- Misused services, such as space-conditioning rooms that are open to the outdoors.
- Conflicting services, such as heating and cooling the same space simultaneously (wasteful even if both services are provided efficiently).
- Parasitic loads, as when the inefficiencies of a central cooling system reappear as additional fed-back cooling loads that make the whole system less efficient than the sum of its parts.
- Misplaced efficiency, such as applying energy-using equipment, however efficiently, to a task that does not need it—say, cooling with a mechanical chiller when groundwater or ambient conditions can more cheaply do the same thing.
- Incorrect metrics, such as measuring lighting by raw quantity (lux or footcandles) unadjusted for its visual effectiveness, which may actually decrease if greater illuminance is improperly delivered.

To forestall a few other semantic quibbles, physicists (including the author) know energy is not "consumed," as the economists' term "consumption" implies, nor "lost," as engineers refer to unwanted conversions into less useful forms. Energy is only converted from one form to another; yet the normal metaphors are clear, common, and adopted here. Thus an 80%-efficient motor converts its electricity input into 80% torque and 20% heat, noise, vibration, and stray electromagnetic fields; the total equals 100% of the electricity input, or roughly 30% of the fuel input at a classical thermal power station. (Note that this definition of efficiency combines engineering metrics with human preference. The motor's efficiency may change, with no change in the motor, if changing intention alters which of the outputs are desired and which are unwanted: the definition of "waste" is as much social or contextual as physical. A floodlamp used to keep plates of food warm in a restaurant may be rather effective for that purpose even though it is an inefficient source of visible light).

More productive use of energy is not, strictly speaking, a physical "source" of energy but rather a way to displace physical sources. Yet this distinction is rhetorical, because the displacement or substitution is real and makes supply fully fungible with efficiency. Also, energy/GDP ratios are a very rough, aggregated, and sometimes misleading metric, because they combine changes in technical efficiency, human behavior, and the composition of GDP (a metric that problematically conflates goods and services with "bads" and nuisances, counts only monetized activities, and is an increasingly perverse measure of well being). Yet the two-fifths drop in U.S. energy intensity and the one-half drop in oil

intensity during the period 1975–2001 reflect mainly better technical efficiency. Joseph Romm has also shown that an important compositional shift of U.S. GDP—the information economy emerging in the late 1990s—has significantly decreased energy and probably electrical energy intensity, as bytes substituted for (or increased the capacity utilization of) travel, freight transport, lit and conditioned floorspace, paper, and other energy-intensive goods and services.

The aim here is not to get mired in word games, but to offer a clear overview of what kinds of energy efficiency are available, what they can do, and how best to consider and adopt them.

1.2 Efficiency along Energy Conversion Chains

The technical efficiency of using energy is the product of five efficiencies successively applied along the chain of energy conversions: (1) the conversion efficiency of primary into secondary energy, times (2) the distribution efficiency of delivering that secondary energy from the point of conversion to the point of end use, times (3) the end-use efficiency of converting the delivered secondary energy into such desired energy services as hot showers and cold beer. Some analysts add another term at the upstream end, (4) the extractive efficiency of converting fuel in the ground or power from wind or from sun in the atmosphere, etc. into the primary energy fed into the initial conversion device, and another term at the downstream end, (5) the hedonic efficiency of converting delivered energy services into human welfare. (Delivering junk mail with high technical efficiency is futile if the recipients did not want it.) Counting all five efficiencies permits comparing ultimate means, the primary energy tapped, with ultimate ends, the happiness or economic welfare created. Focusing only on intermediate means and ends loses sight of what human purposes an energy system is to serve. Most societies pay attention to only three kinds of energy efficiency: extraction (because of its cost, not because the extracted fuels are assigned any intrinsic or depletion value), conversion, and perhaps distribution. End-use and hedonic efficiency are left to customers, are least exploited, and hence hold the biggest potential gains.

They also offer the greatest potential leverage. Because successive efficiencies along the conversion chain all multiply, they are often assumed to be equally important. Yet downstream savings—those nearest the customer—are the most important. Figure 1 shows schematically the successive energy conversions and losses that require about 10 units of fuel to be fed into a conventional thermal power station in order to deliver one unit of flow in a pipe. But conversely, every unit of flow (or friction) saved in the pipe will save approximately 10 units of fuel, cost, and pollution at the power station. It will also make the pump's motor (for example) nearly two and a half units smaller, hence cheaper. To save the most primary energy and the most capital cost, therefore, efficiency efforts should start all the way downstream (see Section 4.2), by asking: How little flow can actually deliver the desired service? How small can the piping friction become? How small, well matched to the flow regime, and efficient can the pump be made? Its coupling? Its motor? Its controls and electrical supplies?

Analyses of energy use should start with the desired services or changes in well being, then work back upstream to primary supplies. This maximizes the extra value of downstream efficiency gains and

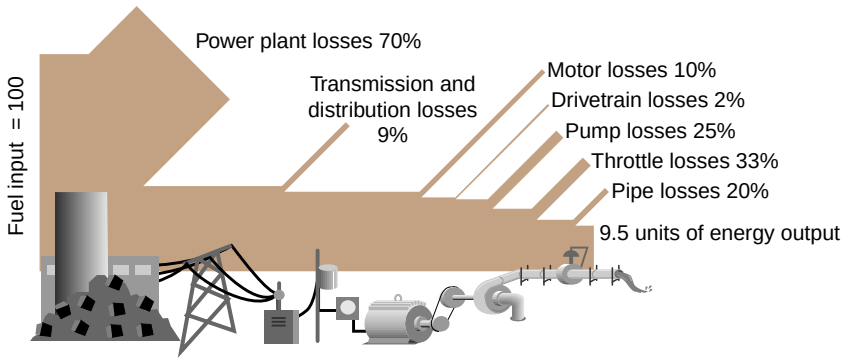

FIGURE 1 To deliver one unit of flow in the pipe requires about 10 units of fuel at the power plant, thus those 10-fold compounding losses can be turned around backward, yielding 10-fold compounding savings of fuel for each unit of reduced friction or flow in the pipe. From the E SOURCE "Drivepower Technology Atlas," courtesy of Platts Research & Consulting.

the capital-cost savings from smaller, simpler, cheaper upstream equipment. Yet it is rarely done. Similarly, most energy policy analysts analyze how much energy could be supplied before asking how much is optimally needed and at what quality and scale it could be optimally provided. This wrong direction (upstream to downstream) and supply orientation lie at the root of many if not most energy policy problems.

Even modest improvements in efficiency at each step of the conversion chain can multiply to large collective values. For example, suppose that during the years 2000–2050, world population and economic growth increased economic activity by six- to eightfold, in line with conventional projections. But meanwhile, the carbon intensity of primary fuel, following a two-century trend, is likely to fall by at least two- to fourfold as coal gives way to gas, renewables, and carbon offsets or sequestration. Conversion efficiency is likely to increase by at least 1.5-fold with modernized, better-run, combined-cycle, and cogenerating power stations. Distribution efficiency should improve modestly. End-use efficiency could improve by four- to sixfold if the intensity reductions sustained by many industrial countries, when they were paying attention, were sustained for 50 years (e.g., the United States decreased its primary energy/GDP intensity at an average rate of 3.4%/year from 1979 to 1986 and 3.0%/year from 1996 to 2001). And the least understood term, hedonic efficiency, might remain constant or might perhaps double as better business models and customer choice systematically improve the quality of services delivered and their match to what customers want. On these plausible assumptions, global carbon emissions from burning fossil fuel could decrease by 1.5- to 12-fold despite the assumed six- to eightfold grosser world product. The most important assumption is sustained success with end-use efficiency, but the decarbonization and conversion-efficiency terms appear able to take up some slack if needed.

1.3 Service Redefinition

Some major opportunities to save energy redefine the service being provided. This is often a cultural variable. A Japanese person, asked why the house is not heated in winter, might reply, "Why should I? Is the house cold?" In Japanese culture, the traditional goal is to keep the person comfortable, not to heat empty space. Thus a modern Japanese room air conditioner may contain a sensor array and moveable fans that detect and blow air toward people's locations in the room, rather than wastefully cooling the entire space. Western office workers, too, can save energy (and can often see better, feel less tired, and improve esthetics) by properly adjusting venetian blinds, bouncing glare-free daylight up onto the ceiling, and turning off the lights. As Jørgen Nørgård remarks, "energy-efficient lamps save the most energy when they are turned off"; yet many people automatically turn on every light when entering a room. This example also illustrates that energy efficiency may be hard to distinguish from energy supply that comes from natural energy flows. All houses are already $\sim$98% solar-heated, because if there were no Sun (which provides 99.8% of Earth's heat), the temperature of Earth's surface would average approximately -272.6°C rather than $+15^{\circ}$C. Thus, strictly speaking, engineered heating systems provide only the last 1–2% of the total heating required.

Service redefinition becomes complex in personal transport. Its efficiency is not just about vehicular fuel economy, people per car, or public transport alternatives. Rather, the underlying service should often be defined as access, not mobility. Typically, the best way to gain access to a place is to be there already; this is the realm of land-use management—no novelty in the United States, where spatial planning is officially shunned, yet zoning laws mandate dispersion of location and function, real-estate practices segregate housing by income, and other market distortions maximize unneeded and often unwanted travel. Another way to gain access is virtually, moving just the electrons while leaving the heavy nuclei behind, via telecommunications, soon including realistic "virtual presence." This is sometimes an effective alternative to physically moving human bodies. And if such movement is really necessary, then it merits real competition, at honest prices, between all modes—personal or collective, motorized or human-powered, conventional or innovative. Creative policy tools can enhance that choice in ways that enhance real-estate value, saved time, quality of life, and public amenity and security. Efficient cars can be an important part of efficient personal mobility, but also reducing the need to drive can save even more energy and yield greater total benefit.

1.4 Historic Summaries of Potential

People have been saving energy for centuries, even millennia; this is the essence of engineering. Most savings were initially in conversion and end use:

preindustrial households often used more primary energy than modern ones do, because fuelwood-to-charcoal conversion, inefficient open fires, and crude stoves burned much fuel to deliver sparse cooking and warmth. Lighting, materials processing, and transport end uses were also very inefficient. Billions of human beings still suffer such conditions today. The primary energy/GDP intensities in developing countries average about three times those in industrialized countries. But even the most energy-efficient societies still have enormous, and steadily expanding, room for further efficiency gains. Less than one-fourth of the energy delivered to a typical European cookstove ends up in food, less than 1% of the fuel delivered to a standard car actually moves the driver, U.S. power plants discard waste heat equivalent to 1.2 times Japan's total energy use, and even Japan's economy does not approach one-tenth the efficiency that the laws of physics permit.

Detailed and exhaustively documented engineering analyses of the scope for improving energy efficiency, especially in end-use devices, have been published for many industrial and some developing countries. By the early 1980s, those analyses had compellingly shown that most of the energy currently used was being wasted—i.e., that the same or better services could be provided using severalfold less primary energy by fully installing, wherever practical and profitable, the most efficient conversion and end-use technologies then available. Such impressive efficiency gains cost considerably less than the long-run, and often even the short-run, marginal private internal cost of supplying more energy. Most policymakers ignore both these analyses, well known to specialists, and less well-known findings show even bigger and cheaper savings from whole-system design integration (see Section 4).

Many published engineering analyses show a smaller saving potential because of major conservatisms, often deliberate (because the real figures seem too good to be true), or because they assume only partial adoption over a short period rather than examining the ultimate potential for complete practical adoption. For example, the American Council for an Energy-Efficient Economy estimates that just reasonable adoption of the top five conventional U.S. opportunities—industrial improvements, 40-mile per gallon (U.S. gallons; = 4.88 liters/100 km) light-vehicle standards, cogeneration, better building codes, and a 30% better central-air-conditioning standard—could save 530 million T/year of oil equivalent—respectively equivalent to the total 2000 primary energy use of Australia, Mexico, Spain, Austria, and Ireland. But the full long-term efficiency potential is far larger, and much of it resides in innumerable small terms. Saving energy is like eating an Atlantic lobster: there are big, obvious chunks of meat in the tail and the front claws, but a similar total quantity of tasty morsels is hidden in crevices and requires some skill and persistence to extract.

The whole-lobster potential is best, though still not fully, seen in bottom-up technological analyses comparing the quantity of potential energy savings with their marginal cost. That cost is typically calculated using the Lawrence Berkeley National Laboratory methodology, which divides the marginal cost of buying, installing, and maintaining the more efficient device by its discounted stream of lifetime energy savings. The levelized cost in dollars of saving, say, 1 kWh, then equals $Ci/S[1-(1+i)^{-n}]$, where C is installed capital cost (dollars), i is annual real discount rate (assumed here to be 0.05), S is energy saved by the device (kilowatt-hours/year), and n is operating life (years). Thus a \$10 device that saved 100 kWh/year and lasted 20 years would have a levelized "cost of saved energy" (CSE) of 0.8¢/kWh. Against a 5¢/kWh electricity price, a 20-year device with a 1-year simple payback would have CSE = 0.4¢/kWh. It is conventional for engineering-oriented analysts to represent efficiency "resources" as a supply curve, rather than as shifts along a demand curve (the convention among economists). CSE is methodologically equivalent to the cost of supplied energy (e.g., from a power station and grid): the price of the energy saved is not part of the calculation. Whether the saving is cost-effective depends on comparing the cost of achieving it with the avoided cost of the energy saved. (As noted in Section 2, this conventional engineering–economic approach actually understates the benefits of energy efficiency.)

On this basis, the author's analyses in the late 1980s found, from measured cost and performance data for more than 1000 electricity-saving end-use technologies, that their full practical retrofit could save about three-fourths of U.S. electricity at an average CSE $\sim$ 0.6¢/kWh (1986 dollars)—roughly consistent with a 1990 Electric Power Research Institute analysis in which the differences were mainly methodological rather than substantive. Similarly, the author's analysis for Royal Dutch/Shell Group found that full use of the best 1987–1988 oil-saving end-use technologies, assuming turnover of vehicle stocks, could save about 80% of U.S. oil use at an average levelized CSE below \$2.5/barrel (1986 dollars). Both analyses have proven systematically

conservative: today's potential is even larger and cheaper. (The analyses explicitly excluded financing and transaction costs, but those would only slightly affect the results. There is also a huge literature accurately predicting and rigorously measuring the empirical size, speed, and cost of efficiency improvements delivered by actual utility and government programs.) Such findings are broadly consistent with equally or more detailed ones by European analysts: for example, late-1980s technologies could save three-fourths of Danish buildings' electricity or half of all Swedish electricity at $0.016/kWh (1986 dollars), or four-fifths of German home electricity (including minor fuel switching) with a ~40%/year aftertax return on investment. Such findings with ever greater sophistication have been published worldwide since 1979, but have been rejected by nontechnological economic theorists, who argue that if such cost-effective opportunities existed, they would already have been captured in the marketplace, even in planned economies with no marketplace or mixed economies with a distorted one. This mental model—"don't bother to bend over and pick up that banknote lying on the ground, because if it were real, someone would have picked it up already"—often dominates government policy. It seems ever less defensible as more is learned about the reality of pervasive market failures (see Section 5) and the astonishing size and cheapness of the energy savings empirically achieved by diverse enterprises (discussed in Section 3). But by now, the debate is theological—about whether existing markets are essentially perfect, as most economic modelers assume for comfort and convenience, or whether market failures are at least as important as market function and lie at the heart of business and policy opportunity. To technologists and physical scientists, this seems a testable empirical question.

1.5 Discontinuous Technological Progress

This engineering/economics divergence about the potential to save energy also reflects a tacit assumption that technological evolution is smooth and incremental, as mathematical modelers prefer. In fact, although much progress is as incremental as technology diffusion, discontinuous technological leaps, more like "punctuated equilibrium" in evolutionary biology, can propel innovation and speed its adoption, as with 5×-efficiency light vehicles (see Section 4.1).

Technological discontinuities can even burst the conventional boundaries of possibility by redefining the design space. Generations of engineers learned that big supercritical-steam power plants were as efficient as possible (~40% from fuel in to electricity out). But through sloppy learning or teaching, these engineers overlooked the possibility of stacking two Carnot cycles atop each other. Such combined-cycle (gas-then-steam) turbines, based on mass-produced jet engines, can exceed 60% efficiency and are cheaper and faster to build, so in the 1990s, they quickly displaced the big steam plants. Fuel cells, the next innovation, avoid Carnot limits altogether by being an electrochemical device, not a heat engine. Combining both may soon achieve 80–90% fuel-to-electric efficiency. Even inefficient distributed generators can already exceed 90% system efficiency by artfully using recaptured heat.

As another example, most authors today state that the theoretical efficiency limit for converting sunlight into electricity using single-layer photovoltaic (PV) cells is 31% (~50% using multicolor stacked layers; the best practical values so far are around 25 and 30%). This is because semiconductor bandgaps have been believed too big to capture any but the high-energy wavelengths of sunlight. But those standard data are wrong. A Russian-based team suspected in 2001, and Lawrence Berkeley National Laboratory proved in 2002, that indium nitride's bandgap is only 0.7 eV, matching near-infrared (1.77 μm) light and hence able to harvest almost the whole solar spectrum. This may raise the theoretical limit to 50% for two-layer and to ~70% for many-layer thin-film PVs.

Caution is likewise vital when interpreting Second Law efficiency. In the macroscopic world, the laws of thermodynamics are normally considered ineluctable, but the definition of the desired change of state can be finessed. Ernie Robertson notes that when turning limestone into a structural material, one is not confined to just the conventional possibilities of cutting it into blocks or calcining it at ~1250°C into Portland cement. It is possible instead grind it up and feed it to chickens, in which ambient-temperature "technology" turns it into eggshell stronger than Portland cement. Were we as smart as chickens, we would have mastered this life-friendly technology. Extraordinary new opportunities to harness 3.8 billion years of biological design experience, as described by Janine Benyus in *Biomimicry*, can often make heat-beat-and-treat industrial processes unnecessary. So, in principle, can the emerging techniques of nanotechnology using molecular-scale self-assembly, as pioneered by Eric Drexler.

More conventional innovations can also bypass energy-intensive industrial processes. Making artifacts that last longer, use materials more frugally, and are designed and deployed to be repaired, reused, remanufactured, and recycled can save much or most of the energy traditionally needed to produce and assemble their materials (and can increase welfare while reducing GDP, which swells when ephemeral goods are quickly discarded and replaced). Microfluidics can even reduce a large chemical plant to the size of a watermelon: millimeter-scale flow in channels etched into silicon wafers can control time, temperature, pressure, stoichiometry, and catalysis so exactly that a very narrow product spectrum is produced, without the side-reactions that normally require most of the chemical plant to separate undesired from desired products. Such "end-run" solutions (rather like the previous example of substituting sensible land-use for better vehicles, or better still, combining both) can greatly expand the range of possibilities beyond simply improving the narrowly defined efficiency of industrial equipment, processes, and controls. By combining many such options, it is now realistic to contemplate a long-run advanced industrial society that provides unprecedented levels of material prosperity with far less energy, cost, and impact than today's best practice. The discussion in Section 4.1, drawn from Paul Hawken *et al.*'s synthesis in *Natural Capitalism* and Ernst von Weizsäcker *et al.*'s earlier *Factor Four*, further illustrates recent breakthroughs in integrative design that can make very large energy savings cost less than small ones; and similarly important discontinuities in policy innovation are summarized in Section 6.

In light of all these possibilities, why does energy efficiency, in most countries and at most times, command so little attention and such lackadaisical pursuit? Several explanations come to mind. Saved energy is invisible. Energy-saving technologies may look and outwardly act exactly like inefficient ones, so they are invisible too. They are also highly dispersed, unlike central supply technologies that are among the most impressive human creations, inspiring pride and attracting ribbon-cutters and rent- and bribe-seekers. Many users believe energy efficiency is binary—you either have it or lack it—and that they already did it in the 1970s. Energy efficiency has relatively weak and scattered constituencies, and major energy efficiency opportunities are disdained or disbelieved by policymakers indoctrinated in a theoretical economic paradigm that claims they cannot exist (see Section 3).

2. BENEFITS OF ENERGY EFFICIENCY

Energy efficiency avoids the direct economic costs and the direct environmental, security, and other costs of the energy supply and delivery that it displaces. Yet the literature often overlooks several key side-benefits (economists call them "joint products") of saving energy.

2.1 Indirect Benefits from Qualitatively Superior Services

Improved energy efficiency, especially end-use efficiency, often delivers better services. Efficient houses are more comfortable; efficient lighting systems can look better and help you see better; efficient motors can be more quiet, reliable, and controllable; efficient refrigerators can keep food fresher for longer; efficient cleanrooms can improve the yield, flexibility, throughput, and setup time of microchip fabrication plants; efficient fume hoods can improve safety; efficient supermarkets can improve food safety and merchandising; retail sales pressure can rise 40% in well-daylit stores; and students' test scores suggest 20–26% faster learning in well-daylit schools. Such side-benefits can be one or even two more orders of magnitude more valuable than the energy directly saved. For example, careful measurements show that in efficient buildings, where workers can see what they are doing, hear themselves think, breathe cleaner air, and feel more comfortable, labor productivity typically rises by about 6–16%. Because office workers in industrialized countries cost about 100 times more than office energy, a 1% increase in labor productivity has the same bottom-line effect as eliminating the energy bill, and the actual gain in labor productivity is about 6–16 times bigger than that. Practitioners can market these attributes without ever mentioning lower energy bills.

2.2 Leverage in Global Fuel Markets

Much has been written about the increasing pricing power of major oil-exporting countries, especially Saudi Arabia, with its important swing production capacity. Yet the market power of the United States—the Saudi Arabia of energy waste—is even greater on the demand side. The United States can raise its oil productivity more and faster than any oil exporter can adjust to reducing its oil output. This was illustrated

from 1977 to 1985, when U.S. GDP rose 27% while total U.S. oil imports fell by 42%, or 3.74 million barrels (bbl)/day. This was largely due to a 52% gain in oil productivity, causing U.S. oil consumption to fall by 17% and oil imports from the Persian Gulf to fall by 91%. That took away an eighth of OPEC's market. The entire world oil market shrank by a tenth; OPEC's share was slashed from 52 to 30%, and its output fell by 48%. The United States accounted for one-fourth of that reduction. More efficient cars, each driving 1% fewer miles on 20% less gasoline—a 7-mile per (U.S.) gallon gain in 6 years for new American-made cars—were the most important single cause; 96% of those savings came from smarter design, with only 4% deriving from smaller size.

Those 8 years around the second oil shock (1979) demonstrated an effective new source of energy security and a potent weapon against high oil prices and supply manipulations. The United States showed that a major consuming nation could respond effectively to supply disruptions by focusing on the demand side and boosting oil productivity at will. It could thereby exercise more market power than suppliers, beat down their prices (breaking OPEC's pricing power for a decade), and enhance the relative importance of less vulnerable, more diversified sources of supply. Had the United States simply continued its 1979–1985 rate of improvement of oil productivity, it would not have needed a drop of oil from the Persian Gulf after 1985. That is not what happened, but it could be if the United States chose to repeat and expand its previous oil savings.

2.3 Buying Time

Energy efficiency buys time. Time is the most precious asset in energy policy, because it permits the fullest and most graceful development and deployment of still better techniques for energy efficiency and supply. This pushes supply curves downward (larger quantities at lower prices), postpones economic depletion, and buys even more time. The more time is available, the more information will emerge to support wiser and more robust choices, and the more fruitfully new technologies and policy options can meld and breed new ones. Conversely, hasty choices driven by supply exigencies almost always turn out badly, waste resources, and foreclose important options. Of course, once bought, time should be used wisely. Instead, the decade of respite bought by the U.S. efficiency spurt of 1979–1985 was almost entirely wasted as attention waned, efficiency and alternative-supply efforts stalled, research and development teams were disbanded, and underlying political problems festered. From the perspective of 2004, that decade of stagnation looked like a blunder of historic proportions.

2.4 Integrating Efficiency with Supply

To the first order, energy efficiency makes supply cheaper. But second-order effects reinforce this first-order benefit, most obviously when efficiency is combined with onsite renewable supplies, making them nonlinearly smaller, simpler, and cheaper. Consider the following examples:

- A hot-water-saving house can achieve a very high solar-water-heat fraction (e.g., 99% in the author's home high in the Rocky Mountains) with only a small collector, so it needs little or no backup, partly because collector efficiency increases as stratified-tank storage temperature decreases.
- An electricity-saving house needs only a few square meters of PVs and a simple balance-of-system setup (storage, inverter, etc.). This can cost less than connecting to the grid a few meters away.
- A passive-solar, daylit building needs little electricity, and can pay for even costly forms of on-site generation (such as PVs) using money saved by eliminating or downsizing mechanical systems.
- Such mutually reinforcing options can be bundled: e.g., 1.18 peak MW of photovoltaics retrofitted onto the Santa Rita Jail in Alameda County, California, was combined with efficiency and load management, so at peak periods, when the power was most valuable, less was used by the jail and more was sold back to the grid. This bundling yielded a internal rate of return of over 10% including state subsidies, and a customer present-valued benefit/cost ratio of 1.7 without or 3.8 with those subsidies.

2.5 Gaps in Engineering Economics

Both engineers and economists conventionally calculate the cost of supplying or saving energy using a rough-and-ready tool kit called "engineering economics." Its methods are easy to use but flawed, ignoring such basic tenets of financial economics as risk-adjusted discount rates. Indeed, engineering economics omits 207 economic and engineering considerations that together increase the value of decentralized electrical resources by typically an order of magnitude. Many of these "distributed benefits," compiled in the author's *Small Is Profitable*, apply as much to decentralized efficiency as to

generation. Most of the literature on the cost of energy alternatives is based solely on accounting costs and engineering economics that greatly understate efficiency's value. Properly counting its benefits will yield far sounder investments.

Efficient end use is also the most effective way to make energy supply systems more resilient against mishap or malice, because it increases the duration of buffer stocks, buying time to mend damage or arrange new supplies, and it increases the share of service that curtailed or improvised supplies can deliver. Efficiency's high "bounce per buck" makes it the cornerstone of any energy system designed for secure service provision in a dangerous world.

3. ENGINEERING VS. ECONOMIC PERSPECTIVES

Engineering practitioners and economic theorists view energy efficiency through profoundly different lenses, yet both disciplines are hard pressed to explain the following phenomena:

1. During the period 1996–2001, U.S. aggregate energy intensity fell at a near-record pace despite record low and falling energy prices. (It fell faster only once in modern history, during the record high and rising energy prices of 1979–1985.) Apparently, something other than price was getting Americans' attention.
2. During the period 1990–1996, when a kilowatt-hour of electricity cost only half as much in Seattle as in Chicago, people in Seattle, on average, reduced their peak electric load 12 times as fast, and their use of electricity about 3640 times as fast, as did people in Chicago—perhaps because Seattle City Light encouraged savings while Commonwealth Edison Co. discouraged them.
3. In the 1990s, DuPont found that its European chemical plants were no more energy efficient than its corresponding U.S. plants, despite long having paid twice the energy price—perhaps because all the plants were designed by the same people in the same ways with the same equipment; there is little room for behavioral change in a chemical plant.
4. In Dow Chemical Company's Louisiana Division during the period 1981–1993, nearly 1000 projects to save energy and reduce waste added $110 million/year to the bottom line and
yielded returns on investment averaging over 200%/year, yet in the latter years, both the returns and the savings were trending upward as the engineers discovered new tricks faster than they used up the old ones. (Economic theory would deny the possibility of so much "low-hanging fruit" that has fallen down and is mushing up around the ankles: such enormous returns, if real, would long ago have been captured. This belief was the main obstacle to engineers' seeking such savings, then persisting after their discovery.)
5. Only about 25–35% of apartment dwellers, when told that their air conditioner and electricity are free, behave as economists would predict—turning on the air conditioner when they feel hot and setting the thermostat at a temperature at which they feel comfortable. The rest of the apartment dwellers show no correlation between air-conditioning usage and comfort; instead, their cooling behavior is determined by at least six other variables: household schedules, folk theories about air conditioners (such as that the thermostat is a valve that makes the cold come out faster), general strategies for dealing with machines, complex belief systems about health and physiology, noise aversion, and wanting white noise to mask outside sounds that might wake the baby. Energy anthropology reveals that both the economic and the engineering models of air-conditioning behavior are not just incomplete but seriously misleading.
6. The United States has misallocated $1 trillion of investments to about 200 million refrigerative tons of air conditioners, and 200 peak GW (two-fifths of total peak load) of power supply to run them, that would not have been bought if the buildings had been optimally designed to produce best comfort at least cost. This seems explicable by the perfectly perverse incentives seen by each of the 20-odd actors in the commercial real-estate value chain, each systematically rewarded for inefficiency and penalized for efficiency.
7. Not just individuals but also most firms, even large and sophisticated ones, routinely fail to make essentially riskless efficiency investments yielding many times their normal business returns: most require energy efficiency investments to yield roughly six times their marginal cost of capital, which typically applies to far riskier investments.

Many economists would posit some unknown error or omission in these descriptions, not in their theories. Indeed, energy engineers and energy economists seem not to agree about what is a hypothesis and what is a fact. Engineers take their facts from tools of physical observation. Three decades of conversations with noted energy economists suggest

to the author that most think facts come only from observed flows of dollars, interpreted through indisputable theoretical constructs, and consider any contrary physical observations aberrant. This divergence makes most energy economists suppose that buying energy efficiency faster than the "spontaneous" rate of observed intensity reduction (for 1997–2001, 2.7%/year in the United States, 1.4%/year in the European Union, 1.3%/year worldwide, and 5.3%/year in China) would require considerably higher energy prices, because if greater savings were profitable at today's prices, they would already have been bought; thus the engineers' bottom-up analyses of potential energy savings must be unrealistically high. Economists' estimates of potential savings at current prices are "top-down" and very small, based on historic price elasticities that confine potential interventions to changing prices and savings to modest size and diminishing returns (otherwise the economists' simulation models would inconveniently explode). Engineers retort that high energy prices are not necessary for very large energy savings (because they are so lucrative even at present prices) but are not sufficient either (because higher prices do little without enlarged ability to respond to them).

Of course, engineering-based practitioners agree that human behavior is influenced by price, as well as by convenience, familiarity, fashion, transparency, competing claims on attention, and many other marketing and social-science factors—missing from any purely technological perspective but central to day-to-day fieldwork. The main difference is that they think these obstacles are "market failures" and dominate behavior in buying energy efficiency. Most economists deny this, and say the relatively slow adoption of efficiency must be due to gross errors in the engineers' claims of how large, cheap, and available its potential really is. This theological deadlock underlies the debate about climate protection. Robert Repetto and Duncan Austin showed in 1997 that all mainstream climate-economics models' outputs are hard-wired to the input assumptions, and that realistic inputs, conforming to the actual content of the Kyoto Protocol and its rules, show that climate protection increases GDP. Florentin Krause has shown that the main official U.S. government analyses, taken together, concur. Yet the official U.S. position at the end of 2003 was still that climate protection, even if desirable, cannot be mandated because it is too costly.

In fact, climate protection is not costly but profitable; its critics may have the amount about right, but they got the sign wrong. The clearest proof is in the behavior and achievements of the smart companies that are behaving as if the United States had ratified the Kyoto Protocol, because energy efficiency is cheaper than the energy it saves. For example, large firms such as DuPont, IBM, and STMicroelectronics (ST; one of the world's largest chipmakers) have lately been raising their energy productivity by 6%/year with simple paybacks of a few years. DuPont expects by 2010 to cut its greenhouse gas emissions by 65% below the 1990 level; ST expects to achieve zero emissions (despite making 40 times more chips). British Petroleum announced that its 10% reduction by 2010 had been achieved 8 years early at zero net cost; actually, the 10-year net-present-valued saving was $650 million. Other examples abound; the Web sites www.cool-companies.org and www.pewclimate.org contain examples of the achievements of actively engaged businesses. The companies involved, many of them well known in the business world, are hardly naïve or deluded. Anyone ignoring this market reality is mistaking the econometric rearview mirror for a windshield. Econometrics measures how human populations behaved under past conditions that no longer exist and that it is often a goal of energy policy to change. Where price is the only important explanatory variable, econometrics can be a useful tool for extrapolating history into how price may influence near-term, small, incremental changes in behavior. But limiting our horizons to this cramped view of technical possibilities and human complexity rules out innovations in policies, institutions, preferences, and technologies—treating the future like fate, not choice, and thus making it so.

4. DIMINISHING VS. EXPANDING RETURNS TO INVESTMENTS IN ENERGY EFFICIENCY

Among the most basic, yet simply resolved, economic/engineering disagreements is whether investing in end-use efficiency yields expanding or diminishing returns. Economic theory says diminishing: the more efficiency we buy, the more steeply the marginal cost of the next increment of savings rises, until it becomes too expensive (Fig. 2). But engineering practice often says expanding: big savings can cost less than small or no savings (Fig. 3) if the engineering is done unconventionally but properly.

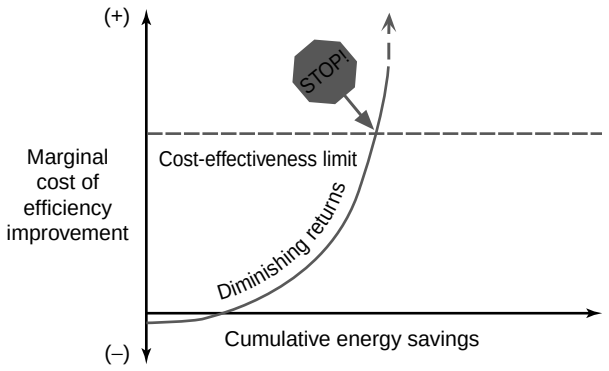

FIGURE 2 Diminishing returns (greater energy savings incur greater marginal cost) can be true for some (not all) components, but need not be true for most systems.

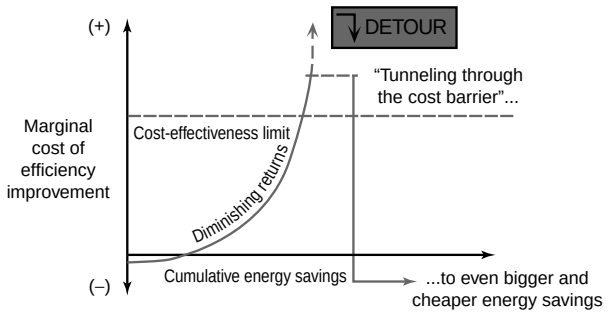

FIGURE 3 Optimizing whole systems for multiple benefits, rather than isolated components for single benefits, can often "tunnel through the cost barrier" directly to the lower-right-corner destination, making very large energy savings cost less than small or no savings. This has been empirically demonstrated in a wide range of technical systems.

4.1 Empirical Examples

Consider, for example, how much thermal insulation should surround a house in a cold climate. Conventional design specifies just the amount of insulation that will repay its marginal cost out of the present value of the saved marginal energy. But this is methodologically wrong, because the comparison omits the capital cost of the heating system: furnace, ducts, fans, pipes, pumps, wires, controls, and fuel source. The author's house illustrates that in outdoor temperatures down to –44°C, it is feasible to grow bananas (28 crops at this writing) at 2200 m elevation in the Rocky Mountains with no heating system, yet with reduced construction cost, because the superwindows, superinsulation, air-to-air heat exchangers, and other investments needed to eliminate the heating system cost less to install than the heating system would have cost to install. The resulting ~99% reduction in heating energy cost is an extra benefit.

Similarly, Pacific Gas and Electric Company's Advanced Customer Technology Test for Maximum Energy Efficiency (ACT^2) demonstrated in seven new and old buildings that the "supply curve" of energy efficiency generally bent downward, as shown schematically in Fig. 3. For example, an ordinary-looking new tract house was designed to save 82% of the energy allowed by the strictest U.S. standard of the time (1992 California Title 24); if this design were widely implemented rather than restricted to a single experiment, it was estimated by PG&E that it would cost about $1800 less than normal to build and $1600 less (in present value) to maintain. It provided comfort with no cooling system in a climate that can reach 45°C; a similar house later did the same in a 46°C-peak climate. Another example, the 350-m^2 Bangkok home of architecture professor Suntoorn Boonyatikarn, provided normal comfort, with 10% the normal air-conditioning capacity, at no extra construction cost. These examples illustrate how optimizing a house as a system rather than optimizing a component in isolation, and optimizing for life-cycle cost (capital plus operating cost, and preferably also maintenance cost), can make a superefficient house cheaper to build, not just to run, by eliminating costly heating and cooling systems. Similarly, a retrofit design for a 19,000-m^2 curtainwall office building near Chicago found 75% energy-saving potential at no more cost than the normal 20-year renovation that saves nothing, because the $200,000 capital saving from making the cooling system four times smaller (yet four times more efficient), rather than renovating the big old system, would pay for the other improvements.

In a striking industrial example, a pumping loop for heat transfer originally designed to use 70.8 kW of pumping power was redesigned to use 5.3 kW, 92% less, with lower capital cost and better performance. No new technologies were used, but only two changes in the design mentality:

1. Use big pipes and small pumps rather than small pipes and big pumps. The friction in a pipe falls as nearly the fifth power (roughly −4.84) of its diameter. Engineers normally make the pipe just fat enough to repay its greater cost from the saved pumping energy. This calculation improperly omits the capital cost of the pumping equipment—the pump, motor, inverter, and electricals that must overcome the pipe friction. Yet the size and roughly the cost of that equipment will fall as nearly the fifth power of pipe diameter, while the cost of the fatter pipe will rise as only about the second power of

diameter. Thus conventionally optimizing the pipe as an isolated component actually pessimizes the system! Optimizing the whole system together will clearly yield fat pipes and tiny pumps, so total capital cost falls slightly and operating cost falls dramatically.

2. Lay out the pipes first, then the equipment. Normal practice is the opposite, so the connected equipment is typically far apart, obstructed by other objects, at the wrong height, and facing the wrong way. The resulting pipes have about three to six times as much friction as they would have with a straight shot, to the delight of the pipefitters, who are paid by the hour, who mark up a profit on the extra pipes and fittings, and who do not pay for the extra electricity or equipment sizing. But the owner would do better to have short, straight pipes than long, crooked pipes.

Together, these two design changes cut the measured pumping power by 12-fold, with lower capital cost and better performance. They also saved 70 kW of heat loss with a 2-month payback, because it was easier to insulate short, straight pipes. In hindsight, however, the design was still suboptimal, because it omitted seven additional benefits: less space, weight, and noise; better maintenance access; lower maintenance cost; higher reliability and uptime; and longer life (because the removed pipe elbows will not be eroded by fluid turning the corner). Properly counting these seven benefits would have saved not 92% but nearer 98% of the energy, and cost even less, so about a factor-four potential saving was left uncaptured.

Other recent design examples include a 97% reduction in air-conditioning energy for a California office retrofit, with attractive returns and better comfort; lighting retrofit savings upward of 90% with better visibility and a 1- to 2-year payback; an energy cost reduction $>40\%$ with a 3-year payback in retrofitting an already very efficient oil refinery; $\sim 75\%$ electrical savings in a new chemical plant, with $\sim 10\%$ lower construction time and cost; $\sim 89\%$ in a new data center at lower cost; and ~ 70–90% in a new supermarket at probably lower cost. The obvious lesson is that optimizing whole systems for multiple benefits, not just components for single benefits, typically boosts end-use efficiency by roughly an order of magnitude at negative marginal cost. These enormous savings have not been widely noticed or captured because of deficient engineering pedagogy and practice. Whole-system design integration is not rocket science; rather, it rediscovers the forgotten tradition of Victorian system engineering, before designers became so specialized that they lost sight of how components fit together.

It is not even generally true, as economic theory supposes, that greater end-use efficiency costs more at the level of components. For example, the most common type of industrial motor on the 1996 U.S. market, the 1800-revolution per minute (rpm) totally enclosed fan-cooled (TEFC) motor (National Electrical Manufacturers' Association Design B), exhibited no empirical correlation whatever between efficiency and price up to at least 225 kW. (Premium-efficiency motors should cost more to build because they contain more and better copper and iron, but they are not priced that way.) The same is true for most industrial pumps and rooftop chillers, Swedish refrigerators, American televisions, and many other products. But even if it were true, artfully combining components into systems can definitely yield expanding returns.

Perhaps the most consequential example is in light vehicles. A small private company (see its Web site at www.hypercar.com) completed in 2000 the manufacturable, production-costed virtual design of a midsize sport utility vehicle (SUV) concept car that is uncompromised, cost-competitive, zero emission, and quintupled efficiency. It is so efficient (2.38 liters/100 km, 42 km/liter, 99 mpg, U.S. gallons) not just because its direct-hydrogen fuel cell is about twice as efficient as a gasoline-fueled Otto engine, but also because it is so lightweight (but crashworthy) and so low in aerodynamic drag and rolling resistance that it can cruise at highway speed on no more power to the wheels than a conventional SUV uses on a hot day just for air conditioning. This design suggests that cars, too, can "tunnel through the cost barrier," achieving astonishing fuel economy at no extra cost and with many other customer and manufacturing advantages. With aggressive licensing of existing intellectual property, such vehicles could start ramping up production as early as 2008. All major automakers have parallel development programs underway, totaling $\sim$\$10 billion of commitments through 2000, since the basic concept was put into the public domain in 1993 to maximize competition.

A full U.S. fleet of such light vehicles of various shapes and sizes would save about as much oil as Saudi Arabia produces (~ 8 million bbl/day); a global fleet would save as much oil as OPEC sells. Moreover, such vehicles can be designed to plug into the grid when parked (which the average car is $\sim 96\%$ of the time), acting as a power station on wheels, selling back enough electricity and ancillary

services to repay most of its cost. A U.S. fleet of light vehicles doing this would have ~5–10 times as much electric generating capacity as all power companies now own. This is part of a wider strategy that combines hydrogen-ready vehicles with integrated deployment of fuel cells in stationary and mobile applications to make the transition to a climate-safe hydrogen economy profitable at each step, starting now (beginning with ultrareliable combined heat and power in buildings). The resulting displacement of power plants, oil-fueled vehicles, and fossil-fueled boilers and furnaces could decrease net consumption of natural gas, could save about $1 trillion of global vehicle fueling investment over the next 40 years (compared with gasoline-system investment), and could profitably displace up to two-thirds of CO_2 emissions. It could also raise the value of hydrocarbon reserves, in which hydrogen is typically worth more without than with the carbon. It is favored by many leading energy and car companies today, and it is not too far off: over two-thirds of the fossil fuel atoms burned in the world today are already hydrogen, and global hydrogen production (~50 MT/year), if diverted from its present uses, could fuel an entire fleet of superefficient U.S. highway vehicles.

4.2 The Right Steps in the Right Order

Breakthrough energy efficiency results need not just the right technologies but also their application in the right sequence. For example, most practitioners designing lighting retrofits start with more efficient luminaires, improving optics, lamps, and ballasts. But for optimal energy and capital savings, that should be step six, not step one. First come improving the quality of the visual task, optimizing the geometry and cavity reflectance of the space, optimizing lighting quality and quantity, and harvesting daylight. Then, after the luminaire improvements, come better controls, maintenance, management, and training. Likewise, to deliver thermal comfort in a hot climate, most engineers retrofit a more efficient and perhaps variable-speed chiller, variable-speed supply fans, etc. But these should all be step five. The previous four steps are to expand the comfort range (by exploiting such variables as radiant temperature, turbulent air movement, and ventilative chairs); reduce unwanted heat gains within or into the space; exploit passive cooling (ventilative, radiative, ground coupling); and, if needed, harness nonrefrigerative alternative cooling (evaporative, desiccant, absorption, and hybrids of these). These preliminary steps can generally eliminate refrigerative cooling. If refrigerative cooling is still nonetheless desired, it can be made superefficient (e.g., system coefficient of performance 8.6 measured in Singapore), then supplemented by better controls and by coolth storage. Yet most designers pursue these seven steps in reverse order, worst buys first, so they save less energy, pay higher capital costs, yet achieve worse comfort and greater complexity.

Whole-system engineering optimizes for many benefits. There are, for example, 10 benefits of superwindows and 18 benefits of premium-efficiency motors or dimmable electronic lighting ballasts, not just the one benefit normally counted. (The arch that holds up the middle of the author's house has 12 different functions but is paid for only once.) Superwindows cost more per window, but typically make the building cost less because they downsize or eliminate space-conditioning equipment. Similarly, 35 retrofits to a typical industrial motor system, properly counting multiple benefits, can typically save about half its energy (not counting the larger and cheaper savings that should first be captured further downstream, e.g., in pumps and pipes) with a 16-month simple payback against a 5¢/kWh tariff. The saving is so cheap because buying the correct seven improvements first yields 28 more as free by-products. Such motor-system savings alone, if fully implemented, could save about 30% of all electricity worldwide. Such design requires a diverse background, deep curiosity, often a transdisciplinary design team, and meticulous attention to detail. Whole-system design is not what any engineering school appears to be teaching, nor what most customers currently expect, request, reward, or receive. But it represents a key part of the "overhang" of practical, profitable, unbought energy efficiency absent from virtually all official studies so far.

5. MARKET FAILURES AND BUSINESS OPPORTUNITIES

In a typical U.S. office, using one-size-fatter wire to power overhead lights would pay for itself within 20 weeks. Why is that not done? There are several answers: (1) The wire size is specified by the low-bid electrician, who was told to "meet code," and the wire-size table in the National Electrical Code is meant to prevent fires, not to save money. Saving money by optimizing resistive losses requires wire

about twice as fat. (2) The office owner or occupant will buy the electricity, but the electrician bought the wire. An electrician altruistic enough to buy fatter wire is not the low bidder and does not win the job. Correcting this specific market failure requires attention both to the split incentive and to the misinterpretation of a life-safety regulation as an economic optimum. This microexample illustrates the range and depth of market failures that any skilled practitioner of energy efficiency encounters daily. A 1997 compendium, *Climate: Making Sense and Making Money*, organizes 60–80 such market failures into eight categories and illustrates the business opportunity each can be turned into. Some arise in public policy, some are at the level of the firm, and some are in individuals' heads. Most are glaringly perverse. For example, in all but two states in the United States, regulated distribution utilities are rewarded for selling more energy and penalized for cutting customers' bills, so naturally they are unenthusiastic about energy efficiency that would hurt their shareholders. Nearly all architects and engineers, too, are paid for what they spend, not for what they save; "performance-based fees" have been shown to yield superior design, but are rarely used. Most firms set discounted-cashflow targets for their financial returns, yet tell their operating engineers to use a simple-payback screen for energy-saving investments (typically less than 2 years), and the disconnect between these two metrics causes and conceals huge misallocations of capital. When markets and bidding systems are established to augment or replace traditional regulation of energy supply industries, negawatts (saved watts) are rarely allowed to compete against megawatts.

In short, scores of market failures—well understood but widely ignored—cause available and profitable energy efficiency to get only a small fraction of the investment it merits. Thus most of the capital invested in the energy system is being misallocated. The most effective remedy would be to put systematic "barrier-busting" atop the policy agenda, turning obstacles into opportunities and stumbling-blocks into stepping-stones, so market mechanisms could work properly, as economic theory correctly prescribes.

Using energy in a way that saves money is not only a perquisite of the rich, it is also arguably the most powerful key to global economic development for the poor. Using quintupled-efficiency compact fluorescent lamps in Bombay or installing superwindows in Bangkok takes about a thousand times less capital compared to expanding the supply of electricity to produce the same light and comfort via inefficient lamps and office/retail air conditioners. The efficiency investment is also repaid about 10 times faster. The resulting $\sim$10,000-fold decrease in capital requirements could turn the power sector, which now uses about one-fourth of global development capital, into a net exporter of capital to fund other development needs. This is also true at the microscale of a rural village: a package of photovoltaics and superefficient end-use devices (lamps, pumps, mobile phone, water purification, vaccine refrigerator, etc.), with normal utility financing and no subsidy, often incurs debt service lower than what the villagers were already paying for lighting kerosene, candles, and radio batteries, so they have a positive cash flow from day one. Conversely, when Chinese authorities imported many assembly lines to make refrigerators more accessible, the saturation of refrigerators in Beijing households rose from 2 to 62% in 6 years, but the refrigerators' inefficient design created unintended shortages of power and of capital to generate it (an extra half-billion dollars' worth). A Chinese Cabinet member said this error must not be repeated: energy and resource efficiency must be the cornerstone of the development process. Otherwise, resource waste will require supply-side investment of the capital meant to buy the devices that were supposed to use those resources. This realization contributed to China's emphasis on energy efficiency (halving primary energy/GDP elasticity in the 1980s and nearly re-halving it since), laying the groundwork for the dramatic 1996 initial shift from coal to gas, renewables, and efficiency. This greatest contribution of any nation so far to reducing carbon emissions was a by-product of two other domestic goals: eliminating the bottleneck in China's development and improving public health.

6. OLD AND NEW WAYS TO ACCELERATE ENERGY EFFICIENCY

6.1 Old but Good Methods

In the 1980s and 1990s, practitioners and policymakers greatly expanded their tool kits for implementing energy efficiency. During the period 1973–1986, the United States doubled its new-car efficiency, and from 1977 to 1985, cut its oil use 4.8%/year. From 1983 to 1985, 10 million people served by Southern California Edison Company were cutting the decade-ahead forecast of peak load by

$8\frac{1}{2}$%/year, at ~1% of the long-run marginal cost of supply. In 1990, New England Electric System signed up 90% of a pilot market for small-business retrofits in 2 months. In the same year, Pacific Gas and Electric Company (PG&E) marketers captured a fourth of the new commercial construction market for design improvements in 3 months, so in 1991, PG&E raised the target, and got it all in the first 9 days of January.

Such impressive achievements resulted from nearly two decades of refinement of program structures and marketing methods. At first, utilities and governments wanting to help customers save energy offered general, then targeted, information, and sometimes loans or grants. Demonstration programs proved feasibility and streamlined delivery. Standards knocked the worst equipment off the market. (Congress did this for household appliances without a single dissenting vote, because so many appliances are bought by landlords, developers, or public housing authorities—a manifest split incentive with the householders who will later pay the energy bills.) Refrigerator standards alone cut electricity usage by new U.S. units by fourfold from 1975 to 2001 (5%/year), saving 40 GW of electric supply. In Canada, labeling initially did nearly as well. Utilities began to offer rebates—targeted, then generic—to customers, then to other value-chain participants, for adopting energy-saving equipment, or scrapping inefficient equipment, or both. Some rebate structures proved potent, such as paying a shop assistant a bonus for selling an energy-efficient refrigerator but nothing for selling an inefficient one. So did leasing (20¢ per compact fluorescent lamp per month, so that it is paid for over time), paying for better design, and rewarding buyers for beating minimum standards. Energy-saving companies, independent or utility owned, provided turnkey design and installation to reduce hassle. Sweden aggregated technology procurement to offer "golden carrot" rewards to manufacturers bringing innovations to market; once these new products were introduced, competition quickly eliminated their modest price premia. These engineered-service/delivery models worked well, often spectacularly well. Steve Nadel's 1990 review of 237 programs at 38 U.S. utilities found many costing <1¢/kWh (1988 dollars). From 1991 to 1994, the entire demand-side management portfolio of California's three major investor-owned utilities saved electricity at an average program cost that fell from about 2.8 to 1.9 current ¢/kWh (1.2¢ for the cheapest), saving society over $2 billion more than the program cost.

6.2 New and Better Methods

Since the late 1980s, another model has been emerging that promises even better results: not just marketing negawatts (saved watts), maximizing how many customers save and how much, but making markets in negawatts, i.e., also maximizing competition in who saves and how, so as to drive quantity and quality up and cost down. Competitive bidding processes let saved and produced energy compete fairly. Savings can be made fungible in time and space; transferred between customers, utilities, and jurisdictions; and procured by "bounty hunters." Spot, futures, and options markets can be expanded from just megawatts to embrace negawatts too, permitting arbitrage between them. Property owners can commit never to use more than x MW, then trade those commitments in a secondary market that values reduced demand and reduced uncertainty of demand. Efficiency can be cross-marketed between electric and gas distributors, each rewarded for saving either form of energy. Revenue-neutral "feebates" for connecting new buildings to public energy supplies (fees for inefficiency, rebates for efficiency) can reward continuous improvement. Standardized measurement and reporting of energy savings allow savings to be aggregated and securitized like home mortgages, sold promptly into liquid secondary markets, and hence financed easily and cheaply (see the Web site of the nonprofit International Performance Measurement and Verification Protocol, Inc., www.ipmvp.org). Efficiency techniques can be conveniently bundled and translated to "vernacular" forms, which are easily chosen, purchased, and installed. Novel real-estate value propositions emerge from integrating efficiency with on-site renewable supply (part of the revolutionary shift now underway to distributed resources) so as to eliminate all wires and pipes, the trenches carrying them, and the remote infrastructure to which they connect. Performance-based design fees, targeted mass retrofits, greater purchasing aggregation, and systematic barrier busting all show immense promise. Aggressively scrapping inefficient devices, paying bounties to destroy them instead of reselling them, could both solve many domestic problems (e.g., oil, air, and climate in the case of inefficient vehicles) and boost global development by reversing "negative technology transfer."

Altogether, the conventional agendas for promoting energy efficiency—prices and taxes, plus regulation or deregulation—ignore nearly all the most effective, attractive, transideological, and quickly spreadable methods. And they ignore many

of the new marketing "hooks" just starting to be exploited: security (national, community, and individual), economic development and balance of trade, protection from disruptive price volatility, avoiding costly supply overshoot, profitable integration and bundling with renewables, and expressing individual values. Consider, for example, a good compact fluorescent lamp. It emits the same light as an incandescent lamp but uses four to five times less electricity and lasts 8–13 times longer, saving tens of dollars more than it costs. It avoids putting a ton of carbon dioxide and other pollutants into the air. But it does far more. In suitable numbers (half a billion are made each year), it can cut by a fifth the evening peak load that causes blackouts in overloaded Mumbai, it can boost profits of poor American chicken farmers by a fourth, or it can raise the household disposable cash income of destitute Haitians by up to a third. As mentioned previously, making the lamp requires 99.97% less capital than does expanding the supply of electricity, thus freeing investment for other tasks. The lamp cuts power needs to levels that make solar-generated power affordable, so girls in rural huts can learn to read at night, advancing the role of women. One light bulb does all that. It can be bought at the supermarket and self-installed. One light bulb at a time, the world can be made safer. "In short," concludes Jørgen Nørgård, by pursuing the entire efficiency potential systematically and comprehensively, "it is possible in the course of half a century to offer everybody on Earth a joyful and materially decent life with a per capita energy consumption of only a small fraction of today's consumption in the industrialized countries."

6.3 Deemphasizing Traditionally Narrow Price-Centric Perspectives

The burgeoning opportunities for adoption of energy efficiency approaches suggest that price may well become the least important barrier. Price remains important and should be correct, but is only one of many ways to get attention and influence choice; ability to respond to price can be far more important. End-use efficiency may increasingly be marketed and bought mainly for its qualitatively improved services, just as distributed and renewable supply-side resources may be marketed and bought mainly for their distributed benefits. Outcomes would then become decreasingly predictable from economic experience or using economic tools. Meanwhile, disruptive technologies and integrative design methods are clearly inducing dramatic shifts of, not just along, demand curves, and are even making them less relevant by driving customer choice through nonprice variables. Ultralight cars, for example, would do a complete end run around two decades of trench warfare in the U.S. Congress (raising efficiency standards vs. gasoline taxes). They would also defy the industry's standard assumption that efficient cars must trade off other desirable attributes (size, performance, price, safety), requiring government intervention to induce customers to buy the compromised vehicles. If advanced cars can achieve not incremental but fivefold fuel savings as a by-product of breakthrough design integration, yet remain uncompromised and competitively priced, then the energy-price-driven paradigm becomes irrelevant. People will prefer such vehicles because they are better, not because they are clean and efficient, much as most people now buy digital media rather than vinyl phonograph records: they are simply a superior product that redefines market expectations. This implies a world in which fuel price and regulation become far less influential than today, displaced by imaginative, holistic, integrative engineering and marketing. In the world of consumer electronics—ever better, faster, smaller, cheaper—that world is already upon us. In the wider world of energy efficiency, the master key to so many of the world's most vexing problems, it is coming rapidly over the horizon. We need only understand it and do it.

forward contract A supply contract between a buyer and seller, whereby the buyer is obligated to take delivery, and the seller is obligated to provide delivery, of a fixed amount of a commodity at a predetermined price on a specified future date. Payment in full is due at the time of, or following, delivery.

futures contract A contract between a buyer and seller, whereby the buyer is obligated to take delivery, and the seller is obligated to provide future delivery, of a fixed amount of a commodity at a predetermined price at a specified location. Futures contracts are most often liquidated prior to the delivery date and are generally used as a financial risk management and investment tool rather than for supply purposes.

margin The amount of money or collateral deposited by a customer with a broker, or deposited by a broker with a clearing member, or by a clearing member with the clearinghouse, for the purpose of insuring the broker or clearinghouse against adverse price movement on open futures contracts.

spread (futures) The simultaneous purchase and sale of futures contracts for different months, different commodities, or different grades of the same commodity.

spread (options) The purchase and sale of options that vary in terms of type (call or put), strike prices, and/or expiration dates. May also refer to an options contract purchase (sale) and the simultaneous sale (purchase) of a futures contract for the same underlying commodity.

Energy futures trading in the 1980s focused on growth of the liquid petroleum markets for crude oil, natural gas liquids, and the major refined products of gasoline, heating oil, and fuel oil. In the 1990s, the boundaries of the energy complex expanded to include, first, natural gas (in 1990), then electricity (in 1996), and to add a wide range of options contracts based on the underlying futures markets.

1. INTRODUCTION

In the second half of the 19th century, a "petroleum exchange" flourished in New York. Again, in the early 1930s, when market discipline was briefly disrupted by the explosive growth of oil production in Oklahoma and Texas and oil prices fell dramatically, an oil futures market (in West Texas Intermediate crude oil) was established in California. It soon collapsed as a formidable alliance of "big oil" and "big government" restored discipline to the marketplace. Nearly 40 years of relative price stability ensued, leaving little incentive for the emergence of an oil futures market.

Only with the traumatic price increases accompanying the Arab oil embargo of late 1973 was another attempt made, this time back in New York at the Cotton Exchange. The contract called for Rotterdam delivery (to avoid the constraints of U.S. price regulations). That attempt was stillborn, however, doomed by continuing U.S. government price controls and a skeptical oil industry. In the decade that followed, the commercial realities and—equally important—the perceptions of those realities by the international oil industry had gradually changed; the point at which oil futures could fulfill the industry's need for risk management and could provide an outlet for the speculative impulses of investors had been reached. Investors' interest in oil had been captured by the commodity's new prominence in daily headlines and nightly newscasts.

The emergence of oil futures markets and their remarkable growth was a natural, indeed inevitable,

consequence of three concurrent, but only partly interrelated, trends in petroleum, financial, and commodity markets. By far the most important determinant was the structural change in oil markets. The nationalization of production by members of the Organization of Petroleum Exporting Countries (OPEC) and non-OPEC governments alike, and the subsequent pressures to eliminate large third-party crude resales, resulted in a disintegration of an oil market that had been highly integrated since the days of J. D. Rockefeller. In the 10 years following the 1973 Arab oil embargo, the crude oil available to the major companies fell by nearly 50%, from about 30 million barrels (bbl)/day to just over 15 million bbl/day. Equity oil available to the majors fell even more sharply, by some 75%. The net result was a drop in the major's share of internationally traded oil from 62% to just 37%.

In addition to the newly created national oil companies, a host of oil trading firms and independent refineries entered the picture. The links that had traditionally tied upstream and downstream (vertical) integration were weakened to the breaking point. The reduction of horizontal integration (as large third-party crude sales were curtailed and joint venture production was nationalized) further eroded the ability of the largest oil companies to exercise control over markets. Simply put, there were too many actors with divergent commercial and political interests to guarantee market stability. The consequences were not long in coming (see Table I).

After a decade of virtually universal confidence that oil prices would rise, prices began to weaken and fluctuate over an ever-wider range, climaxing in the dramatic events of 1986, when prices fell from nearly $30/bbl to less than $10/bbl in a period of only 9 months. Although many market observers feel stability returned in 1987, it is interesting to note that prices oscillated between $15 and $22/bbl between September and December of that year alone. The fact is that stability has yet to rear its hoary head in current-day oil markets.

Along with the structural change that was reshaping oil markets during the decade, a second important trend was emerging from the financial markets. High interest rates (along with high oil prices) at the beginning of the 1980s were making inventory maintenance very expensive, causing oil company management teams to rethink traditional approaches to inventory and risk management. Also, hedging of financial risks was increasingly becoming a fact of life in foreign currency and interest rate markets. These trends ensured that oil companies were increasingly receptive to the hedging potential of the fledgling oil future markets. Finally, the third important factor that set the stage for the ultimate success of energy futures was the general growth and diversification of futures contracts in a wide variety of new markets, and the growing sophistication with which they were being used and modified to offer an ever wider range of hedging tools. For almost 100 years, futures markets (then commonly called commodity markets) were largely confined to the

traditional agricultural products (especially grains). In the past two decades, however, there has been an explosion in the variety of products served by these markets. The first waves of expansion brought in new agricultural contracts (especially meats) and precious metals. The second phase, starting in the 1970s, saw the introduction of financial instruments, including currency, interest rate, and stock index contracts. A third phase brought in oil and a number of other industrial products. The fourth stage saw the introduction and rapid acceptance of options on futures contracts. The fifth stage saw an explosion of trading in over-the-counter (OTC) derivatives, often in direct competition with exchange-traded instruments. The introduction and success of oil futures was a product of the first three trends. The growing volatility and loss of confidence in the future stability of oil prices demanded the emergence of new market structures and institutions. One obvious sign of the change was the rapid growth of spot markets and the trading companies that thrived on price volatility.

Prior to 1979, less than 5% of internationally traded crude moved at spot prices, that is, outside of official term supply contract arrangements. By the end of 1985, virtually all crude moved at some sort of market-related pricing, and experts estimated that oil companies were acquiring anywhere from 30 to 50% of their supplies on a spot, noncontract basis. Although the proportion of oil sold on a purely spot basis has subsequently shrunk, the price risks remain, because term contracts today almost universally call for market-related prices. The trading companies, independent refineries, and increasingly the larger companies developed trading techniques to cope with the growing price volatility of these markets. The first response was to create informal, forward markets, at first only 30 days out, then 60 days out, and more recently 90 days out. A second response was an explosive growth in the demand for rapid, often real-time, pricing and other market information. Against this backdrop, futures became inevitable: a time-proven and efficient technique for coping with broad market instability.

Although the breadth of energy markets has expanded, their fundamental purposes remain the same. Futures markets, basically spot markets for standardized forward contracts, serve three functions:

1. Price discovery, giving an instantaneous reading of marginal price movements.
2. Risk management, allowing companies to hedge their price risks for limited periods of time (however, the hedging opportunity rarely extends more than 6 months forward as a result of market illiquidity in the more distant months).
3. Speculative opportunity, attracting additional risk capital to the market from outside the oil industry (low margin requirements—lower than in equity markets—enhance the attraction of futures as a vehicle for speculation).

These are the necessary but not sufficient conditions for a successful contract. In reality, however, new futures contracts often fail. The reason is that the criteria for a successful futures contract are simply too stringent, with too few physical markets that can actually meet those criteria.

2. *CRITERIA FOR SUCCESSFUL FUTURES MARKETS*

Assessing the suitability of any commodity/market for futures trading requires analysis of a number of conditions. These are considered in the following sections.

2.1 Price Volatility

Price volatility is perhaps the single most important criterion for assessing futures trading. It provides the basic economic justification for futures trading, which is to provide protection to the hedger against adverse price fluctuations. If a commodity is characterized by a relatively stable—or at least predictable—price, there would be little associated risk and there would be no need for a futures market. Price volatility is also necessary to attract risk capital from speculators and is essential to ensure sufficient liquidity to maintain the market.

Quantitative indicators: Variations of $\pm 20\%$ per annum are assumed to be the minimum necessary to sustain futures trading. In general, the greater the degree of volatility, the more likely a futures market will survive.

2.2 Uncertain Supply and Demand

Uncertainty in supply and demand is generally the cause of price volatility and therefore is generally present when price volatility is found.

Quantitative indicators: In energy markets, which typically display a rather high inelasticity of price demand, variations of $\pm 10\%$ during a 2-year period should be sufficient to sustain futures trading.

2.3 Sufficient Deliverable Supplies

Sufficiency of supply is the Catch 22 of futures trading. If sufficient deliverable supplies of the commodity meeting the quality specification of the contract are not available, futures trading will fail. However, there must be some uncertainty about the sufficiency of supplies if the previous conditions are to be met. In the United States, this dilemma is heightened by the regulatory requirements of the Commodity Futures Trading Commission (CFTC), whose fear of market squeezes at times forces exchanges to overstate deliverable supplies in order to gain government approval.

Quantitative indicators: Storage capacity equal to at least 30 days average demand is highly desirable.

2.4 Product Homogeneity

Product homogeneity is another prerequisite. Futures contracts are traded on the premise that product taken on a delivery will meet certain quality specifications. The commodity must therefore have certain key characteristics that are quantifiable, allowing the clear differentiation of product from other grades. Standardized tests and generally accepted procedures are essential. For example, the various American Petroleum Institute (API), German Institute for Standardization, and American Society for Testing and Materials (ASTM) standards generally provide the necessary references for oil. In addition, the existence of generally trusted independent inspection agencies or inspectors to administer these tests is an important aspect. A range of different products (for example, several types of crude oil) may be suitable for delivery, if the price differences between the various grades are relatively stable and if the technical characteristics of the various deliverable grades are sufficiently close to one another. This is often a difficult aspect of contract design, because the price variation between various grades of products fluctuates from time to time. For example, it may be desirable to allow several grades to be deliverable, perhaps with price adjustments for quality, in order to ensure sufficient deliverable supplies. However, if buyers are uncertain of what grades they will receive and if they place different values on the quality differences among the grades, they may be deterred from trading.

Quantitative indicators: The quality of the product must be capable of being described by objective, quantifiable standards.

2.5 Product Perishability

The perishability of a product can be a deterrent to trading. In general, a product should have a shelf life sufficiently long enough to permit storage and delivery as called for under the contract. In addition, the maintenance of inventories of the commodity will both facilitate deliveries and provide a ready pool of potential hedgers. While perishability is not usually a major concern in oil and natural gas markets, the stability of some oil product blends is an issue. Long storage of gasoline, for example, can result in separation of blended product.

Quantitative indicators: Products should have a minimum shelf or stock life of 6–12 months.

2.6 Market Concentration

Market concentration is a difficult factor to quantify. A successful futures market is a highly competitive market, marked by a large number of buyers and sellers. No one market participant, or plausible combination of market participants, should possess sufficient market power to exert unilateral control either on the supply or the demand for the commodity, either in the short or medium term. In oil markets, however, the existence of OPEC has not prevented the emergence of highly successful futures markets. The answer lies in the inability of OPEC to act decisively, and in the availability of alternative sources of supply and stocks that seriously limit OPEC's ability to achieve its stated objectives. However, the concentration of producers and/or consumers can be a serious obstacle in specific regional oil markets. Thus, a U.S. West Coast gasoline market would be risky, given the relative concentration of production in the hands of a small number of refiners. Similarly, an East Coast residual fuel market might be too heavily dominated by the demand from a small number of very large utilities to sustain liquid futures trading.

Quantitative indicators: In general, the market share of the top five firms should be less than 50%, and the top 10 firms should have less than 80%.

2.7 Availability of Price Information

Readily available price information is critical to market success. It should be noted that the opening of a futures market will probably, in turn, stimulate a rapid growth of price information services. However, at the outset, market participants must have a sufficiently broad base of price information to permit evaluation of spot prices and their relationship to

futures prices. Convergence between these two prices as the delivery period approaches is essential. A market in which all products are traded on the basis of long-term contracts for which prices remain undisclosed would be a very difficult market in which to establish futures trading.

Quantitative indicators: Daily cash market prices should be available from at least two independent sources.

2.8 Uniqueness

The uniqueness of a trading opportunity is another key factor. If an existing market for a commodity has reasonable liquidity and is serving its customers well, it is extremely difficult to launch a copycat contract. Inertia, habit, and personal relationships will tend to keep the traders loyal to the preexisting market. In addition, even if there is no active market at present, recent failures of similar contracts can be a substantial (but not fatal) deterrent.

Quantitative indicators: The ideal candidate would be a commodity that is not currently traded on any futures exchange in the world and has not been the subject of a failed attempt in the previous 5 years. However, special circumstances may override these concerns.

2.9 Market Timing

Market timing and blind luck are often critical to the success or failure of a contract. However, forecasting is often impossible. Ideally, contracts should be introduced to coincide with periods of high volatility and high levels of cash market activity. For example, a heating oil or natural gas contract would be best introduced in the fall months, when physical trading is at its yearly high. Conversely, a gasoline contract would be best introduced in the spring, prior to an anticipated surge of summer driving.

Quantitative indicators: Contracts should be introduced to coincide with high levels of cash market activity, to the extent that this is predictable. Alternatively, an astrologer might just as well be consulted.

3. EXCHANGES AND THEIR CONTRACTS

Two exchanges currently dominate trade of energy futures contracts: the New York Mercantile Exchange and the London International Petroleum Exchange. In addition several smaller exchanges also have offered energy futures contracts, albeit with limited and often transitory success, including the Singapore International Monetary Exchange (SIMEX; currently known as the Singapore Exchange Ltd.) and the Kansas City Board of Trade. The future of open-outcry trading on exchange floors is increasingly being challenged by the advent of electronic trading. Although the exchanges and their floor traders still have the upper hand, the growth of electronic trading and the success of all-electronic marketplaces (such as the Internet) pose serious challenges for the exchanges and their trading floors.

3.1 New York Mercantile Exchange

Founded more than 100 years ago, the New York Mercantile Exchange (NYMEX), or the "Merc," as it is often called, has enjoyed a diverse and colorful history. Evolving from a lower Manhattan produce exchange that dealt in contracts for butter, eggs, and even apples, NYMEX began to diversify some two decades ago, adding precious metals and—briefly—even stocks to its portfolio. Nevertheless, by the end of the 1970s, it was one of the smallest exchanges in the United States, outpaced by the growth of the large Chicago markets and by most other New York exchanges as well. After an abortive attempt to start a residual fuel oil contract in 1974, the Merc launched its first successful energy futures contract—New York heating oil—in 1978. Trading grew slowly but steadily while a companion contract for residual fuel was stillborn. With the addition of a leaded gasoline contract for New York delivery in 1981 (later replaced by an unleaded version of the same contract) and West Texas Intermediate crude oil in 1983, NYMEX achieved international prominence in the 1980s; its energy contracts grew at spectacular rates. The subsequent addition of options on crude oil, heating oil, and gasoline as well as futures contracts on propane, natural gas, and electricity added another dimension and further impetus to the growth of the NYMEX energy complex.

Since its merger with the Commodities Exchange (COMEX) in the mid-1990s, NYMEX has been known as the NYMEX Division of the merged exchange. Today, the NYMEX Division is the leading energy futures exchange and the third largest futures exchange in the world, following only the Chicago Board of Trade and the Chicago Mercantile Exchange. Although contracts for platinum and

palladium still survive on the Merc's trading floor, energy contracts regularly account for more than 90% of its turnover. NYMEX, for most of its life, was a nonprofit organization. However, in 2000, its members voted to "demutualize" and the exchange became a for-profit corporation, the first New York commodity exchange to do so.

3.2 International Petroleum Exchange

An independent outgrowth of London's loosely linked futures markets, the International Petroleum Exchange (IPE) was created in 1981 by a diverse coalition of oil traders and commodity brokerage firm members who saw the emerging success of the NYMEX heating oil contract in New York and were determined to build an energy futures market on the other shore of the Atlantic. Early success with a gas oil contract was followed by a series of unsuccessful attempts to trade crude oil. Finally, in 1988, the right set of circumstances and contract terms allowed IPE to launch a Brent crude oil market that has established good liquidity and a substantial following. Although IPE occupies second place among the world's energy exchanges, the gap between IPE and NYMEX is very large, with London's turnover averaging well under half of New York's volume. Following the NYMEX demutualization, the IPE too converted to for-profit status in 2001 and subsequently merged with the U.S.-based Intercontinental Exchange.

3.3 Singapore Exchange Ltd

The Singapore International Monetary Exchange was created in 1983 as a restructuring of the former Gold Exchange of Singapore (founded in 1978) with the strong support of the Chicago Mercantile Exchange (CME). CME and SIMEX offered customers an innovative mutual offset agreement, whereby positions on one exchange can be offset against positions on the other. Initially, the exchange concentrated on financial futures. but in February 1989 SIMEX launched a high-sulfur residual fuel oil contract that enjoyed a brief success. In the mid-1990s, they traded Brent crude oil for several years.

In 1999, SIMEX merged with the Stock Exchange of Singapore to form the Singapore Exchange Ltd. (SGX). Their futures trading is organized under the SGX Derivatives Trading Division (SGX-DT), which has recently launched a contract on Dubai crude oil—the second attempt to trade Middle Eastern crude. Like the other major exchanges, the SGX has also converted to a for-profit corporation.

3.4 Other Exchanges

From time to time, other futures exchanges, most recently Kansas City, have launched energy futures contracts. However, none of these has succeeded in building the liquidity needed to attract significant trading.

4. FUTURES PRESENT

Since 1974, there have been over 60 attempts to launch energy futures and options markets. The success rate has averaged about 20%, typical of the experience in other commodity markets. In spite of thorough research by the exchanges, often excruciating governmental reviews (particularly in the United States), and extensive marketing campaigns, roughly 80% of all future markets opened fail to reach the critical mass needed for takeoff (commonly defined as reaching an average open interest of 5000 contracts). Table II lists the various attempts to launch new futures markets in energy from 1970 through 2002.

When first introduced in late 1978, heating oil futures attracted smaller, independent marketers and refiners, who turned to the New York Merc as an alternative source of supply. Physical deliveries were initially quite high, as these smaller firms sought alternatives in a marketplace dominated by the larger companies. These initial participants were quickly joined by the spot oil traders and by a growing number of pure speculators on and off the trading floor, drawn from other financial and commodity markets. This phase lasted until well into 1983. Then, with the introduction of crude oil futures and the increasing instability of prices, the larger refiners and integrated companies reluctantly entered the market.

By 1984, more than 80% of the 50 largest companies were using futures. Larger end-users, such as airlines and other major energy consumers, also appeared. In addition, a far wider range of speculators entered the scene, as trading volume and open interest rose high enough to meet the minimum liquidity requirement of the commodity funds. Finally, another phase, dating from 1986, brought in almost all the remaining holdouts among the large U.S. companies, more foreign participation, and a new group of traders, the Wall Street refiners. These were companies such as Morgan Stanley and Bear Stearns, which were attracted by the rising volatility of oil prices and the speculative opportunities presented by that price instability, particularly relative to other markets. put it, "Plywood was dead, so we looked around for some better action and found it in oil." The low internal cost of capital for margin maintenance and a built-in trading infrastructure made these new entrants formidable competitors for the older oil trading and supply companies. However, even today, participation by independent producers and smaller end-users remains limited. Participation of the producers is limited by the lack of liquidity in the more distant months; participation of the end-users is limited by ignorance of how the markets operate, the high management cost of setting up a futures trading department, and, for a number of domestic as well as international companies, a very real basis-risk problem.

Futures trading has thus survived adolescence and entered a period of youthful maturity. But growth in the coming years will have to come from an expansion of futures trading opportunities in the form of new contracts rather than from bringing in new participants. In other words, to continue to grow, the exchanges will have to offer a bigger and more diverse menu, not just put more seats around the table. The recent success of options would seem to confirm this point of view. Today, after the smoke has settled from various attempts by exchanges in New York, Chicago, London, and Singapore, there are six well established energy markets in New York and London: (1) NYMEX West Texas Intermediate (WTI) crude oil, (2) NYMEX natural gas, (3) IPE Brent crude oil, (4) NYMEX heating oil, (5) NYMEX unleaded gasoline, and (6) IPE gas oil. In addition, options contracts have been successful as extensions of those future markets. The latest innovations by the exchanges include the introduction of trading in smaller contracts (the e-miNY at NYMEX), the expansion of electronic and after-hours trading, and the introduction of OTC trading and clearing services. Trading volumes of the major contracts are shown on Table III.

5. TRADING FUTURES: A PRIMER

Many readers of this article will be thoroughly familiar with the basic mechanisms and concepts of futures trading. This section is not for them. However, for those who are new to any type of futures trading, it is important to understand a few fundamentals about futures markets.

Futures markets offer hedgers or commercials (i.e., those who use a particular commodity in their business) and speculators the opportunity to buy or sell standardized contracts for a given commodity. In many cases, the same exchanges also offer options contracts on those same commodities. Options contracts as presently traded are options on the futures contract for the same commodity, which is often called the underlying futures.

5.1 Contract Identification

Both futures and options contracts are identified not only by the particular type of commodity being

traded (e.g., heating oil, unleaded gasoline, Brent crude oil), but also by the delivery month called for in the contract. In practice, traders often abbreviate the names of months, so that it is common to hear references to "Feb Brent" or "Jan gas." Options contracts are further identified by their strike prices and whether they are options to buy (call) or sell (put). Thus an options trader will talk about "Jan gas 55 puts," meaning options to sell January unleaded gasoline futures contracts at 55 ¢/gallon. A buyer of a commodity contract is said to be long while he holds that contract. A seller is said to be short. The contracts traded are highly standardized with respect to volume, quality, and delivery terms. Exchanges do, however, change the terms of these contracts from time to time, to keep pace with changes in the physical market. The appropriate exchange can provide a copy of the latest contract terms.

5.2 Placing Orders

Except in the case of exchange members operating on their own account, all transactions must be conducted through a member of the exchange, who must also be registered to accept customer orders by the Commodities Futures Trading Commission in the United States or its counterparts in other countries. Orders can be placed anytime a broker is willing to answer the telephone, but exchange trading hours tend to fall between 9:00 a.m. and 5:00 p.m., with the New York exchanges closing earlier and the London exchanges closing later.

A buyer normally places an order by telephone to a broker, who may be located anywhere in the world. The broker in turn executes this order by telephone through exchange members on the floor of the appropriate exchange. Buyers can place various conditions on their orders, including price limits or time limits, and they may also simultaneously request a broker to close out the position if losses exceed a certain amount. Although brokers will generally accept such conditions on orders, they usually offer no guarantees that they can execute the order as given. Only a market order, in which the buyer (or seller) agrees to accept the prevailing market price, is virtually guaranteed for execution. Brokers will most often execute orders through the employees of their own firm on the floor. But in order to camouflage larger orders, execution will sometimes be shared with independent floor brokers, who execute orders on behalf of others.

On the exchange floor, all trading must be by open outcry, giving all present—at least in theory—an equal opportunity to take the other side of the trade. Assuming a willing seller is then found to meet the buyer's order, the trade is posted with the exchange. In practice, exchanges publish price quotations over the various electronic information services to provide an up-to-date record of pricing trends even before the official record of the transaction is entered. The actual trade is usually entered into the exchange's computer within a few minutes of the transaction. The buyer and seller, however, are not matched permanently. At the end of the day, each broker is assigned an appropriate long or short position with the exchange's clearing house. Thus, although there must be an equal number of buyers and sellers each day, their respective positions are maintained totally independently, and each buyer and seller is free to close his/her position at any time. To do so, the buyer will simply sell his/her contract back into the market, effectively clearing his position from the exchange's books.

5.3 Spreads

In addition to straightforward orders to buy or sell a single commodity for a single month, many traders take spread positions, which are positions in several different contracts to profit from the relative price movements between those contracts. For example, spreads can be placed between contracts for different delivery months for a single commodity. Or they can cover different commodities for delivery in the same month. Or they can cover different commodities and different months. One popular type of spread position in the energy contracts is the "crack spread," in which a position in crude oil is balanced against positions in both gasoline and heating oil, to approximate the refining process (in which crude oil is transformed by catalytic cracking into refined products). NYMEX has offered option contracts of such spreads since 1994. A newer type of spread trading is the "spark spread," which pairs positions in natural gas with those in electricity to approximate the gross margin of power generation using natural gas.

5.4 Margins and Clearing Houses

Exchanges collect margins (or deposits, as they are called in England) from each broker on behalf of the customer (and in most cases, the broker in turn collects similar funds from the customer). These margins, which are usually in the range of 5–10% of the contract's total face value, are normally designed to be equal to the average daily fluctuation in value

of the contract being traded. Exchanges will therefore tend to lower margins in times of low price volatility and to raise them in times of high price volatility. Every night, based on the final closing or settlement price, the exchange calculates the effect of that price on each position and either requests additional margin or pays excess margin to each broker. Thus, if prices go up from one day to the next, a buyer's margin is credited with a gain and a seller's margin is debited. The rules of margin maintenance by customers to brokers vary considerably from country to country.

The exchange and its clearinghouse are therefore always in a very strong position to guarantee all outstanding positions. Moreover, the clearinghouse holds its member brokers—not the ultimate customer—responsible for performing under the contracts. In the unlikely event that an individual broker is unable to perform as called for under the contract, all the members of the clearinghouse are called upon to guarantee performance. Futures markets therefore offer several levels of financial performance guarantees.

Prices on an exchange are freely determined by the interplay of buyers and sellers. However, exchanges do place certain limits on both the minimum and maximum amounts of fluctuation that can occur in a given time period. The minimum price change is referred to as a tick and, in the oil contracts, is typically equal to 1.00¢/bbl, 25.00¢/MT, or 0.01¢/gallon in New York. In all cases, there are no limits on the spot contract, which is the contract that is next scheduled to go to delivery, but all other contracts face limits. In New York, these limits are typically $1/bbl, $15/MT, or 2.00¢/gallon. In a given day, no trades may take place outside these ranges. However, if a limit is reached on one day, the limits are expanded by 50% for the next day's trading, and so on, up to a maximum of $2/bbl or 4.00¢/gallon. In London, the limits do not apply for a full day, but rather trigger cooling-off periods before trading is resumed.

5.5 Delivery

These markets should always be thought of primarily as financial markets, being used in parallel with physical movement of oil and natural gas. Nevertheless, delivery does take place and serves to ensure that the prices on futures markets remain closely linked to the real world. The standardization of contracts and their delivery terms are often unnecessarily rigid for the commercial participants, who prefer greater flexibility in their day-to-day operations. As a consequence, delivery typically occurs in only about 2% or less of all futures contracts. In simplest form, all those holding positions in a given contract at the closing bell on the last day of trading for a given contract are automatically required to take or make delivery of the specified commodity. The timing and methods of delivery are clearly spelled out in each contract and in the exchange's rules. The exchanges' staffs match buyers and sellers and the matched companies then must meet their respective obligations. Exchanges have found it useful, however, to permit several variations of this simple process. Prior to the exchange-matching process (typically the day after the end of trading), any two market participants may agree to an exchange for physicals (EFP), transferring title to oil (or natural gas) by mutual agreement in lieu of closing out their position on the exchange. EFPs can also be used to establish future positions by mutual agreement. In fact, in the U.S. crude markets, this mechanism is widely used as a routine means of buying and selling crude, because it has the attraction of the exchange's financial performance guarantees. A recent innovation, introduced by NYMEX, is an Exchange of Futures for Swaps (EFS), which adds additional flexibility.

Once trading in a given contract has ended and participants are matched, the two matched companies may elect to use an alternative delivery procedure (ADP), which also allows the two to make alternative arrangements. In the case of both EFPs and ADPs, the exchanges are relieved of any responsibility for guaranteeing performance.

5.6 Regulation

Exchanges are self-regulating and (since 2000) for-profit corporations, owned by their members/shareholders. The degree of governmental oversight and regulation has traditionally been most extensive in the United States (by the Commodities Futures Trading Commission) and least intrusive in the United Kingdom.

The exchanges maintain active compliance and market surveillance programs to enforce trading rules and to detect any evidence of market manipulation. Traders caught violating rules are typically fined, and in relatively infrequent instances, barred from trading. If evidence of market manipulation is uncovered, exchanges possess a wide range of powers to remedy the situation. These powers include the right to order a given participant to reduce or even eliminate his or her position, to substitute alternative delivery points or additional

supplies (i.e., by broadening quality specifications), or even to impose a cash settlement in place of physical delivery (assuming the contract calls for such delivery). These powers are not often used, but their very existence serves as a powerful disincentive to would-be market manipulators.

Perhaps the most controversial aspect of futures trading (particularly in the United States) is the permitting of dual trading; that is, allowing the same individuals to trade for their own account while simultaneously executing orders for customers as a floor broker. Many critics have argued that this practice provides opportunities for floor brokers to jump ahead of large customer orders, profiting from the market movements that those large orders are likely to provoke. Although such actions are a clear violation of exchange rules, detection is not always easy. Exchanges counter with the argument that dual trading promotes liquidity and that exchange enforcement activities are sufficient to prevent serious abuses. As periodic prosecutions in both Chicago and New York have demonstrated, there will always be temptations. Clearly, exchanges can improve their rules and surveillance. At a minimum, exchanges that want to allow dual trading have an obligation to create clear audit trails so that violations are easier to eventually detect. It seems likely however, that dual trading will be prohibited in futures trading as it is in securities trading. But the exchanges and their floor communities can be expected to resist this development until the bitter end.

6. FUTURE DIRECTIONS

The world oil market is relatively mature, but will continue to evolve as the supply/demand balances shift. On the supply side, this implies an increasing dependence on the Middle East and the Caspian Basin, creating pressures for the evolution of new marker crudes to replace the gradually diminishing supplies of WTI and Brent. On the oil products side, the inevitable growth of demand in the developing world will also challenge the traditional role of Rotterdam and the U.S. Gulf of Mexico as the pricing reference points. This may in turn increase the importance of Singapore and eventually lead to a more favorable market for the evolution of futures and options in that city.

Natural gas is still an emerging market. The growth of liquid natural gas (LNG) and interregional pipeline trade in the world should provide new opportunities for futures markets. Electricity continues to be a challenge for the futures exchanges. As of 2003, the attempts to launch and sustain electricity futures markets had been hampered by a variety of obstacles, especially the Enron scandal. But it seems likely that the exchanges will continue to seek opportunities to serve the electricity trading market. In addition, price volatility seems unlikely to retreat, so the need for risk management instruments, both on and off exchanges, will remain a constant in these markets for decades to come.

7. SUMMARY

The oil markets led the way for the entire futures complex. This was no accident. As the largest and most global energy source, oil is the natural leader. In addition, government regulations were first removed from oil before deregulation hit the natural gas and power markets. Although the natural gas and power markets have distinct characteristics, there is no doubt that the experience of oil markets in deregulation provides an important indicator of future directions for all energy markets. However, the rapid growth of e-commerce in natural gas and power has propelled those markets into a period of rapid growth, temporarily leaving oil the laggard. The explosive growth of electronic commerce is rapidly closing the gap between physical trading and futures. Within the first years of the 21st century, the convergence of wet and paper markets will be completed as the old "analog"(open-outcry) physical markets evolve to "digital" (Web-based) exchanges. At some point in the not too distant future, risk management tools will simply be a mouse click or a pull-down menu away, as companies and traders make their deals and fulfill them on the net.

Among energy markets, natural gas and electricity have leapt ahead to embrace e-commerce, leaving the oil patch to catch up. Ironically, the early deregulation of most national oil markets and the far-flung nature of global oil markets brought innovation to those markets in the 1970s and 1980s. However, the relatively quick deregulation of natural gas and electricity markets, the high level of market inefficiency spawned by decades of government economic regulation, and the greater homogeneity of product quality have encouraged those markets to move more quickly into the Internet era. Electronic exchanges blossomed in the late 1990s, and energy was one of the largest categories of business-to-business e-commerce. Electronic commerce will have a growing impact on the energy industry, including reducing

costs and improving service all along the supply chain, enhancing existing businesses, especially in the area of customer service, transforming existing business models, especially through the creation of "infomediaries" (companies that provide and analyze market information for other participants), and creating new businesses.

By lowering entry costs and facilitating access, Web-based exchanges can expand the range of energy products traded. The process has already started in the chemical industry, and Web sites (e.g., Chemdex, ChemConnect, and e-Chemicals) have been launched to compete for business. There will, however, remain two challenges for these sites. First, markets will remain focused on the liquidity of new products. Traders have notoriously short attention spans and will "tune out" if sites do not offer sufficient volume to move reasonable quantities quickly. Second, as these sites grow in importance and their impact on pricing grows, they will inevitably come under regulatory scrutiny, at least by the United States Government and possibly by the European Commission and other jurisdictions as well. The regulation (and taxation) of Internet transactions will likely be a major political and economic battle. Third, as these markets grow, there will be significant pressure to develop new risk management instruments as integral offerings. The growth of electronic trading should lower the hurdle rates for new risk management instruments. However, the launching of new futures and options instruments will always depend on their ability to attract liquidity early—as mentioned, traders are notoriously impatient and will not support illiquid markets. It is probable that the future instruments will therefore include a modest expansion of formal futures and options markets and a continued rapid expansion of off-exchange derivatives, perhaps with more standardized settlement terms and, eventually, common clearing mechanisms. The exchanges have realized the opportunity and NYMEX has been especially innovative in trying to capture more of these traditionally off-exchange activities.

Ideally, the market would like to have a complete suite of energy markets serving both the Atlantic and Pacific basins, which would imply the development of additional futures and options markets for crude oil, products, gas, and electricity markets, especially in Asia. Obviously, the growth in interconnections of gas and power grids would tend to accelerate that trend, as would the continued expansion of international LNG trade. There seems little risk (or hope?) that volatility will soon depart the energy scene. And as long as there is volatility, there will be risk and a desire to manage that risk. However demand and production will shift, trade patterns will change, and product specifications will evolve, all requiring changes in contract design and continuous innovation.

argumentative analogy An analogy in which the secondary term is used to bring to bear an already-organized set of equations or network of concepts on the primary term, so that the primary term becomes a mode of the secondary.

constructivism The view that that nature is how we represent it and that the real depends on intersubjective agreement.

context of discovery The manner in which a theory or datum was historically discovered.

context of justification The manner in which a theory or datum is justified by reference to all the available evidence on hand.

corporeal template The use of the first-person experiences of a sentiently felt body to forge or model new concepts.

energeia A term in Aristotle's metaphysics constructed out of ergon, meaning act or deed, used to refer to the activity of tending toward or enacting a goal (literally, en-act-ment).

filtrative analogy An analogy in which the secondary term calls attention to certain of its conventionally understood features in the primary term.

paradigm A framework that provides the conditions, criteria, and examples for explaining problems and phenomena of a standard type.

realism The view that nature has a fixed structure prior to the way human beings represent it.

vis viva Living force, later formulated as mv^2 and thus an ancestor of the modern notion of kinetic energy, that some early modern philosophers argued existed in addition to quantity of motion or dead force (formulated as mv).

One important and controversial issue in the history and philosophy of science concerns whether the phenomena named by concepts precede the development of the concepts themselves. While realists claim that nature has a fixed structure and only concepts have histories, constructivists claim that, inasmuch is nature is how we represent it, natural phenomena are themselves histories. The history of energy sheds some light on this issue, exposing the ambiguities that lead to each position, by highlighting the significance of the fact that the environment in which scientists work is not simply a human-environment relation but one mediated by technology.

1. THE PUZZLE OF ENERGY

Few things in the history of science raise more hackles than the issue of whether the phenomena named by concepts precede the development of the concepts themselves. The natural and commonsensical realist assumption, which it is fair to say is shared by most people and nearly all scientists, is that nature has a fixed structure, and that while scientific concepts have histories—they arise, are transformed, and occasionally pass away—the phenomena to which these concepts refer do not. Conceptual evolution merely testifies to the weakness of the science of the past, and to the success of contemporary science at obtaining a better grip on the world.

The opposite constructivist extreme is the view that nature is how we represent it, and the real depends on intersubjective agreement. Sociologist Bruno Latour, for instance, has provocatively argued that things, not just words, have histories; has claimed that microbes (and not just the concept of a microbe) did not exist before Pasteur; and has remarked that Pharaoh Ramses II could not have

died of tuberculosis (as now thought) because the bacillus had no real existence before Robert Koch discovered it in 1882.

The history of energy is an intriguing episode in the history of science that sheds some light on this issue. It does so because the phenomenon of energy nicely illustrates the presence of factors such as the technological transformation of the world, and even the role of more metaphysical considerations such as the changing patterns of thought that sometimes have to occur for a concept to be taken as applying to nature.

2. THE WORD ENERGY

The word energy has a well-charted and uncontroversial history. Energy comes from the Greek energeia, or activity. For practical purposes one may say that the word was all but invented by Aristotle, who treats it as a noun form of a nonexistent verb. The word was constructed out of ergon, meaning act or deed; en-erg-eia might be literally translated as "en-act-ment." In his substance ontology, Aristotle uses it to refer to the activity of tending toward or enacting a goal, a meaning much different from today's. Aristotle saw bodies as composites of matter (hyle) and form (eidos). But for him, matter was only the possibility of a body, with no inherent structure and no perceptible or corporeal properties of its own—only a body can be soft or hard, hot or cold—and obtains a structure only via its form. Inextricably related to this distinction is another related to a body's activity. Every existing thing, he said, has an energeia, which maintains it in being and is the activity of tending toward or enacting a goal, its end or function (telos) to which it is naturally fitted. Aristotle has various names for how that activity is related to its end. A body's sheer potential or capacity for action he calls dynamis (potency), while its being at work en route to or at its telos he calls its en-ergeia. Every existing thing, then, has some activity or energeia, which maintains that thing in being. Aristotle seems only to have sensed, but not explicitly described, a difference between brute mechanical power and accumulated energy, or what we might call force and energy.

As philosophers such as Stephen Toulmin have emphasized, Aristotle's view was a product of the everyday situations with which Aristotle was specifically concerned. When he did concern himself with situations involving what we would call force and energy, they were mechanical horse-and-cart like situations in which a body (such as a horse) moves against a resistance (sources such as friction) to keep a body (cart) in motion. Aristotle compared other situations he was interested in to this type of example in formulating explanations of them. His analysis was therefore based on what Stephen Toulmin rather loosely (and prior to Thomas Kuhn's more elaborate and technical account) called a particular paradigm. It would not have occurred to Aristotle, Toulmin notes, to explain a familiar horse-and-cart situation with reference to "idealized, imaginary states-of-affairs that never in practice occur, ideals to which even the motions of the planets can only approximate." Unless we understand this context in which Aristotle was making and justifying explanations, we not only misunderstand him, but risk coming away thinking that he was guilty of elementary, unscientific blunders.

Aristotle's conception of energeia is, of course, worlds away from the modern conception of energy as the sheer capacity to do work. Energeia is not found in a specific place, but suffused everywhere and in different forms. It cannot be created and stored, converted or dissipated; it has a directionality toward forms to be realized and cannot be detached from these ends. The notion that energeia could be set up independently over and against the objects on which it does work, or stored apart from them, or collected or harnessed, would not have made sense to Aristotle.

Energy, the eventual English anglicization of energeia, came to lose the technical meaning Aristotle had given it and, for a while, virtually any value as a scientific term. In the mid-18th century, philosopher David Hume, for instance, complained that the words power, force, and energy are virtually synonymous, and "obscure and uncertain." As late as the seventh edition of the *Encyclopaedia Britannica* (1842), the word only merits a short entry: "ENERGY, a term of Greek origin, signifying the power, virtue, or efficacy of a thing. It is also used figuratively, to denote emphasis of speech."

3. THE CONCEPT OF ENERGY

How, then, did the word come to refer to a precise technical concept? The word would become a technical term only by being linked, at the beginning of the 19th century, with a concept that itself had undergone a complex evolution, and this evolution was the product of a number of factors.

One factor was a metaphorical extension of the subjective experience individuals have of themselves as a bodily center of action, which was then projected into nonhumans as one of their properties. This

illustrates what philosopher Maxine Sheets-Johnstone calls "the living body serv[ing] as a semantic template," a process which, she points out, is key to the emergence of many early scientific concepts. It is a classic case of the use of analogical thinking, or the use of the familiar to understand the unfamiliar. What is remarkable in this instance is that the familiar has its basis in the tactile-kinesthetic experiences of bodily life; thus, in a corporeal template.

Yale science historian Stanley Jackson, for instance, has written about how such a subjective experience was analogously extended into the concepts of early modern physics in the works of scientists such as Johannes Kepler and others. Kepler, like many scientists of his time, analogically projected a secular version of a soul-like animistic force into his mechanics. "If we substitute for the word 'soul' the word 'force' then we get just the principle which underlies my physics of the skies," Kepler wrote, adding that though he now rejected such souls, he had come "to the conclusion that this force must be something substantial—'substantial' not in the literal sense but... in the same manner as we say that light is something substantial, meaning by this an unsubstantial entity emanating from a substantial body."

What, then, was this unsubstantial entity? In the 17th century, this question sparked a furious metaphysical and scientific controversy on the existence, nature, and measure of force. René Descartes spoke of quantity of motion (mass times velocity, or mv), while Gottfried Leibniz argued that the force was not just a quantity but a quality of matter, called living force or *vis viva*, whose proper measure was mv^2. The *vis viva* controversy, as it was known, continued through the 18th century and was the subject of young Immanuel Kant's first essay. In 1807, Thomas Young, lecturing to the Royal Institution on "Collisions," said that "the term energy may be applied, with great propriety, to the product of the mass or weight of a body, into the square of the number expressing its velocity." He thereby tied the word, apparently for the first time, to its modern concept. But Young's "energy" was not ours, only what we call kinetic energy, and not even our formulation of it ($\frac{1}{2}$ mv^2).

The first half of the 18th century witnessed an intense discussion of the proper way to understand notions of activity, work, force, and *vis viva* among engineers and scientists including James Joule, Sadi Carnot, Hermann von Helmholtz, James Mayer, Emmanuel Clausius, William Thomson, and others. One of the most important motivations for this activity was to achieve a formulation adequate to the phenomena that scientists and engineers of the day were occupying themselves with: most notably, steam and heat engines, which were revolutionizing the engineering and industry of the day. In particular, scientists and engineers were concerned with the question of how to evaluate and measure the efficiency of steam and heat engines.

A second, closely allied factor involved what might be called a metaphysical shift, which opened up the possibility of seeing phenomena that look and act very differently as but different modes of one force. Thomas Kuhn emphasizes this point in an article on energy conservation, saying that such a metaphysical shift helps to explain why "many of the discoverers of energy conservation were deeply predisposed to see a single indestructible force at the root of all natural phenomena." The metaphysical shift in question itself may perhaps be specified more fully as the working out of another kind of analogical thinking, in this case, the use of an extended argumentative or scientific metaphor. Analogies and metaphors come in many different kinds, one common form being filtrative. In filtrative analogies or metaphors ("man is a wolf," "love is a rose") the secondary term (wolf, rose) calls attention to certain conventionally understood features of these things in the primary term (man, love). The focus is therefore on the primary term, and the secondary term only provides an assist. In argumentative or scientific analogies or metaphors, on the other hand, the priority of the two terms is reversed, and the secondary term is used to bring to bear an already-organized set of equations or network of concepts in order to understand the primary term—and the secondary term grows into the salient, technically correct term, often expanding its meaning in the process, with the primary term being merely one mode of the secondary. One classic illustration of an argumentative or scientific analogy occurred when Thomas Young and others began to call light (the primary term) a wave (the secondary term). Waves originally referred to a state of disturbance propagated from one set of particles in a medium to another set, as in sound and water waves. When Young and other early investigators called light a wave, they assumed that it, too, moved in some medium—but this proved erroneous, and scientists were soon saying that waves propagated in the absence of a medium. Despite this change, the same concepts and equations nevertheless governed light, which was now just another mode of an expanded conception of wave. Wave had grown into the technically correct term for characterizing light,

though in the process it became transformed and expanded (and the evolution would continue when waves turned up in quantum mechanics).

This kind of argumentative or scientific metaphor was at work in the beginning of the 19th century, in allowing engineers and scientists to see the presence of energy in quite different phenomena, from falling water and expanding air to heat and electricity. Only the kind of metaphorical sensitivity allowed the early investigators to realize the significance of the conversion processes that were so critical to the development of the concept of energy. It was doubtless key in allowing William Thomson, in a famous footnote (1849) to a work addressing a dispute between Joule and Carnot over conceptual and experimental problems in the heat formation of heat engines, to intimate that something involving both work and *vis viva* was conserved, though not yet visible "in the present state of science."

The specific changes in state that then made the conserved something visible are discussed at length in other entries. If any date marks the emergence of this new conception of energy into visibility, it is 1868, with the publication of the mechanics textbook, *A Treatise on Natural Philosophy*, by William Thomson and Peter Tait. The full articulation of this insight, involving the recognition that heat was energy—and only one of many forms—revolutionized science, and by the time of the ninth edition of the *Britannica* (1899), the entry on energy was six pages long and full of technical terms and equations.

The factors just mentioned are extremely significant for the history and philosophy of science, for they illustrate an inversion of the traditional conception of the relationship between theory and practice, as well as the fact that the environment in which scientists work is not simply a static human-environment relation, but a dynamic, ever-changing one mediated by technology. The practical coping with technologies can precede and even help give birth to theoretical reflection. Technologies therefore can become a kind of philosophical springboard for scientists: familiarity with them reshapes the theoretical imagination, allowing scientists to perceive and project new kinds of concepts or extend them to larger terrains.

4. ENERGY PRIOR TO 1800?

These developments help to shed light on the puzzle, mentioned at the outset, concerning whether the phenomena named by concepts precede the development of the concepts themselves and how the two vastly different positions mentioned can arise.

The puzzle is posed here by the question: Was there energy prior to 1800? This question would surely make most people, including and especially scientists, roll their eyes. Such people would interpret the question as asking whether the phenomenon named by the word existed. In this commonsense view, the answer is surely yes. Energy, after all, was not discovered or invented. It has powered the sun for billions of years, made organisms grow for millions, and driven industrial machines for hundreds. Our opinions, ideas, and representations of energy may have evolved, but energy apart from these—what we are trying to get at through them—does not. But if the question is interpreted as asking whether the abstract notion of a capacity to do work that comes in various forms convertible into each other existed prior to 1800, then the answer to the question is just as surely no.

Traditional philosophers of science would try to resolve the puzzle by appeal to the extremely influential distinction between the context of discovery, or the manner in which a theory or datum was historically discovered, and the context of justification, or the manner in which that theory or datum is justified by reference to all the available evidence on hand—and say that the convoluted, fortuitous, and often idiosyncratic process by which a discovery or concept enters science does not matter. There is some truth to this. But a term like energy cannot be justified in a bare environment, but only within a network or horizon of other historically given concepts (force, work, heat, etc.) and technologies (steam engines, instruments to measure temperature, etc.). These phenomena lead us to interpret other things in their light, changing our view of world and its findings, structures, and laws, leading us to project them as elements of the world—past, present, and future. This does not make scientific concepts arbitrary, an artifact of language or culture, but nor does it legitimate us thinking that these concepts refer to things apart from time and history.

The various interpretations of the question arise because the formulation of concepts such as energy is indebted both to a set of purely theoretical considerations and to a practical, technologically shaped world. This latter world is constantly changing, giving rise to new kinds of phenomena to be explained and related to phenomena that already appear. The network of theory and technologically shaped world forms a horizon in which scientific claims can be tested and be judged true or false.

If one emphasizes the values which permeate the horizon at the expense of the theoretical considerations, and the dependence on them that the invariance that phenomena such as energy show—if one emphasizes let us say the role of the development of steam and heat engines, the social and economic interest in creating more efficient types of such engines, and so forth; and if one emphasizes that a concept such as energy could not have emerged without such interests—it promotes a position such as Latour's.

On the other hand, if one emphasizes the theoretical considerations at the expense of the practical and technologically rich horizon thanks to which phenomena such as energy can show themselves as being invariant in myriad guises—if one emphasizes let us say the tightness and interdependence of the connection between concepts such as energy, power, work, and so forth—it promotes the view that science represents an ahistorical reality apart from a worldly context. But because the horizon is relatively stable, we tend to forget that it, too, can change, and that we justify things only in it.

So was there energy before 1800? If this means an abstractly defined concept of a quantity conserved in closed systems and related in precise quantitative ways to other concepts like power and work, no; if this means this is how we currently understand the world and its phenomena, yes. The history of the term energy is an episode in the history of science that helps to reveal the complexities of the history of science.

The scientific tradition as it has developed up to the present has shaped the contemporary notion of energy such that everything is a modality of energy. In cosmology, for instance, starting with radiant energy, some radiant energy becomes particles (thus mass energy), some particles become atoms, which in turn become molecules and condensed matter, and so forth. Energy is, as it were, the dynamic existential materia prima of the universe. This has both a theory side that gives to the present an illusion of wild nature that exceeds all representations and is beyond human creation, and a practical, representable, and controllable side that gives to the present an illusion of being merely socially constructed.

noncommercial fuels Typically, traditional fuels that are not bought or sold in the marketplace.

Tobit analysis A statistical technique named for the economist James Tobin who developed it to factor into regression analyses dependent variables where a large portion of the sample being used had a value of zero (0) for the dependent variable.

traditional fuels Fuels that have been used by households since time immemorial (such as firewood or crop residues or dung). They are frequently gathered by individuals but are occasionally bought and sold in markets.

The energy ladder is a concept that has been used to describe the transition of households from utilizing traditional energy carriers for their energy service needs to utilizing more modern, technologically sophisticated energy carriers to meet those needs. It draws an analogy between household fuel choice and a ladder. Households using traditional fuels—such as firewood or dung—are assumed to be on the lower rungs of the ladder. Households using modern, commercial fuels—such as LPG, natural gas, or electricity—are assumed to be poised on the upper rungs of that ladder. Although this transition is of most concern to households in developing countries, a similar process is assumed to have taken place in developed countries as they went through the process of industrialization. The idea is that as a household unit's status changes—either through an increase in income, a shift in status, or a change in the society around it—it will begin to utilize a different mix of energy carriers to perform its energy needs. A household that chooses to begin utilizing kerosene or liquefied petroleum gas (LPG) for cooking instead of fuelwood is said to be moving "up" the energy ladder. In contrast, a household unit that makes the reverse decision—shifts from utilizing kerosene or LPG to using fuelwood—is said to make a move "down" the energy ladder.

the energy-use patterns prevalent in developing countries. Researchers and policy analysts have used the concept to better understand household fuel choice and to better design energy policies by anticipating their impacts on energy-using households. Typically, poorer households and rural households have limited access to energy resources and fuels and occupy lower rungs on the energy ladder. Wealthier households and urban households generally have greater access to energy resources and occupy higher rungs on the energy ladder.

The same distinctions that have been made initially at the household level can also be applied at the level of a region or a nation. In fact, underlying much of the conceptual background on the energy ladder at the household level is the understanding that as societies as a whole develop, they not only begin to utilize a greater quantity of energy (as measured in calories, toe, or joules) but their energy mix consists of a greater percentage of modernized fuels, such as petroleum, natural gas, and electricity. While this direct analogue of the individual household unit to the national level may introduce certain fallacies of composition, as individual energy consumption patterns sum up to provide a national energy consumption pattern, the individual-national analogue is quite reasonable: national energy use patterns do reflect, *inter alia*, the sum total of the individual energy-use patterns of their citizens.

As most research on the energy ladder in developing countries has focused on either confirming the existence of the household-level energy transition or specifying its form in various contexts, the household level discussion will form the focus for most of this article. However, when the discussion reverts to the use of cross-national comparisons and analyses to generalize using national-level data, the jump from the household or agent level to the national level will be clearly delineated.

2. CONCEPTUAL FOUNDATION

The energy ladder concept is built on the idea that every fuel that can be used by households has its own set of advantages and disadvantages depending on the various end uses in which it is deployed. Modern fuels are considered to have more advantages than traditional fuels and are therefore considered to be higher rungs on the ladder. In developing countries, the primary end uses or energy services that households need to fulfil are cooking, space heating, water heating, and lighting. Household decision making then must consider the qualities of all the available energy sources in carrying out these end uses in order to arrive at the final household decision regarding which fuels to use for which purposes. In many instances, the decisions are quite simple as the opportunity set facing the households is limited. In other instances—notably the peri-urban and urban areas of developing countries—households face a large range of options that make the household energy use decisions quite complex.

Leach argued that our understanding of this energy transition is based on energy surveys in developing countries that confirm "that most families have an ideal fuel preference 'ladder' running from biomass fuels up through kerosene to bottled gas (LPG), natural gas where it is available and electricity" (p. 118). Traditional fuels, such as firewood and dung, are relatively inconvenient to collect and store, require constant management while in use, and emit large quantities of smoke that has a detrimental impact on the health of the users. Modern fuels, such as natural gas and electricity are more convenient, cleaner to use, have power outputs that are easily controlled, and can be delivered directly to the kitchen (once the basic transmission and distribution infrastructure is built). The energy ladder or energy transition embodies the idea that as household income rises through the development process, they choose to utilize modern fuels and choose not to utilize the traditional fuels.

Each household makes energy-use decisions based on its unique circumstances, its preferences, and its environment. When aggregated across households, the resulting observed energy consumption patterns can become quite complex. In general, lower-income groups within a given area tend to rely more heavily on traditional biomass fuels for cooking. If they are able to afford lighting services at all, they will typically use kerosene or candles for lighting. Wealthier groups within that same rural area may also rely on traditional biomass fuels for cooking, but may supplement that biomass with kerosene or liquefied petroleum gas (LPG). For lighting needs, wealthier households may rely on electricity if their household is connected to the grid, but if not, they will also utilize kerosene, LPG, candles, or even battery-powered flashlights or torches. Thus, poorer and wealthier households in both urban and rural areas of developing countries demonstrate different energy use patterns resulting from their different decision made with respect to their energy consumption patterns.

Figure 1 illustrates diagrammatically the range of end uses and fuels faced by households at different

income levels in developing countries. The horizontal axis represents income and the vertical axis represents the fuel used to fulfill an energy service need, moving from the most traditional to the most modern. As represented in this diagram, all households at all economic status levels must utilize energy for cooking, heating and lighting. In poorer households, the options normally used for these purposes are traditional biomass for cooking, and either candles, kerosene, or batteries for lighting. In middle-income households, the options to fulfill these services expand to include biomass, kerosene, and LPG for cooking; biomass, coal, or charcoal for heating; and kerosene, batteries, and candles for lighting. However, at middle-income levels, another set of end uses or energy services begin to be considered. These additional end uses include refrigeration, transport, basic appliances such as radio and television for entertainment, and even water pumping. The fuel options available for providing these services are petroleum-based fuels, batteries, and electricity. Finally, for upper-income households, the options for cooking extend to natural gas, LPG, and electricity, and the options for heating may include gas, coal, oil, or electricity. At this higher income level, electricity will provide in all likelihood provide all of the lighting needs. At the highest income level, electricity will likely provide all of the refrigeration and appliance needs while petroleum-fuels continue to fill the transport needs. In addition, the higher-income households begin to pursue a range of additional energy needs, such as air conditioning, for which the only option is electricity.

Thus, as household incomes increase, the household tends to move "up" the energy ladder to more sophisticated fuels. Not only does the choice of fuels change, but the absolute quantity of energy effectively utilized by the household increases as it begins to pursue a broader range of energy end uses or energy services. For nations as a whole, as the economy develops and the population becomes wealthier, its citizens begin to use a larger share of modern fuels, especially electricity, to provide a larger number of energy services. This results generally in a larger consumption of energy at the national level—hence, the well-documented traditional link between energy consumption and gross national product.

3. THE ENERGY TRANSITION: DRIVERS AND CONSTRAINTS

The resource allocation decisions resulting in a household's fuel-use patterns and, therefore its position on the energy ladder, are determined not just by income but also by a large number of other

factors. Because these factors influence the household's decision-making process, they also are considered to be important either as policy levers or as indicators of policy impact. In the following section, the factors driving or constraining the household's energy-use decisions are briefly discussed with respect to both their impact on the energy ladder decision and their importance as policy measures or as indicators of likely policy success. Some of these may be considered to be supply considerations; others may be characteristics of the fuels; and still others may have to do with the either the physical or economic environment faced by the household in a particular market.

3.1 Household Income

As has already been discussed, household disposable income is one of the most important factors determining household energy decisions in all countries, both developing and developed alike. In general, total energy use is positively correlated with income. In the context of the energy ladder discussion, wealthier households will show a greater predilection to using more sophisticated fuels than will poorer households. Expressed in microeconomic terms, the income elasticity of demand for most modern fuels (electricity, natural gas, LPG) is positive whereas for traditional fuels (over a wide range of incomes) it tends to be negative.

Income becomes an important policy discussion concerning household energy use. As incomes increase, so will the demand for modern fuels, other things being equal. Likewise, households with falling incomes are liable to move down the energy ladder to more traditional fuels. Perhaps a bigger concern for policymakers in developing countries revolves around the energy needs of the extremely poor household—that is, households living on less than $2 per day. Whether or not the incomes and other resources available to these households will enable them to obtain adequate energy remains a concern for energy policymakers. Unfortunately, in such cases the policy options may be so limited that policymakers are unable to influence the energy mix used by these extremely poor households.

3.2 Urbanization

Urbanization is an important indirect influence on a household's energy-use decisions. Households living in urban areas face a different opportunity set than those living in rural areas in two major respects. First, their ability to collect firewood or traditional fuels from their surrounding will tend to be more limited than that of their rural counterparts. Second, because their ability to engage in subsistence agriculture is more limited than that of their rural counterparts, they require a steady cash income from paid employment to be able to meet their budgetary needs. As a result, their monetary income tends to be higher than that of rural households and they will demonstrate a higher reliance on commercial or semicommercial fuels than their rural counterparts. In addition, urban infrastructure is normally more advanced than rural infrastructure meaning that households in urban areas tend to have better access to the electric or natural gas distribution grids as well as to markets for LPG bottles, kerosene, and even commercialized traditional fuels, such as charcoal. Therefore, an urban household will tend to occupy a higher rung on the energy ladder or use a larger share of modern, commercialized energy sources to meet its energy needs than will a rural household of comparable status.

Urbanization is an important consideration when discussing household energy policy and situation with respect to the energy transition. In most developing countries, more policy options have relevance to urban areas because all urban households are engaged in market activities for their livelihoods, supply-focused options are easier to design and implement, and price controls or subsidies are easier to enforce. For example, electrification of urban households or the extension of a natural gas distribution grid to urban households tends to be a far more cost-effective policy option to enhance household access to modern sources of energy sources than is applying those same policies to rural populations. In fact, given the low population densities of most rural areas in developed countries, grid extension as a policy intervention is often too expensive and cost-ineffective a policy option to consider pursuing at all.

3.3 Smoke Emissions and Exposure

One of the reasons that households in developing countries are presumed to prefer modern fuels over traditional ones is that the former are cleaner, in terms of both storage and handling and emissions. Traditional fuels, such as dung, crop residues, and fuelwood, emit noxious fumes when burned contributing respirable particulates to the household environment. Many households in developing countries burn these fuels for cooking indoors and often have no effective

means of venting the emissions from these fuels. This leaves the cooks—typically women—and other household members exposed to extremely high levels of particulate concentrations. Smith has documented that the rural indoor environment in many developing countries may represent the world's single most pervasive and intensive air pollution problem in terms of actual human exposure to particulates. In terms of total human exposure to pollutants, exposure to biomass (or coal) smoke from indoor cooking in developing countries poses a far more serious health threat than second-hand tobacco smoke or any source of ambient industrial emissions. Evidence from developing country households shows that concentrations of respirable particulates can run from 500 to more than 15,000 $\mu g/m^3$ in many indoor environments in developing countries. This level of pollution concentration from the indoor use poses very serious health threats to the exposed population. Although the medical records linking exposure to disease are rather weak in most developing countries, acute respiratory infections in children and chronic obstructive lung disease and *cor pulmonale* in adults exposed to smoke from biomass cooking have all been linked to exposure to cooking smoke in developing countries. Although other anticipated health effects from exposure to biomass cooking smoke—such as adverse pregnancy complications and increased cancer rates—have not yet been sufficiently documented through medical research, they must be assumed to be significant.

Smoke pollution clearly provides a significant incentive for households to move away from using these dirty fuels—such as firewood and coal—toward using more modern, cleaner fuels with fewer negative health impacts. Although many rural households and poorer urban households in developing countries may have no alternative to burning biomass fuels or coal in unventilated cooking devices, for those who do have some alternative, it provides a significant incentive to move "up" the energy ladder to cleaner, more modern fuels. For policymakers, the likely negative health impacts of continued reliance on these traditional fuels should create an incentive to find cooking alternatives that do not threaten the health of women and children in developing countries. One logical policy response might be to devise programs to encourage the use of LPG, natural gas, or electricity for cooking in areas where they are available and affordable to the local population. Government policies to support moves "up" the energy ladder in most developing countries could certainly be justified on the basis of the negative health impacts of continued traditional fuel use.

3.4 Appliance Costs

One of the obstacles to adopting modern fuels is the fact that a specialized piece of equipment—an appliance—is required to utilize them. The cost of these appliances to use more modern fuels may prove to be prohibitive for many poorer households in developing countries. Such costs serve as a transaction barrier to the adoption of more modern fuels by households in developing countries. The cost of LPG bottles, kerosene cooking stoves, LPG stoves, or electrical stoves may represent a major cost obstacle to households adopting and utilizing the more modernized fuels instead of the traditional biomass-based fuels found on the lower rungs of the energy ladder. For many households accustomed to cooking with wood over a traditional three-stone hearth, the additional cost of a fuel-efficient woodstove may prove prohibitive, even in cases where the fuel savings more than justify the additional costs.

Policies may be devised to assist some households in overcoming the financial barrier to purchasing appliances for modern fuels. While financing might help households amortize appliance cost over a longer period of time, such payments will still increase the costs of the more modern fuels, placing it at a disadvantage to the traditional fuel for which no improved appliance is required. Some governments have tried subsidizing or providing tax credits for the purchase of appliances designed to utilize modern fuels, thereby encouraging households to adopt and use the more modern fuels. Several African countries claim to have successfully encouraged a move away from fuelwood and charcoal by subsidizing LPG bottles and cooking devices while encouraging suppliers to provide better distribution networks for this relatively clean and modern fuel. These represent some of the few cases of desirable moves up the energy ladder that have been stimulated by deliberate government policy.

3.5 Relative Fuel Costs and Prices

Relative prices per delivered energy unit play a crucial role in determining what fuels a household will use as well as how much of those fuels to use to meet its own energy needs. In the case of traditional fuels, such as fuelwood, the costs may be measured in terms of the time spent gathering the fuel rather than in monetary units. How a household may choose to make this trade-off—between labor and monetary resources—involves a complex calculation made more difficult because of the different roles found

within the household unit: women may contribute the labor to gather the firewood, but men often control the money required to purchase the fuels. In general, the relative fuel costs and prices will be reflected in the household energy use patterns and will determine where on the energy ladder a household determines itself.

Policymakers have frequently utilized price to steer household energy use decisions. The most common case involves subsidized electricity prices: governments have frequently regulated electricity prices to be less than their actual costs in order to encourage its use and obtain favor with the electricity-consuming populace. By subsidizing connection fees and controlling energy charges at levels below their actual costs, governments encourage households to utilize more electricity than is economically sustainable. The net result is that more households move up the energy ladder than should, consuming more electricity than they can actually afford to purchase. In such cases, the electricity utility's balance sheet suffers.

A second example of governments using prices would be the kerosene subsidy. Many governments have sought to control by regulatory fiat the price at which kerosene can be sold in the market, either through price or controls a cross-subsidy provided from a surcharge on other petroleum fuels. While the goal of such a policy is admirable as it is intended to ensure that poorer households have access to a relatively modern and clean fuel—kerosene—for lighting and cooking, it also has proven to be problematic. Studies have shown that most of the benefits of these subsidies accrue to middle and upper-income families, not to the poor. In addition, the surcharge may be administratively cumbersome and the controlled price quickly becomes unsustainable. The costs of such policies frequently outweigh the benefits and governments should be aware of this prior to implementing such systems.

A strikingly different example of using pricing policy to shape household fuel-use decisions is the case of the stumpage fee imposed on trees being harvested for fuel use. Many governments in Africa have been convinced that there is inadequate control over the harvesting of firewood for sale to households and for the production of charcoal for sale to peri-urban and urban households. The proper response in such cases is to impose a tax or a stumpage fee to compensate for the fact that the harvester has not paid for the planting, protection, and caring for the tree over its lifetime. If a government imposes such a stumpage fee either at the point of harvest, the point of production, or the point of importation into an urban area, it has two relevant effects. First, it raises funds to be able to replace the tree. Second, it serves to raise the price of the fuel creating an incentive for the household to either utilize less wood or charcoal or to find another alternative, one either lower or higher on the energy ladder. Thus, pricing policies can stimulate movements either up or down the energy ladder. Such movements may be intentional or unintentional, depending on the situation.

3.6 Fuel Availability

Perhaps the single most important supply-side determinant of household fuel choice for traditional fuels has to do with fuel availability. While the availability of fuel sounds like a relatively straightforward matter to determine, it actually becomes quite a complex matter to evaluate in any given location. It may be determined by the forest cover, the predominant land-use system, the nature of land tenure system, cropping patterns, and the distance traveled to collect fuel. For rural households accustomed to using firewood, even convenient surrogates such as the distance traveled to collect firewood or the amount of time required to collect a headload may be a misleading measure of fuel availability. While much of the literature on the household energy use in developing countries originally emerged in response to concerns regarding increasing deforestation and the "fuelwood crisis," scientific work has delinked fuelwood use by rural households from deforestation. This does not mean, on the one hand, that in localized areas, households do not experience a severe shortage of fuelwood for domestic purposes or, on the other hand, that fuelwood use has never contributed to tree harvesting that is detrimental to the environment. Rather it means that energy and forest planners must maintain balance in their view and proposed plans for rural resource management and needs. Fuelwood availability, or rather fuelwood's limited availability in certain rural areas of developing countries, may create an incentive for households to choose to utilize fuels either higher (i.e., kerosene, LPG) or lower (crop residues, dung) on the energy ladder.

For those fuels that are lower on the energy ladder than fuelwood, such as crop residues or dung, they present their own challenges of availability. Crop residues are normally only available to rural households at certain post-harvest seasons during the year. As they are frequently used for fodder in rural areas,

their use for cooking may detract from the ability to raise livestock. Dung availability is dependent on livestock ownership in a given area and is easier to collect when livestock are penned in a small corral instead of being allowed to wander freely. As is the case with crop residues, dung has an alternative use as fertilizer, and using significant quantities of dung for cooking fuel will eventually contribute to soil exhaustion.

In many rural areas, modern fuels may simply be unavailable. While kerosene is fairly easy to distribute through formal and informal channels, LPG bottles are often viewed as cumbersome to manage meaning that LPG is not always available for household use. A decision to use electricity is entirely dependent on grid connections and the availability of power. While the availability of traditional fuels may be more a question of ecological status, the availability of modern fuels will be determined by the state of market development.

The question of fuel availability not only influences household fuel-use decisions in rural areas but also helps determine the markets for household fuels in urban and peri-urban areas. In many African countries, urban households rely on charcoal for the domestic cooking needs as firewood is relatively bulky and economically inefficient to transport and charcoal stoves are frequently more efficient than firewood stoves. An added advantage is that while charcoal combustion emits carbon monoxide, it does not emit the same type of noxious, respirable, particulate-laden smoke that firewood does. Hence, urban households using charcoal avoid much of the dangerous ground-level emissions from biomass smoke to which their rural counterparts using firewood are exposed.

In reviewing the question of availability of biomass fuels and its relevance to household fuel choice decisions, Barnes and Floor developed a transition model encompassing three stages that cities pass through in this transition. Stage 1 represents situations where the urban dwellers still rely heavily on wood use—encompassing situations where wood may still be free to the case where it is purchased and its price is fairly high. Stage 2 differs depending on local resource availability. In some parts of Africa (e.g., Senegal, Kenya, Tanzania) and the Caribbean (e.g., Haiti, Dominican Republic, Jamaica), the second stage encompasses heavy dependence on charcoal. For other cases (e.g., Indonesia and China), the second stage involves heavy reliance on coal and kerosene. The final stage, Stage 3, occurs when income in the city is fairly high and virtually all households are dependent on LPG, natural gas, or electricity. Virtually all cities in developed countries fit into this third category, and increasingly so do many cities in middle-income developing countries. The progression of urban areas through this urban energy transition corresponds well to the movements of individual households in those cities up and down the energy ladder.

On the policy front, for rural households, much effort has focused on supporting the planting of trees either in woodlots, on farmland, or in forest reserves. Policy efforts have also focused on ensuring proper ownership of and access to trees on public and private lands to guarantee fuel availability. While these options are intended to ensure continued sustainability of traditional woody biomass for use as a cooking fuel, there is a need to maintain balance between the use of trees for fuel and their use for nonenergy purposes. Trees have many more functions in the rural ecology than just supplying cooking fuel needs.

Other policy efforts in both rural and urban areas have sought to guarantee that households have access to modern fuels. Governments have lent support to the development of marketing and distribution networks for LPG and kerosene to ensure that households have an expanded array of modern fuel options. Rural electrification and urban electrification (i.e., connecting previously unconnected urban households to the electric grid) are both policies designed to provide households with access to electricity, the fuel typically at the top of the energy ladder. Although results demonstrate that households newly connected to the grid own neither appliances nor the wherewithal to use electricity for all of their domestic purposes, gradual accumulation and consolidation of household status is presumed to expand future household use of electricity.

4. EMPIRICAL EVIDENCE FOR THE ENERGY LADDER TRANSITION

The concept of the energy ladder has been used as a foundation for many of the studies of household energy use in developing countries that have been undertaken since the early 1980s. While not all of them have provided confirmation for the linear transformation envisioned in the narrowest interpretation of the energy ladder concept, most of them do demonstrate that households undergoing the development process do shift their energy use

patterns in response to both internal and external conditions. The following sections focus on small fraction of the empirical literature on household energy use and its documentation of ladder-like household energy transitions. Section A discusses the results from various surveys that have been implemented, and Section B examines some of the statistical modeling that has been undertaken to model household energy behavior.

4.1 Survey Evidence

Household surveys undertaken in rural Africa have demonstrated that fuelwood remains the predominate fuel for rural household energy use throughout the continent. However, the determinants of fuel switching or movements up or down the energy ladder may be somewhat difficult to predict in the rural context. A rural household survey undertaken in Kenya in 1981 shows that fuelwood is by far the single most important fuel used by households for cooking. When it was unavailable, households would be forced to switch either to crop residues or kerosene. Fuelwood availability is an extremely localized phenomenon and may be linked to diverse factors, such as land tenure, population density, settlement density, and crop types. On the national level, income may prove less useful as a predictor of household energy use patterns than might be other factors such as level of engagement with the cash economy. Subsistence farmers showed a relatively heavier reliance on firewood and a lesser consumption of kerosene, LPG, and electricity than did cash-crop farmers or even farm workers or schoolteachers. As most of rural Kenya remains unelectrified, the final rung in the energy ladder was occupied by a very small fraction of households. Rural household energy use patterns remain somewhat problematic and difficult to predict given the wide range of other confounding variables found to influence household fuel choice.

A survey undertaken by Davis in several South African rural areas again confirms that fuelwood is the predominant fuel of choice for all households at all income levels. There is a tendency to shift from collecting firewood to purchasing it as incomes increase, but firewood remains relatively constant as the most important cooking fuel in rural areas. Kerosene again emerges as a transitional fuel for cooking. Candles, kerosene, and electricity are the predominant fuels used for lighting in rural areas. For households connected to the grid, there is a decline in expenditures on kerosene and candles for lighting. But there is also a tendency for the lowest income households to continue purchasing and using candles even after they have grid electricity. This is attributable either to limited indoor wiring or to limited cash-flows prohibiting the purchase of cards for pre-payment meters. What does emerge from the South African evidence is the relatively large number of households that use multiple fuels for a single end use. For example, 25% of the electrified households and 56% of the unelectrified ones used both kerosene and fuelwood for cooking. In short, the authors conclude that a household energy transition from traditional to modern fuels is taking place in rural South Africa. However, they express reservations about whether it will result in a simple transition to electricity use or an increase in the use of multiple fuels for a single end use.

In urban areas across Africa, the situation appears to be more predictable. Hosier and Kipondya present data from urban Tanzania showing that charcoal is the predominant fuel used in urban households across all income groups. Although this predominance of charcoal may vary according to the city, its role varies little per income category. Kerosene consumption demonstrates the role of a transitional fuel whose use rises with small increases in income and then decreases at higher income levels. Electricity use increases across all income levels. The urban household energy transition appears to be proceeding slowly in Tanzania, despite the country's rather sluggish economic performance during the period under examination. Policy efforts—especially cross-product subsidies to kerosene and artificially low electricity prices—might have played an important role in ensuring that more urban households were able to move up the energy ladder than down during the period of examination.

A detailed ESMAP-sponsored survey of rural household energy use in six counties of China demonstrated that most households used fuelwood, agricultural residues, or coal for their domestic cooking needs. Households in the poorer counties tended to show greater reliance on firewood while those in the more industrialized counties used very little firewood and more coal. Coal was a major household fuel in four of the six counties, especially where fuelwood was scarce. In other locations where fuelwood was scarce, straw and crop waste were used. Electricity use was again positively related to income. On balance, income is seen to play an important role in driving households to use electricity, but fuelwood shortages—frequently very locally determined—tend to drive households either up or down the energy ladder to other fuels.

From an ESMAP-sponsored analysis of surveys of household energy use in six states of rural India, the evidence shows that there is a slow transition to modern fuels brought on both by increasing economic status of households and by an increasing scarcity of fuelwood. In a cross-sectoral analysis, higher-income households clearly used more electricity and more LPG than did lower-income households. Upper-income households also spent a larger absolute amount of money on their household energy needs, but due to the higher incomes, this represented a smaller fraction of their total income. While a higher fraction of upper-income rural households also utilized electricity for lighting and other purposes, the utilization of biomass energy appeared to decline only at the highest income levels in the rural areas. However, the time devoted to collecting fuelwood in rural areas declined with income as wealthier households would tend to purchase firewood instead of gathering it. From 1980 to 1996, over 8% of rural households acknowledged switching from using firewood for their domestic cooking chores to using some other fuels. Over 60% of these households moved to kerosene and LPG for cooking. The remaining households acknowledged fuel switches either to biogas or down the energy ladder to crop residues or dung. In both urban and rural areas, kerosene is seen to fulfill the role of "first step" up the energy ladder as many households begin using it to cook with prior to moving on to LPG or other modern energy carriers. In urban India, LPG has become the fuel of choice for cooking and has begun to be widely utilized. This has been attributable not just to an increased supply of the fuel, but also to the breaking up of the near-monopoly on LPG distribution maintained by the national petroleum companies. In general, these data from India show that there is a movement among both rural and urban households to more sophisticated modern fuels from traditional, biomass fuels.

In a review of energy use surveys in urban areas in Asia, Sathaye and Tyler presented household energy consumption patterns from cities in India, China, Thailand, the Phillipines, and Hong Kong. While each country and indeed each city within a country demonstrated very different energy use patterns, their findings showed several tendencies. First, as incomes increased, households tended to rely less on biomass and more on modern fuels. Somewhat surprisingly, modern fuels may have been preferred over traditional biomass fuels not only because of their greater convenience but also because of they are cheaper when measured in terms of their cost per unit of energy delivered. Second, as incomes increased, households not only made use of a larger quantity of electricity, but they also made use of electricity for a larger set of end uses. Urban households at all levels of income began purchasing and using electrical appliances, from light bulbs to refrigerators to color television sets. This relatively rapid dissemination of appliances throughout urban Asia would indicate that household electricity demand is likely to grow in the same rapid way as it has in the more developed, Organization for Economic Cooperation and Development (OECD) countries. It also poses an opportunity for electricity conservation: if these appliances can be made more efficient, then household standards of living can continue to rise with a less significant increase in electrical requirements. Finally, kerosene use—which is considered to be an inferior modern fuel—declined in importance through time and as incomes increased. While not confirming the existence of a rigid, linear, and universal energy ladder, the evidence presented from urban Asia confirmed that households do move to more modern fuels across time and as income allows.

4.2 Statistical and Econometric Evidence

Given the complexity of household fuel-use patterns and the large number of factors influencing household fuel choice, tables of descriptive statistics do not go very far in understanding household fuel choice. To push beyond the understanding available from using descriptive statistics, a number of authors have used regression-based and econometric analyses to analysis household fuel choice in developing countries. These analyses are important as they provide insights both into the factors that appear to determine household fuel-choice decisions and into the validity of the energy ladder transition itself.

From the analysis of a number of household energy surveys based in south Asia, Leach developed multiple regression equations designed to explain household energy utilization. Because household size is closely related to income, he chose to use per capita household energy consumption figures as the dependent variable. His analysis concluded that income, household size, and settlement size are the key factors determining household fuel use. Although the elasticities that he estimates demonstrate the expected sign in most cases, he argued that they are not much help to energy planners as the important independent variables are not under the planners' control. Other factors that are under more direct

control of energy policymakers—such as relative fuel prices, the cost of appliances, and the availability of commercial fuels—are still not shown to be crucial determinants of household fuel-use patterns, partly because of the inadequacy of the survey techniques deployed in gathering the data.

Using nationwide household energy data from Zimbabwe, Hosier and Dowd developed a model of household fuel choice. In the aggregate, their data showed that fuelwood and kerosene use decreased with income while electricity use increased with income. They then formulated a multinomial logistic model of fuel choice, where the dependent variable represented the probability of a household choosing one fuel over another to cook with. Their data made a distinction between gathered wood and purchased wood as being distinct alternatives. They also allowed for a separate "transitional" category for households that used both wood and kerosene or electricity. Their system of four equations was able to predict nearly 90% of the household fuel choices correctly. Their results demonstrated that an increase in income and localization in an urban area will both increase the probability that a household will make a move up the energy ladder. They conclude that while energy policies might have an influence on household fuel decisions in the urban areas, fuel decisions in the rural areas appear to be insensitive to readily manipulated policy instruments.

Using urban household energy survey data from Java, Indonesia, Fitzgerald, Barnes, and McGranahan undertook two distinct sets of econometric estimations for cooking and lighting. For the analysis of cooking fuels, they first estimated the demand for energy for cooking from the three fuels used (wood, kerosene, LPG) for cooking in Java using a Tobit analysis to account for the fact that many households did not use at least one of the fuels for cooking. The analysis included household size, the prices of all fuels, the availability of all fuels, urban size, and an index measure of cooking size to estimate the amount of each fuel used for cooking. Their results show that firewood tends to be treated as an inferior good: as household income rises, fuelwood use tends to decline. However, wherever fuelwood is plentiful, all households—even wealthier ones—tend to use it for cooking. The results also show that LPG tends to be the fuel of choice for the highest income households surveyed, but again, its availability limits its distribution. Kerosene again serves as a bridging fuel—it is used sparingly by lower and upper-income households, but fairly heavily among the middle-income groups. Their second estimation examined the demand for energy (measured in MJ) in all forms attempting to isolate the substitution effects between the various fuels. These estimates show that actual substitution effects are slightly different than those derived from technical evaluations of fuels and efficiencies. For lighting, the authors repeated similar analyses of lighting demand and total residential fuel demand. The fuel demand equations demonstrate that electricity is the fuel of choice for all households in urban Java. The lighting substitution analysis demonstrates that a household using kerosene for lighting will have to utilize 10 times as much energy (heating value) for lighting as a similar household lighting with electricity. In addition, a household switching from kerosene to electricity can easily cut its overall lighting expenditures in half while obtaining nearly six times the amount of lighting. Overall, the analysis shows that urban residents of Java show household fuel preferences that resemble those that would be predicted by an energy ladder, with the exception being perhaps that firewood is used across all income groups if it is locally plentiful.

For the cities of Dakar, Senegal, and Abidjan, Cote d' Ivoire, Koumoin studied household energy demand using cross-sectional, time-series data for the years 1978 to 1992 taken from the Food and Agriculture Organization (FAO) production yearbook, the electric utilities in the countries, and a set of World Bank studies of the region. A system of eight equations representing the demand for energy in the urban households of the two cities was estimated in the form of a generalized logit model. His results show that the demand for charcoal is relatively price and income inelastic, meaning that it is used by households at all income levels. Rather than seeing immediate interfuel substitution as might be expected on the basis of the energy ladder concept, the evidence seems to support a gradual transition process with multifuel utilization at the household level being an initial step toward the anticipated substitution. Because of the relative price inelasticity of charcoal, electricity demand may be that sector of the overall household energy consumption which is most sensitive to pricing policies and variations. Local considerations, such as household size, migrant labor, and fuel availability, also seem to be important in shaping the profile of household energy demand. The importance of fuel availability can be seen in that LPG demonstrates a higher than expected penetration because of long-standing policy efforts to promote it as a cooking fuel. In such an economically marginal economic environment, the author concludes that policy efforts might well focus

on ensuring stability in the market for traditional fuels so as not to further threaten the economic base of the population. Interfuel substitution and movements up the energy ladder will likely take place over an extended period of multiple-fuel use given the nature of the prevalent economic and environmental conditions in the cities under examination.

Using a 4-year long study of a village in Mexico supplemented by a household energy survey in four Mexican states, Masera *et al*. discovered that rather than households moving in a straightforward, linear fashion along the energy ladder, in fact, their transition may be from a simple, traditional fuel use to a situation where multiple fuels are used simultaneously. Wealthier households continued to cook with fuelwood indoors even when they owned and also used LPG cooking devices. Multiple fuel use appears to be pursued for two reasons. First, it is a risk-minimization strategy so that if the LPG supply fails, the household will face only minor disruption as they are still accustomed to cooking with firewood. Second, cooking with both wood and LPG is an accepted practice because of preferences for a diet of tortillas—the traditional staple food—which cannot be cooked efficiently on LPG appliances. This cooking pattern has a number of implications. First, households that adopt the more modern fuel, LPG, rarely cease to cook with wood. As a result, their firewood consumption levels drop by only 30% once they begin cooking with LPG. Second, these multifuel using households typically are wealthier members of the community, but they willingly face exposure to nearly twice as many particulates as lower-income households. Fuel stacking, the process by which households continues to use firewood (a traditional fuel) while also adopting LPG (a modern fuel), is seen as a logical resultant of cultural and risk factors found in Mexico, and it appears to continue despite awareness of the potential negative health impacts. Identifying policy solutions to the type of nonlinear, straightforward interfuel substitution found in these areas of Mexico will require much greater thought, study, and a paradigm slightly more complex than that of simplified energy ladder.

5. CRITICISMS OF THE CONCEPT

While it is clear that households facing the development transition will also undergo some form of transformation of their household energy use, the energy ladder concept has been criticized from a number of different perspectives. As it developed from a general understanding of household budgetary decisions, a knowledge of the development process, and a familiarity with the differences in energy use patterns between more developed and less developed countries, it serves as a loose conceptual framework that can neither be proved or disproved, but that rather informs or underlies a discussion of the transition in household energy use patterns in a particular context. Nevertheless, several criticisms of the concept deserve mentioning as they might provide a foundation for conceptual models that will prove even more useful in understanding the household energy transition.

The first such criticism is that the energy ladder fails to account for the complexities of actual household fuel usage, assuming that all households—or at least most households—will move progressively from traditional fuels to more modern fuels in a predetermined succession. It fails to account for households that might skip rungs by jumping from firewood to LPG without using what appears to be the ubiquitous transitional fuel: kerosene. It also fails to account for multiple fuel use as anything other than a transitional option between two rungs even though many households even in developed countries use more than one fuel for cooking, both as risk-minimization strategies and as cultural preferences. Multiple fuel-use strategies might even result in the most efficient overall household energy-use profiles, as fuels are used for those activities for which they are most efficient. Multiple fuel use may be a logical long-term household fuel choice given cultural preferences, local fuel availability or unavailability, system-wide energy efficiency, and other location-specific considerations. Pursuing multifuel use further might lead to the concept of bifurcated household energy ladder or a different stage model incorporating platforms being maintained at various stages rather than merely a simple ladder whose only options are for remaining stationary, ascending, or descending. A more complex model would do a better job of explaining reality, but would also run the risk of sacrificing the main strength of the energy ladder concept: its intuitive appeal.

A second criticism centers on the value-laden nature of the energy ladder. Value-laden judgments regarding the modernity of society and the fuels associated with a society at a particular "stage" of development underpin much of the thinking behind the use of the energy-ladder concept. Modernization theory—wherein all countries are engaged in the homogenizing conveyor belt called "modernization"

resulting in their becoming more like developed countries—has been discredited as a model for development thinking for quite some time. Yet the energy ladder still builds on this paradigm. Because households in developed or OECD countries have followed a certain evolution in their energy-use patterns, households in developing countries have been assumed to fall into the same—or at least—a very similar pattern. It ignores questions about the conspicuous consumption or lifestyle issues that must be raised in the context of developed countries. Clearly, if all of the people in developing countries used energy in the same profligate manner that those in developed countries do, the earth's energy resources would be rapidly depleted. The energy ladder assumes that there exists but one final end point for the household energy transition, and that end point is the same for developed and developing countries alike. It thereby ignores the possibility that developing countries might pursue paths that are more environmentally friendly; more sustainable over the longer term; and consistent with their own cultural traditions.

A third criticism focuses on the fact that the energy ladder has been built mostly on household energy surveys providing a snapshot of energy consumption at a particular point in time. Its basis is cross-sectional in nature, building more on differences between households at one point in time rather than on longitudinal evidence documenting changes in time among the same households. Generalizing from cross-sectional data to draw time-series conclusions may lead to a misrepresentation of trends and relationships, including the underestimation of the importance of price and cost to influence household decision making. More careful analysis of trends over time would clearly help to strengthen the case for the household energy transition as a whole.

Fourth, the energy ladder concept makes no allowance for the dynamics of power and control within each household unit. In rural households, for example, it may not be unusual for women to be charged with collecting firewood and cooking, while men control financial resources and therefore make decisions requiring financial allocations. For the sake of convenience and reducing exposure to toxic smoke, women might want to move up the energy ladder, but are prevented from doing so by an unwilling husband who controls the household's financial resources. Thus, the predictive capability of the model may be limited in cases where such situations occur. Some would argue that using the energy ladder as a concept informing the analysis may preclude the consideration of gender roles in the household energy sector altogether. As earlier discussions have shown, household energy discussion clearly could benefit from greater analysis of the disaggregated nature of household units and the different decision-making frameworks of the individual agents involved.

Finally, the energy ladder yields more predictive insights into the household energy transition are more consistent in urban areas rather than rural areas. By and large, rural household energy-use patterns appear to be overwhelmingly determined by local fuel availability rather than other factors that are readily predicted on the basis of economic theory or factored into regression equations. For the most part, policymakers exert relatively little control over rural household fuel-use patterns. In urban areas, the problem may seem more comprehensible and tractable using the microeconomic theory of consumer behavior. That is not to deny the many instances of documented upward or downward shifts on the energy ladder by rural households. Rather, it merely means that the complexity of rural household energy use may be more difficult to reduce to a simple analogue model than are urban energy-use patterns.

6. CONCLUSIONS

The concept of the energy ladder has informed energy studies and policies in Africa, Asia, and Latin America. Household fuel choices are influenced by a number of factors that are both internal and external to the households making the decisions. Statistical models have attempted to identify these factors and define the strength of their influence in determining household fuel choices. Although it has been used as a conceptual basis to inform much of the work on household energy in developing countries, criticisms have brought to light several limitations. To date, no one has posited an alternative conceptual framework describing household fuel choice and decisions in the process of economic development. As a result, the energy ladder concept will likely continue to be used as an analogue model informing discussions of household energy transitions in developing countries. Its strength lies in its analytical clarity and simplicity. Given the importance of energy to economic development and the continued challenge of providing energy for both the subsistence and development needs of the urban and rural poor in developing

countries, the issues raised in the discussion of the energy ladder will likely continue to be important for energy and development professionals for the foreseeable future.

Glossary

demand-side management (DSM) bidding An auction in which a utility generally solicits proposals from energy service companies interested in achieving specified amounts of DSM savings (e.g., 1000 kW of demand reduction).

energy service company (ESCO) A company that is engaged in developing, installing, and financing comprehensive, performance-based projects, typically 5–10 years in duration, centered around improving the energy efficiency or load reduction of facilities owned or operated by customers.

guaranteed savings The ESCO guarantees to the customer that the project's realized savings will equal (or exceed) the payments made (or financing costs absorbed) by the customer over the term of financing. Also known as chauffage in Canada and Europe.

investment-grade audit A detailed audit that is used as the basis for financing a project as well as for projecting energy and other savings on a performance contract.

non- and limited-recourse project financing Based on payments made exclusively from the cash flow (revenues) of the project and not by the other nonproject assets of the customer or ESCO.

off-balance sheet financing The building or facility owner can receive investments in his or her facility but with no financial liability recorded on the organization's balance sheet.

performance-based projects The ESCO's compensation, and often the project's financing, are meaningfully tied to the amount of energy actually saved, and the ESCO assumes the risk in linking its compensation directly to results.

shared savings projects The ESCO's payments are typically structured as a percentage of the energy savings actually realized by the end user over the length of the contract.

super ESCOs ESCOs that provide traditional energy services and supply gas and/or electricity (and/or other fuels) to customers.

third-party financing Funding of energy savings investments by an outside company, using energy savings to pay for the project.

The energy services industry represents an important group for promoting energy efficiency in developed and developing countries. This article provides an overview of energy service companies (ESCOs), starting with a description of their basic characteristics, and then tracing their origin and growth in the United States. After examining the future prospects for the U.S. ESCO industry, the article ends by briefly examining the ESCO industry in other countries.

1. INTRODUCTION TO THE ENERGY SERVICES INDUSTRY AND ENERGY SERVICE COMPANIES

1.1 ESCOs and Performance Contracting

An energy service company (ESCO) is a company that is engaged in developing, installing, and financing comprehensive, performance-based projects, typically 5–10 years in duration, centered around improving the energy efficiency or load reduction of facilities owned or operated by customers. Projects are performance-based when the ESCO's compensation, and often the project's financing, are meaningfully tied to the amount of energy actually saved, and the ESCO assumes the risk in linking its compensation directly to results. Performance contracting is another term for the performance-based approach.

Energy performance contracts can be distinguished from two contracting approaches commonly utilized by other types of energy-efficiency service providers: (i) contracts for installation of efficient equipment for a specified fee, which is typically backed by a manufacturer's equipment warranty contract, and (ii) energy consulting services, such as building audits and advice on potential energy-efficiency improvements. Contracting based on performance does not necessarily have to be undertaken by an ESCO, but in practice ESCOs have been the pioneers and major users of performance contracting for energy-efficiency projects. ESCOs used performance contracting primarily as a method for assuring their clients that they would confidently achieve energy and cost savings—there were no other companies in the marketplace taking this risk. For this reason, ESCOs are fundamentally different from consulting engineers and equipment contractors specializing in efficiency improvements; the former are typically paid a fee for their advice, whereas the latter are typically paid a fee for their equipment, and both accept no project risk. Such risk creates the highest possible motivation to properly specify, design, engineer, install, and maintain savings over the length of the contract.

1.2 ESCO Diversity

Each ESCO differs in terms of ownership, target markets, technology focus/expertise, in-house capabilities, etc. The following are some of the key areas in which ESCOs can be differentiated:

Ownership: ESCOs may be privately owned (independent) companies, utility subsidiaries or affiliates, nonprofits, joint ventures, manufacturers, or manufacturers' subsidiaries.

Target market: ESCOs typically focus on market niches, by subsector (e.g., hospitals, schools, and government) and by project size (e.g., large customers).

Service specialization: Some ESCOs perform project installation using in-house expertise, whereas others specialize in engineering design and analysis and subcontract other services (e.g., equipment installation).

Technology: Most ESCOs have a technological bias [e.g., lighting or heating, ventilation, and air-conditioning (HVAC) controls], whereas others are comprehensive by seeking to achieve energy savings from the widest possible array of cost-effective measures in a given facility. Also, some ESCOs focus more on electrical end uses than those using other forms of energy (primarily because most projects have involved lighting), but comprehensive ESCO projects almost always involve thermal measures.

Geographic preference: Some ESCOs have established a preference to conduct business in specific geographic regions of one country, whereas others are national and a few have done some international work.

Project financing: ESCO financing capabilities vary with the financial strength of the ESCO. Those with "deep pocket" parent companies typically have a greater capacity to offer off-balance sheet financing. Some ESCOs have significant, well-established financing capabilities, some have limited in-house financing capabilities, and others have none at all and must arrange financing through lenders (the typical case). However, all ESCOs rely to some extent on third-party financing since most ESCOs do not have internal financing capabilities.

1.3 ESCO Capabilities and Skills

ESCOs are diverse: There is no real prototypical ESCO. However, most ESCOs typically have the following capabilities and skills: project development, engineering and design, feasibility analysis, energy analysis, general contracting, the ability to finance directly or arrange third-party financing, project and construction management, purchase and installation of equipment, risk management, monitoring and verification (M&V) of savings, training, operations and maintenance services for the installed equipment, and administrative services. Most of these capabilities reside among the staff of the company (in-house), but some of these skills are contracted out (e.g., installation of equipment). In addition, ESCOs may provide additional services, such as cogeneration and alternative power production.

Some additional comments on these activities are warranted. First, ESCOs use working capital for general corporate purposes such as marketing. They use project financing to construct a project; they also reimburse themselves through project financing for the amount of working capital expended to develop a particular project. All or most of the activities that ESCOs conduct for a project are bundled into that project's cost, which is usually financed entirely with debt and lease financing (i.e., no equity contribution is required to be made by the customer since payments come only from realized savings); project financing using ESCO or third-party equity contributions is rare. In sum, ESCOs attempt to remove the first-cost disincentive and technical uncertainty by

providing outside sources of capital and guaranteeing the performance of the equipment. The first-cost disincentive is a real barrier to investments in energy efficiency, whereas the perception of technical uncertainty is a more formidable barrier than the actual performance of energy-saving measures. The cost of the ESCO service is typically paid for from the stream of energy cost savings resulting from the project.

Second, because ESCO projects are performance based, ESCOs must measure and verify the energy savings, and these savings must be monitored over the project's life to make sure the performance-based savings are accurate and persist. M&V is typically conducted by periodically comparing a customer's energy bills with an established pre-project baseline and/or through energy metering.

Third, maintenance is usually the final component of most performance-based energy-efficiency projects. The maintenance is for all (or some portion) of the new equipment over the life of the contract. The cost of this ongoing maintenance may be folded into the overall cost of the project. Thus, throughout the life of the performance contract, the customer receives not only the benefit of reduced energy costs but also the benefit of reduced maintenance costs. The maintenance component is also important since it enables the ESCO to ensure that the equipment is maintained in a way that preserves optimal performance. As an additional service on most contracts, the ESCO also provides any specialized training needed so that the customer's maintenance staff is equipped to take over at the end of the performance contract period (the period may be 5, 10, or 15 years, and sometimes longer).

Fourth, each ESCO entering into an energy-savings performance contract tries to educate its customer on energy use and seeks to bring that customer into an energy-efficiency partnership whose purpose is to achieve the maximum energy savings available from the customer's facility. This is not only good for the customer but also beneficial for the ESCO as it seeks to maintain a long-term contract with the customer and obtain additional business.

In sum, although none of the discrete skills that an ESCO employs are particularly unique, the added value an ESCO brings is its ability to integrate a wide variety of skills and apply them efficiently to projects ranging from several hundred thousand dollars to tens of millions of dollars. Thus, ESCOs view themselves as project developers and integrators.

1.4 ESCO and Customer Responsibilities in Performance Contracting

In an energy performance contract, project responsibilities are divided between the ESCO and the customer. Once a customer has been contacted, an ESCO has the following responsibilities:

- Conducts walk-through energy audit and preliminary engineering study.
- Prepares engineering proposal and project development agreement based on audit results.
- Presents proposal and agreement to customer for comments and approval.
- Conducts an investment-grade audit.
- Finances purchase of energy-saving and measurement equipment (unless financed by customer or by third-party bank or leasing company).
- Installs equipment.
- Maintains equipment over life of contract (if maintenance provided).
- Delivers agreed level of energy savings.
- Monitors, measures, and verifies energy savings.

Customer responsibilities include the following:

- Reviews and approves engineering proposal (if proposal is not approved, customer pays ESCO a fee).
- Operates host facility as specified.
- Compensates ESCO as appropriate to type of financing used.
- Pays value of share of energy savings (if ESCO financing secured by shared savings).
- Permits ESCO to maintain and measure savings.
- Pays for services (if third-party financing).
- Maintains equipment over life of contract (if maintenance not provided).

1.5 Financing of ESCO Projects

Most ESCOs provide financing for projects from their own funds (working capital); however, they generally are only able to finance the initial stages of a project. Even though the ESCO eventually has no equity investment in the project, the ESCO does provide its equity to fund the initial risk equity by investing its working capital to develop and finance a paid-from-savings project for the customer. Thus, ESCOs seeking to use performance contracting must develop or arrange sources of debt and equity to finance their projects. More often, the ESCO's role is to arrange

financing for its customers with leasing companies, institutional investors, and commercial banks.

The customer usually enters into separate agreements for energy services and for financing. Typically, the ESCO may arrange financing but is not a party to the finance agreement. The end-user credit risk is assumed by the financier, not the ESCO. The ESCO and the end user enter into a turnkey contract or energy services agreement whereby the ESCO provides engineering, equipment installation, and other services such as operations, maintenance, and savings verification. If the savings do not materialize as projected, the end user has recourse against the ESCO.

Many ESCO projects are financed using nonrecourse or limited-recourse financing. Since no capital is required up front and financiers are repaid through energy savings, ESCOs and customers are allowed to develop projects that are much larger than their net worth. Although nonrecourse financing has important advantages (e.g., a positive cash flow immediately for the customer), it also introduces significant business risks into the financing and higher project costs.

The two types of project financing commonly used by ESCOs in the United States are guaranteed savings and shared savings. In a guaranteed savings agreement, the ESCO guarantees to the customer that the project's realized savings will equal (or exceed) the payments made (or financing costs absorbed) by the customer over the term of financing. In guaranteed savings contracts, ESCOs typically guarantee approximately 80–85% of the savings they expect to get out of a project. In these projects, the customer assumes the obligation to repay the project costs to a third-party financier (usually introduced by the ESCO), which is very often a commercial bank or leasing company. If the customer finances the project itself, the customer repays itself by saving energy costs.

If the savings realized fall short of the payments made by the customer due to a failure of the project to perform as guaranteed, the ESCO pays the customer the difference. If, however, actual savings exceed the payments, excess savings are normally returned to the customer. In some cases, the customer and ESCO negotiate the sharing of savings in excess of the amount guaranteed.

In shared savings projects, the ESCO's payments are typically structured as a percentage of the energy savings actually realized by the end user over the length of the contract. The percentage is predetermined, but the percentage of savings allocated to each party can vary over the period of the contract. The ESCO must ensure that the proceeds it receives will cover the costs it has incurred in implementing the project.

In exchange for the ESCO providing project financing and for the ESCO's assumption of performance and credit risk, the customer agrees for a fixed term to pay the ESCO the value of a set percentage of those savings. The portion of savings paid to the ESCO that is attributed to debt service is always higher for shared savings than for guaranteed savings projects, reflecting the ESCO's significantly greater risk and expense. The ESCO uses its payments from the customer to repay debt associated with the project, conduct equipment maintenance, measure and monitor savings, and earn a return. As with guaranteed savings projects, the ESCO measures energy savings throughout the term of the project agreement.

2. ORIGINS AND GROWTH OF THE U.S. ESCO INDUSTRY

2.1 ESCO Driving Forces

The three key driving forces affecting the ESCO industry in the United States during the past 15 years have been energy prices, tax policies, and utility demand-side management (DSM) bidding programs. The U.S. ESCO industry began in the late 1970s and early 1980s, a period during which energy prices were dramatically rising in response to the 1973 oil embargo and the Iranian revolution in 1979, which presented the opportunity for fledgling ESCOs to make a business out of reducing customers' growing energy costs. For example, when energy prices were high (1980–1983), the annual growth rate in ESCO investments during this period was estimated to be 35%; the rising electricity prices from 1989 to 1994 led to another period of increased growth rate (25%) in ESCO investments.

During its formative years, changes in tax policy were also critical in shaping the ESCO industry. For example, the energy tax credit (available for energy-efficiency investments from 1980 to 1983) and the investment tax credit (for general capital investment, including efficiency improvements, from 1980 to 1986) affected the rate of ESCO project investment between 1980 and 1986. After the energy tax credits ended in 1983, ESCO investments decreased by 10% in 1984.

Finally, utility DSM bidding programs significantly impacted the ESCO industry in its early years. In a DSM bidding program, the utility enters into a

long-term conservation purchase agreement with the provider (usually an ESCO) to reduce demand or provide firm energy savings during specified periods. The utility pays for these savings on a unit basis, often simply per kilowatt-hour, much as it would pay for private power under a purchase agreement. The first utility DSM bidding program began in late 1987, initiating a period of substantial utility contributions to the pool of investment capital underwriting performance-based efficiency projects. Most observers believe, however, that the influence of these utility programs on the U.S. ESCO industry peaked in 1994: Some utilities froze or canceled DSM programs in the atmosphere of uncertainty that commenced with the California restructuring proposal in April 1994.

2.2 Types of ESCOs

Four main groups of ESCOs dominate the U.S. ESCO industry: original ESCOs, engineer-based ESCOs, manufacturer-based ESCOs, and utility-based ESCOs. Whatever their origins, all ESCOs are characterized by their project development capabilities and their assumption of performance risk for their projects.

The original ESCOs entering the marketplace were start-up ventures established specifically to pursue energy performance contracting. The engineer-based ESCOs grew out of businesses providing engineering services for a fee. Most of these consulting engineers specialized in performing detailed energy audits of clients' buildings, proposing designs for new energy systems, and suggesting improvements to operating practices. Some engineering firms fundamentally altered their business strategy and changed from fee-based energy services consulting to project development. These firms were willing and able to back their designs with performance guarantees and to secure financing for projects with the savings these projects were guaranteed to produce.

Manufacturer-based ESCOs are manufacturers of building control systems designed to regulate energy-using equipment in buildings and facilities. The earliest firms offered control systems specifically designed to reduce their customers' energy bills. Like the consulting engineers, these manufacturers extended their traditional business activity (e.g., controls) to assume the risks associated with project development. In the early 1980s, these companies established energy service divisions to develop performance-based projects centered around their control systems. These companies further evolved by developing comprehensive projects that include the full range of available energy-efficiency measures.

Utility-based ESCOs include those ESCOs formed in response to the growth of utility DSM programs, either by the utilities or by private investors. Numerous utilities have launched DSM programs that complement ESCO projects: For example, utility customers have used rebate programs to improve the cost-effectiveness and comprehensiveness of their performance-based projects. Similarly, some utilities have offered DSM bidding programs in which ESCOs have been encouraged to participate. Nevertheless, the utility-created ESCO has historically been rare. Utility entry into the ESCO market or acquisition of existing ESCOs have accelerated significantly as utilities seek to position themselves to compete effectively in a retail energy services environment.

2.3 The Maturation and Growth of the ESCO Industry

The U.S. ESCO industry has matured in the past decade. The more positive image of the industry and its resultant growth stem from a combination of factors, including (i) the trend toward guaranteed energy savings, (ii) the development of standardized monitoring and verification protocols, (iii) the involvement of the National ESCO Industry Association (NAESCO) in accreditation and M&V protocols, (iv) DSM bidding programs, (v) the facilitation of energy performance contracting in the federal government, and (vi) improvements in performance and reductions in costs of energy-efficiency measures.

There are no firm data on the ESCO industry's size in the United States, and traditional financial measures are difficult to apply in an industry composed primarily of privately held companies and large public firms that do not report the financial results of their efficiency divisions separately. Nevertheless, there are more than 60 national and regional ESCOs actively operating in the United States. Approximately 12 companies account for 75% of the industry revenues. ESCOs typically develop projects in the $600,000 to $2 million range, and they install between $800 million and $1 billion worth of energy-efficient equipment (including labor and profit) each year. Since 1990, the installed cost of all projects implemented by ESCOs in the United States is $6–7.2 billion. During the late 1990s, the ESCO industry grew by approximately 25% per year, mainly driven by rising electricity prices during

from 1984 to 1994. In 2002, ESCO industry revenues for energy-efficiency-related services in the United States ranged from $1.8–2.1 billion.

2.4 ESCO Markets and Marketing

ESCOs have established themselves in well-defined niche markets using either geographic or industry-specific market segmentation strategies. For example, ESCOs that have been selected in DSM bidding programs naturally target certain types of customers (e.g., hospitals and small retail) in specific utility service territories. ESCOs have also tended to focus on regions in which retail electricity prices are high in order to maximize differences between project cost and benefits to customers from energy-efficiency investments. Other ESCOs, particularly those affiliated with the large controls and equipment companies, utilize a decentralized and extensive branch sales force that targets certain industries or sectors (e.g., schools and state and local governments).

The focus of most ESCOs has been on medium to large commercial and institutional customers: Local and state government, schools, and universities account for approximately 65–75% of overall ESCO activity. ESCOs have also achieved success among other groups of commercial-sector customers (e.g., owner-occupied office buildings, shopping malls, hotels, and a few national franchises). The federal government, for which military projects have huge energy bills, is also targeted by many ESCOs.

Industrial customers have hosted fewer performance-based efficiency projects, but their share of projects has increased slightly over time as energy services are becoming integrated with other services. In the industrial sector, ESCOs have attempted to differentiate themselves through specialized expertise in certain technologies (e.g., adjustable-speed drives and controls) or processes (e.g., pulp/paper and automotive).

Because the typical ESCO project costs more than $350,000, small commercial and industrial companies and residential customers are generally not served by ESCOs. Some ESCOs do work in certain niche markets (e.g., large multifamily projects and water and wastewater facilities), but these are rare.

The so-called MUSH institutional markets (municipal governments, universities, schools, and hospitals) have been the focus of ESCO marketing because they tend to be very capital constrained; have a longer investment horizon; are faced with an aging infrastructure and equipment in need of modernization; and often have limited technical expertise to develop, coordinate, and manage a comprehensive energy-efficiency project. Furthermore, ESCOs have been able to arrange relatively attractive financing terms with the MUSH markets because financial institutions have regarded these customers as relatively good credit risks (i.e., they are unlikely to go out of business or relocate).

2.5 Energy Measures in ESCO Projects

In 1980, approximately 66% of ESCO investment was in electrical efficiency measures, and the rest was in thermal energy measures. From 1980 to 1987, ESCOs gradually invested in more thermal energy measures and fewer electricity measures, until the investment ratio in 1987 was 55% of investments in electricity measures and 45% of investments in thermal energy measures. Beginning in 1988, when utility DSM bidding programs were predominantly sponsored by electric utilities, investments in electricity measures increased, resulting in an ESCO investment ratio of 75% electrical versus 25% thermal. Recently, thermal energy measure investments have increased so that the relative shares in 1997 were approximately 65% electrical versus 35% thermal.

A number of technologies have come to form the core of the typical performance-based energy-efficiency project, including high-efficiency lighting, high-efficiency HVAC equipment, efficient motors and variable-speed drives, and centralized energy management systems. Along with the core technologies are a full array of weatherization services where appropriate and, sometimes, more innovative applications, such as integrated cogeneration or renewable energy technologies.

2.6 Measurement and Verification and Protocols for Measurement and Verification

All ESCOs measure and verify the energy saved by their projects over the projects' lives—as demanded by the customer and as the essence of energy performance contracting. The purpose of monitoring energy savings over time is to ensure that those savings persist and to identify immediately any anomalies in consumption patterns that may occur. It also serves to ensure the quality and effectiveness of ongoing maintenance, entailed in most ESCO projects.

The development of standardized procedures for the measurement and verification of savings has helped both end users and the financial community to understand this key dimension of performance contracting. ESCOs have led the effort to verify, rather than estimate, energy savings, particularly when public and utility ratepayer funds are paying for them.

U.S. ESCOs have adopted the U.S. Department of Energy's (DOE) International Performance Measurement and Verification Protocol (IPMVP) as the industry standard approach to measurement and verification. States ranging from Florida to New York require the use of the IPMVP for state-level energy-efficiency retrofits. The U.S. federal government, through the Department of Energy's Federal Energy Management Program, uses the IPMVP approach for energy retrofits in federal buildings.

2.7 NAESCO

NAESCO was established in 1983 to bring credibility to the ESCO industry. Its members include independent performance contracting ESCOs; ESCOs affiliated with electric and natural gas utilities; energy-efficiency equipment suppliers, manufacturers, and other energy service providers; and a "miscellaneous" group (e.g., consulting firms, financial companies, and public-sector members). The primary activities of NAESCO include conferences, regulatory intervention (i.e., lobbying), accreditation, and publications.

NAESCO has a model energy performance contract that has been in use for 10–15 years and that forms the basis for most energy performance contracts today. NAESCO also serves an important policing service, ensuring that ESCOs are doing business in a fair and equitable fashion. The NAESCO board holds its members to a high standard of performance, as reflected in the accreditation process. To receive the accreditation, an ESCO goes through a rigorous review of credentials, references, technical capabilities, financial capabilities, project history, and interviews of former and existing clients. Certification must be renewed every year.

2.8 Utility Programs and ESCOs

Utility DSM bidding programs have played a critical role in the development of the ESCO industry. Although not all ESCOs have participated in utility DSM bidding programs and some ESCO participants in these programs have negative views of their experience, most observers of the ESCO industry agree that these programs have helped to promote the ESCO industry.

2.9 Energy Performance Contracting in the Federal Government

In the past 25 years, both federal and state governments have adopted legislation for improving energy efficiency. Although most of this legislation has had indirect impacts on ESCOs (e.g., the promotion of energy efficiency), the real impact has been on prompting governments as customers to seek assistance from ESCOs. Governmental facilities are prime candidates for ESCO projects: These facilities tend to use energy inefficiently, the owners of the buildings have constrained budgets, and there are many buildings.

ESCOs can contract directly with the government, mainly through a vehicle called an energy savings performance contract (ESPC). An ESPC can be a type of shared savings contract, with no government capital required up front. ESCOs can finance ESPC with their own internal funds or with third-party financing. Under an ESPC, an ESCO typically provides the government with design, installation, and ongoing maintenance services as well as the capital needed to finance efficiency improvements. Payments are made to the ESCO based on a share of savings that resulted from the energy-savings measures implemented (i.e., a shared savings contract).

The Federal Energy Management Program (FEMP) of the U.S. DOE developed the broad-area FEMP Energy Saver Performance Contract (Super ESPC). The first broad-area contract, covering eight states in DOE's western region, was awarded in 1997. Under these contracts, federal agencies award delivery orders from existing contracts and reduce the lead time and resources to award individual contracts. Performance-based energy services are available to federal agencies with government-owned facilities within a region. These contracts involve the competitive selection of a small number of contractors (i.e., ESCOs) that are allowed to conduct negotiations with individual facilities for the awarding of delivery orders under the contracts. The selected contractors are able to add work to their contracts for a limited time without the need for additional extensive, time-consuming competition and evaluation.

3. FUTURE PROSPECTS FOR THE U.S. ESCO INDUSTRY

3.1 Opportunities and Challenges in a More Competitive Utility Environment

The future prospects for ESCOs and other energy service providers will be affected by both the length of the transition period to a more competitive electricity industry and the ultimate organization and institutional structure of bulk power and retail service markets. The issues surrounding electricity industry restructuring are enormously complex and multifaceted. The pace of industry restructuring is likely to vary state by state given regional differences in electricity prices and resource endowments and the influence of state regulation. Because the pace and ultimate outcome of industry restructuring cannot be determined, ESCOs and other energy service providers face a retail market environment with significant uncertainties, many of which are regulatory (rather than market) driven.

Many observers believe that the restructuring of the utility industry will lead to lower power prices, resulting in a reduction in energy-efficiency programs and projects (e.g., energy-efficiency projects will be less attractive and paybacks will be longer if energy is sold at 5 rather than 9¢/kWh). Short-term impacts have already been felt: (i) Energy is receiving the attention of top management in businesses as well as utilities, (ii) gas and electricity savings due to lower prices are seen as more important to end users than energy-efficiency savings (i.e., low-cost energy providers are expected to prevail), (iii) energy is primarily seen as a commodity (rather than as a service), (iv) more emphasis is being placed on short-term contracts, and (v) customers are requiring shorter paybacks and shorter returns on projects. The end result is that customers will be less motivated to implement energy-efficiency projects.

On the other hand, despite the expectation of lower prices, there is a great opportunity for energy efficiency and new types of energy-efficiency services. In a competitive marketplace, as price differences among power suppliers narrow, value-added products and services (such as energy efficiency) will be offered to customers by various ESCOs and other types of energy service providers. In addition, state adoption of a system benefits charge will encourage and fund energy-efficiency activities during the transition to a competitive electric industry.

In summary, in a restructured electricity industry, it is likely that support for energy efficiency will continue, although most likely on a diminished basis. For ESCOs that have historically targeted larger institutional and C&I customers and that have depended on utility DSM funding, ratepayer funding for energy efficiency in the form of financial incentives (e.g., rebates) may be unavailable or available only for a short period (e.g., 2–5 years).

3.2 New Customer Needs

Customers have an array of needs that ESCOs will be asked to address. Customers are also quickly realizing that they will have more options and choice in a restructured electricity industry and will demand more products and services. Furthermore, customers will want changes in the way ESCOs do business with them, such as more flexible contracts, less risk, more warranties, simpler and clearer agreements, more customer control and involvement in projects, more convenience, and bundling or unbundling of products and services.

3.3 New ESCO Products and Services

ESCOs have the potential to interact with customers with more creativity, and it is likely that ESCOs will offer packages of comprehensive energy services, different fuels, varieties of pricing plans, and other creative ideas (including energy efficiency) as the market develops and grows. Occasionally, ESCOs will need to unbundle products and services for clarity and competitiveness, whereas at other times they will need to bundle products and services for convenience. Some ESCOs may manage a customer's fuel and energy needs through bill consolidation, analysis, and payment. The more innovative ESCOs may also be asked to provide nontraditional, performance-based customer service, such as providing "total comfort" or lighting based on $/ft^2$ or $/load.

Hence, ESCOs may find more opportunities in providing assistance in other areas besides utility-related issues, including facilities management and operations, capital equipment budgets, environmental concerns, and compliance with government regulations. For example, some ESCOs are considering guaranteeing environmental compliance as well as energy savings when they change a process to improve the environment (e.g., indoor air quality). They will be responsible for any mistakes (e.g., if the facility does not comply with environmental regulations or if savings do not occur), and they will fix the mistakes.

In sum, today's ESCO may become tomorrow's super ESCO—a fully integrated (full-service) energy

services company that brokers power and offers energy efficiency and other energy services. The ESCOs that respond to these challenges may emerge stronger than before and ahead of their new competitors as they provide "energy services" in its broadest sense.

3.4 Changes in ESCO Practices

In addition to providing new services, ESCOs will need to change their business practices to remain competitive. Many of them will form partnerships, joint ventures, mergers, and strategic alliances (both regionally and nationally). All of them will take more risks in providing new services, developing new alliances, being entrepreneurial and agile developers, energy brokering and marketing, and integrating energy efficiency with power supply and communication services. More ESCOs will be asked by customers to act as problem solvers to address multiple and complex customer demands and to identify resource efficiency opportunities. Accordingly, ESCOs will be looked upon as technology integrators, resource managers, and networkers. Finally, ESCOs are expected to continue to target large (especially institutional) customers and wholesale markets (federal government) that need engineering and financial assistance. However, they will also be aggregating smaller customers (small C&I and residential) to strategically position themselves at the forefront of the ESCO industry.

3.5 New ESCO Competitors (or Partners?)

The restructuring of the electric and natural gas industries will change the nature of competition and competitors in the energy-efficiency performance contracting market. In a more competitive electricity industry, the competitors to ESCOs will likely include power marketers, utilities, utility affiliates, financial institutions, equipment suppliers, property managers, cable companies, telecommunication companies, building control companies, high-technology companies, independent power producers, and energy traders.

ESCOs will need to determine whether they want to compete with these entities or form partnerships or joint ventures. Most non-comprehensive ESCOs will continue to seek to partner with other firms to develop business and to implement large-scale projects. Full-service providers will also be expected to partner with other firms to compete for customers by offering a range of potential energy services, making it more difficult for specialized or small energy providers to develop their own work independently. Partnering or consolidation of full-service providers with utilities or large, well-capitalized firms can be expected to increase the level of competition and the effectiveness of competition for customers.

As they prepare for competition, many utilities are using the regulated distribution business unit as an incubator to test various customer and energy services, whereas others have located these activities in unregulated retail service companies. Increasingly, the markets sought and the services offered by utility distribution companies and ESCOs are becoming indistinguishable. This presents existing ESCOs with both a competitive challenge and a partnering opportunity, from ad hoc marketing agreements to formal joint ventures and acquisitions. In addition to retention of electricity and/or gas commodity sales, these utility/ESCO partnerships can sell comfort, light, power, reliability, and end-use commodities (e.g., refrigeration, steam, chilled water, and compressed air). They can also offer a variety of building-related services that enhance the initial energy-efficiency services, such as facilities management, operations and maintenance services, and energy management/control.

The benefits to ESCOs of these alliances are primarily reductions in the transaction costs of lead generation, qualification, and closing. The benefits to utilities are defensive (e.g., customer retention), offensive (e.g., value added to wholesale and eventually retail offers), and potential revenue enhancement (through technology applications, fuel switching, customer growth, etc.).

4. INTERNATIONAL ESCO ACTIVITIES

The ESCO industry has been developing in countries besides the United States, particularly since the mid- to late 1990s. In most cases, the number of ESCOs are small (less than 10) and revenue from the projects is generally less than $10 million. The impediments to the successful development of an ESCO industry in other countries are similar to those encountered in the United States. In particular, the following appear to be formidable:

- The concept of ESCOs and energy performance contracting is new to nearly all of the parties that need to be familiar with it (i.e., there is a lack of

awareness): financiers, attorneys, contractors, insurers, utilities, government agencies, and customers.
- Government policies regarding energy performance contracting are uncertain.
- Legal and contractual issues specific to performance contracting are unclear.
- Economic conditions are adverse (e.g., stagnant economic development) for investments in energy efficiency in many countries.
- There is a lack of capital (equity financing or equity investments) for establishing ESCOs in many countries.

Nevertheless, several countries have developed an ESCO industry and have started to promote the development of a vibrant ESCO industry. Several countries have established associations of energy service companies (e.g., China, Egypt, Japan, Korea, and the Ukraine). Revenue from the ESCO industry in a few countries exceeds $50 million (e.g., Brazil, Canada, China, and Japan). In 2001, ESCO industry revenues for energy-efficiency-related services outside the United States ranged from $560–620 million.

5. CONCLUSIONS

The ESCO industry is expected to grow significantly in the United States and in selected countries in the near future. There will be numerous new entrants in the ESCO market, including supply-side bidders (e.g., independent power producers) and utility subsidiaries. In the United States, ESCOs with technical strengths and deep pockets (or access to sizable funding) will survive; small ESCOs that specialize will disappear in a period of consolidation, some of which may be acquired by utilities. In the United States, the consolidation of ESCOs and the trend for utilities to acquire or develop full-service ESCOs to compete for other utilities' customers (particularly large customers) have become more prominent during the past few years. These are expected to also occur overseas, where the energy industry is being restructured.

Glossary

air cooling The process by which radiator-type coils containing steam transfer heat to air passing over the coils; water is added to the cooling system only for periodic maintenance and cleaning (~200,000 gallons/day).

closed-cycle cooling The process by which cooling water cycles through a generating facility, absorbs heat from steam passing through a condenser, and then evaporates the heat to the atmosphere through cooling towers before it recycles through the facility; water is added to the cooling system to replace that lost by evaporation (~8 million gallons/day at a large facility).

condenser An apparatus used to convert steam coming from electricity-generating turbines back to water before the water is discharged from or recycled through a facility.

cooling water intake system (CWIS) The combination of intake cribs, screens, pressurized washes, debris and fish return sluices, and circulating water pumps used to withdraw cooling water.

delta T The temperature change of water passing through a cooling water system (delta T = discharge temperature − intake temperature).

diurnal cycle A response to daily changes in light intensity (e.g., the daily movement of aquatic organisms up and down in the water).

entrainment The uptake of small organisms or life stages during the process of water withdrawal.

fish return system An apparatus consisting of a pressurized wash that removes impinged fish from traveling screens and a flume that conveys the fish back to the water body from which they were removed.

impingement The entrapment of organisms on intake screens used to prevent debris from entering cooling water intake structures.

once-through cooling The process of pumping water across a heat exchanger to condense steam from electricity-generating turbines; the heat-laden water is then discharged back to the surface water source, and the condensed steam is recycled to the facility's boilers (millions to billions of gallons of water/day are required).

traveling screen A mechanical device used to exclude organisms and debris from entering pump systems and condensers; screens are hung in front of a cooling water intake, partially above the water level, and are designed to rotate vertically to allow impinged organisms and debris to be removed when sprayed with pressurized wash water.

young-of-the-year A juvenile fish observed in the same calendar year as its hatching.

Many electricity-generating facilities withdraw cooling water from surface waters to absorb and transport waste heat. Incidental to the withdrawal of water is the concurrent uptake or entrapment of the organisms that live in those waters. Entrainment refers to the uptake of small organisms or life stages (e.g., eggs, larvae) during the process of water withdrawal, whereas impingement is the entrapment of larger organisms on screens used to prevent debris from entering cooling water intake structures.

covering the intake (i.e., smaller organisms become entrained rather than impinged). The typical screen mesh size of a cooling water intake structures (CWIS) is 0.375 inch; therefore, entrained organisms are usually smaller than this, whereas impinged organisms are usually larger than 0.375 inch.

1.1 Factors Affecting Entrainment and Impingement Rates

Entrainment and impingement rates generally increase with increasing intake volumes and velocities unless the CWIS is equipped with a barrier to prevent organisms from approaching the CWIS. Entrainment rates are several orders of magnitude higher than impingement rates because smaller organisms and younger life stages (e.g., eggs, some larvae) are more abundant and have less capacity to overcome intake velocities compared with larger organisms. Ultimately, entrainment and impingement rates are influenced by a combination of the facility's intake flow, the location of the CWIS relative to the water body's physical characteristics, and the temporal and spatial distribution of organisms in the water body relative to intake rates.

Although entrainment and impingement can occur with any type of water withdrawal, the potential for the largest effects is at electricity-generating facilities that use once-through cooling because they typically withdraw water in significantly larger volumes than do other industries. Other cooling technologies (e.g., closed-cycle cooling, air cooling) require significantly less water; therefore, electricity-generating facilities using these technologies have less potential for impacts to resident and migrating aquatic species.

In addition to intake flow rates, the siting of power plants and their CWIS affects the incidence of entrainment and impingement (Fig. 1). Most CWIS are located in nearshore areas of lakes, rivers, estuaries, and marine coasts. Whether in fresh or salt water, these areas have great ecological importance. Their shallow waters, submerged and emergent vegetation, and sheltered inlets provide feeding, resting, spawning, and nursery habitat for a wide variety of vertebrate and invertebrate species. In addition, when rock structures such as jetties are used to protect cooling water intakes, fish with habitat preferences for these structures (e.g., cunner, tautog) experience high rates of entrainment. CWIS have also been known to impinge waterfowl, seals, turtles, and crustaceans. Not surprisingly, when power plants that use once-through cooling withdraw their water directly from the shores of these productive waters, entrainment and impingement rates can be very high. On the other hand, offshore waters are typically cooler, provide less vegetation for shelter, and may be lower in dissolved oxygen, especially in deep, slow-moving freshwater systems. Although these offshore waters also harbor many species, most of them seek shallow nearshore areas to spawn. Consequently, offshore intakes may have lower entrainment and impingement rates.

Annual schedules of cooling water withdrawal also influence rates of entrainment. Egg and larvae

The trash rack and rotating screens keep large objects (including fish) from entering the cooling water system. abundances are greatest in the water column during the spring when most organisms spawn. Consequently, facilities that withdraw large quantities of cooling water at this time are likely to have high rates of entrainment during the spring. Some facility managers have scheduled their annual maintenance outages (when cooling water withdrawal is minimal) in March or April to minimize entrainment during this biologically active period.

1.2 Importance of Measuring Entrainment and Impingement

Quantifying entrainment and impingement rates is an important step in understanding the losses to biological populations that can occur due to cooling water withdrawal. Large power plants can entrain and impinge a significant proportion of young organisms or life stages that would otherwise recruit to local biological populations. Although predators, meteorological events, fishing, and disease all contribute to mortality rates, the additional population reduction caused by power plants may contribute to the destabilization of natural oscillations in population abundances, potentially resulting in significant long-term reductions. Because entrainment and impingement rates are controllable variables, knowing the magnitude of losses due to power plants can lead to a variety of management decisions aimed at minimizing losses and maintaining biological populations.

In the United States, the Environmental Protection Agency (EPA) and state regulatory bodies are charged with protecting biological resources. The Federal Water Pollution Control Act of 1977 and its amendments (known collectively as the Clean Water Act) require that the location, design, construction, and capacity of a CWIS reflect the best technology available for minimizing adverse environmental impact. Because the law does not clearly define the term "adverse environmental impact," vigorous and sometimes contentious debates have emerged as to the impact of cooling water withdrawal on local populations of aquatic organisms and how government agencies should regulate these impacts. The implementation of the Clean Water Act and other regulations may require facility owners to upgrade to withdrawal technologies with lower impacts (e.g., closed-cycle, air cooling). These technological upgrades or operational changes may cost tens or hundreds of millions of dollars. In some cases, implementation costs may prevent the construction of new intakes altogether. Under Section 316(b) of the Clean Water Act, a company faced with attaining regulatory requirements can assert that the investment is "wholly disproportionate" to the environmental benefits to be gained from the modifications. Furthermore, some industry representatives contend that significant upgrades will affect the availability and price of energy across regional grid structures. It is the responsibility of the EPA to evaluate the balance of information and to determine whether technological upgrades are warranted. Clearly, managing entrainment and impingement impacts has important consequences for natural resources as well as for the energy industry.

2. COLLECTING ENTRAINMENT AND IMPINGEMENT DATA

With such important economic and resource protection decisions dependent on entrainment and impingement values, quantifying these parameters reliably is critical. However, there is no standard methodology or procedure for collecting entrainment and impingement data. Methods for estimating entrainment and impingement are determined on a site-by-site basis by the characteristics of the facility's CWIS, the flow rate through the facility, the life history of the species at risk, the characteristics of the water body, the priorities of the regulatory community, and the costs of the various methodologies.

2.1 Entrainment Sampling

Because of the patchy distribution of larvae and eggs, achieving the sampling effort necessary to calculate a reliable estimate of abundances can be challenging. To quantify entrainment impacts, estimates of the number of larvae and eggs going through the plant must be compared with estimates of the number of larvae and eggs of each species in the source water body adjacent to the plant. These ratios will provide species-specific estimates of the cropping of biological populations by the power plant.

Entrainment rates are highly dependent on the spatial and temporal distribution of larvae and eggs. Water currents, diurnal cycles, time from hatching, and species type all can affect entrainment estimates by influencing densities of larvae and eggs adjacent to intakes. In addition, flow rate and CWIS configuration influence the proportion of larvae and eggs adjacent to the intake that are drawn into a facility's cooling system. For example, increasing flow rate usually increases entrainment rate; however, larvae may be

able to avoid becoming entrained by avoiding the part of the water column from which a plant withdraws its cooling water. Because of the multitude of influences on entrainment rates, data collections need to occur frequently enough so that they are representative of the various combinations of conditions present in the source water body. Moreover, interannual variability is often great enough to warrant replication across years as well as within years.

Early efforts to quantify the mortality of larvae within cooling water systems used conical nets suspended in both the intake structures and discharge plumes of electricity-generating facilities. (It should be noted that larval sampling techniques also capture floating eggs; thus, entrainment of eggs and larvae are often assessed simultaneously.) However, one of the problems with this method is that the survival of larvae is influenced by the velocity of water flowing through the net, with higher velocities leading to increased mortality. Higher velocities also increase the risk of extrusion through the net and increase the limitations of the net to catch larvae, resulting in an incomplete sample. Furthermore, discharge plumes often have much greater velocities than do intakes. As a consequence, larvae collected in discharges may have higher mortality due to the force of the discharge water trapping them in collection nets. In short, traditional net sampling can add another source of mortality when only the mortality caused by the cooling system is of interest.

To reduce sampling-related mortality, some researchers have used a flume-like sampling station, floated in front of the intake or discharge, onto which water can be pumped. Unlike net sampling, a larval table equalizes sampling stresses for both intake and discharge samples by withdrawing water at a constant rate in both areas. However, the pump used to bring larvae onto the sampling table can cause a significant amount of mortality to the larvae.

To avoid pump-related mortality, samples may be taken using a pump that is downstream of the sampling screen. In this way, water and entrained organisms are pulled rather than pushed onto the sampler and its screens; therefore, no organisms have to go through the pump system. Other sampling efforts have eliminated the pump altogether, using the velocity of water in the discharge to bring water into the floating sampling station. However, this method does not work in intake structures where the velocity of water is not great enough to force water onto the floating sampling station.

Although innovations in sampling techniques have produced methods that increase the reliability of larval mortality estimates, conical nets and pumps are still commonly used due to cost or design issues associated with sampling in intakes and discharges. For example, only one of the nine entrainment studies conducted for power plants along the coast of Massachusetts between 1994 and 2003 reported the use of a larval table, whereas all of the others used conical net sampling.

2.2 Impingement Sampling

Impingement is easier to measure than is entrainment because the presence or absence of larger organisms is more obvious and, therefore, easier to quantify. Impingement samples can be collected directly from traveling screens or from collection pens built into a fish return system. Often, impingement rates are assessed for only part of a 24-h period and long-term rates are extrapolated from the short-term assessment intervals. Impingement rates are usually reported as number of fish per year or number of fish per volume of flow through the power plant.

The most frequently impinged fish are usually young-of-the-year fish, although older juveniles and adults are also impinged. Schooling juvenile fish (e.g., menhaden) often follow shoreline margins and can become impinged in large numbers, especially during the late summer and fall. Impingement rates for juvenile schooling fish can exceed 1000 fish per hour and tens of thousands weekly.

3. SOURCES OF MORTALITY TO ENTRAINED AND IMPINGED ORGANISMS

Entrained and impinged organisms can incur several types of mortality associated with a CWIS. The risks of mortality arise due to physical, chemical, or thermal stresses within the cooling water system. In addition, there is the possibility of latent mortality after an organism has been discharged from the cooling water system.

3.1 Physical Stress

Physical stresses result in direct damage to the tissues of entrained organisms as they pass through the pumps and pipes of a cooling system. Within the system, they are subject to abrasion, compression, and shear stress. Physical impacts to impinged organisms may include suffocation while pressed

against the intake screens and tissue damage from pressurized screen washes and the velocity of the return sluice. Some sluices have been known to drop fish several vertical feet into the receiving water, whereas others have sent fish to rocky areas that are dry at low water. Such poorly designed sluices may stun or injure fish, leaving them more susceptible to predation. For example, birds have been known to frequent the outfalls of fish return systems, plucking the returned fish from the water. Furthermore, some sluices deliver fish directly to the discharge channel, where they experience turbulence as well as elevated temperatures that may contribute to mortality. In addition, sluices that return fish too close to intake structures may contribute to reimpingement, especially if the fish are stunned by the physical stress of impingement, high-pressure spray, and a turbulent return sluice.

3.2 Chemical Stress

Chemical mortality results from deleterious physiological effects induced by chemicals added to the cooling water as it flows through the facility. Biocides (typically chlorine) are used to keep the cooling water system free of fouling organisms such as algae, barnacles, and mussels. Biocides injected directly into cooling water will kill entrained larvae and eggs. Ultimately, these biocides are discharged to the receiving water body and, therefore, may also affect the organisms in the vicinity of the outfall. If biocides are used to keep traveling screens free of fouling organisms, impinged fish can also be dosed with toxic chemicals.

3.3 Thermal Stress

Thermal stress to entrained organisms occurs as the water that surrounds them absorbs heat from condenser tubes. Excessive temperatures cause the breakdown of proteins and can result in developmental problems or death. The delta T of a plant directly influences entrainment mortality. Minimizing delta T will increase the rate of survival because most organisms have the physiological ability to withstand small increases in temperature. However, for all organisms, there is a temperature threshold above which acclimation to higher temperatures will not occur and mortality will follow. The duration of exposure to elevated temperatures also affects survival. Therefore, the risk of mortality to organisms that have survived being entrained will increase as they spend increasing amounts of time in a heated discharge or if they are reentrained into the power plant.

Increased temperatures may affect impinged organisms if a facility is designed to clean its screens by backflushing, which involves using heated water to dislodge debris and fouling organisms attached to the intake screens. This method can also physically damage impinged fish while subjecting them to excessive temperatures. In addition, impinged organisms can be thermally stressed if the return sluice deposits them in the plant's thermal effluent.

3.4 Latent Mortality

The combination of physical, chemical, and thermal stresses experienced during entrainment or impingement can make organisms more susceptible to pathogens, infections, or predation after they are returned to the water body. The mortality associated with these combined effects is called latent mortality. Latent mortality is difficult to quantify because long-term effects might not manifest themselves during the time frames of most studies. However, some researchers have attempted to quantify latent mortality by holding recently entrained larvae and impinged fish in tanks and monitoring their survivorship. Still, in practice, most assessments conservatively assume 100% through-plant mortality in the interest of expediency and cost savings, obviating the need for a latent mortality estimate.

4. QUANTIFYING IMPACTS TO LOCAL POPULATIONS OF ORGANISMS

The simplest method of evaluating cooling water withdrawal effects is to estimate the annual absolute losses of all life stages of species entrained or impinged. The magnitude of the impact can then be assessed relative to management criteria or historical trends in species abundances. Beyond calculating absolute losses, there are a number of methods for quantifying power plant impacts due to entrainment and impingement. These include equivalent adult analysis, calculating production forgone, calculating indirect losses to predators due to mortality to forage species, calculating conditional mortality, comparing equivalent adults or production forgone to commercial landings, and modeling populations.

4.1 Entrainment Impact Assessments

The equivalent adult method of assessing entrainment and impingement effects provides managers with the number of individuals (eggs, larvae, or juveniles) that would have survived to reproductive age if they had incurred only those mortality pressures independent of the generating facility. Equivalent adult losses can be calculated for those species whose life stage-specific mortality rates are known. Typically, these values are known for only a select few commercially or recreationally important fish species.

A second means of calculating impacts is called the production forgone method. Production forgone is similar to calculating equivalent adults except that it is used to determine the biomass (measured in pounds or kilograms) that would have been produced if the entrained and impinged organisms had experienced sources of mortality only in the absence of the plant. Equivalent adult analysis is usually applied to species that are part of a commercial or recreational fishery, whereas production forgone is usually used to measure impacts to nonfished species.

Another impact assessment method takes into account the indirect losses caused by the mortality of species that are prey to species that are part of a managed fishery. This assessment occurs in three steps. First, production forgone is calculated for the prey species. Next, for each predator species in the fishery, production forgone of their prey is multiplied by a food conversion efficiency factor that accounts for the biomass of prey consumed by the predators that results in an increase in predator biomass. Finally, the loss of predator biomass due to entrainment of young life stages of their prey is calculated by apportioning the biomass of prey to individual predator species based on the specific proportions of each prey species in a predator's diet and the relative biomass of each predator in the area of interest. In effect, this method converts biomass of prey species to biomass of predator species that have known commercial or recreational value.

Yet another assessment method, and perhaps the most controversial because it is the most subjective, is to determine conditional mortality rates. Conditional mortality is the fractional reduction of a population of organisms due only to entrainment and impingement. To estimate conditional mortality, one must (1) define the boundaries of the local populations of organisms entrained and impinged, (2) estimate the abundance of organisms in these populations, and (3) compare entrainment and impingement data for individual species with population abundances adjacent to the intake. In the absence of genetic and behavioral information that could truly bound a population of interbreeding organisms, impact assessments rely on subjective semi-arbitrary boundaries defined by geographical features, hydrodynamics, and policy decisions by resource agencies. Increasing population boundaries, and thus a population's size, decreases the magnitude of impacts. Given that the magnitude of impacts can lead to expensive plant upgrades, spirited discussions can surround the definition of population boundaries.

A similar approach has been used to determine the percentage of larvae flowing past a plant that is entrained. In this assessment, the rate of larvae flowing through a plant (i.e., the density in the discharge multiplied by the plant's flow rate) is divided by the flux of larvae flowing past the intake structure (i.e., the density in the water body multiplied by the net current flow). This method provides an estimate of the plant's ability to affect the pool of larvae in its source water. The reliability of this estimate of impact is dependent on empirical data and accurate measurements of flow rate and larval density. In addition, because ocean currents and some rivers can flow in opposite directions depending on the tide, the opportunity for larvae to be entrained is dependent on how many times they flow back and forth in front of a CWIS.

Some impact assessments have compared entrainment and impingement losses with annual commercial landings of affected fish species. However, this estimate of impact can be misleading if the commercial landings data are from an area that is larger than the area of interest immediately adjacent to an intake structure. Another reason why commercial landings are not a good point of comparison is that they are influenced by fishing effort, management policies restricting effort, and the market price of various fish species. Because of the variability in these factors, commercial landings are not a reliable measure of species abundance.

After bounding the populations of interest and estimating current impacts, further analysis may involve predicting future impacts to populations using mathematical models. Models may be used to project how a population will respond to various operating or mitigation scenarios.

In models, the distribution of larvae and eggs is often represented as uniform, with their densities averaged across a section of water column. This simplification keeps model projections manageable while decreasing run time and financial costs.

However, in reality, the distribution of larvae and eggs is heterogeneous and the risk of higher density patches of organisms becoming entrained will vary over time. To take advantage of the simplicity of projection models and account for the real-world patchiness of eggs and larvae, cross-sectional averages of organism densities determined by models can be converted to more realistic densities by multiplying by a ratio called the withdrawal factor (W). W is the ratio of the density of entrained organisms in the intake structure to the density of entrainable organisms found in the adjacent water body.

Some models include a recirculation factor to account for the proportion of entrained organisms that reenter the CWIS because the discharge is close enough to the intake to reentrain discharge water. Recirculation can be determined through modeling or dye studies of the movement of the discharge plume. The amount of recirculation is site specific and may be as great as 25%. Incorporating recirculation of flow into a model tends to decrease estimates of impacts because a portion of the organisms in the cooling water is assumed to have already been killed by the plant's cooling system.

When the goal of an impact assessment is to quantify the specific sources of mortality to entrained organisms, also known as the entrainment mortality factor (f), the individual mortality rates due to the physical, chemical, or thermal stresses associated with passing through the cooling water system are estimated. Estimating f entails separating out mortality incurred through the sampling process (i.e., physical stresses due to pumps, nets, and handling time) from the mortality caused solely by the cooling water system. Because there are so many potential sources of mortality once eggs and larvae are in a cooling system, and because quantifying them reliably to the satisfaction of regulatory agencies can be an onerous and costly task, many impact assessments will conservatively estimate that 100% of all entrained eggs and larvae suffer mortality.

When the 100% entrainment mortality assumption is not used, through-plant mortality (f) is important to modeling operational procedures needed to reduce entrainment mortality because trade-offs exist between delta T and flow rate. When the flow of water passing through a cooling water system decreases, the relative amount of heat per volume of cooling water increases, thereby increasing delta T. Under certain operational scenarios, the potential increase in mortality to entrained larvae and eggs associated with an increased delta T can offset reductions in entrainment achieved by flow reductions. However, when through-plant mortality is assumed to be 100%, flow rate becomes the most important factor because delta T has no effect on impact assessment. A further consideration is that there is also a trade-off between flow and thermal output to the receiving waters. Increasing flow through the plant can decrease delta T and reduce thermal impacts within the cooling system and in the receiving water.

4.2 Impingement Impact Assessments

Impacts due to impingement are relatively easier to quantify than are entrainment impacts. Representative samples of impinged organisms can be collected directly from traveling screens by special sampling trays or can be sampled from the return sluiceway. Although fish are usually the most frequently collected organisms, crustaceans, turtles, birds, and seals can also be impinged. However, in practice, most impact assessments focus on the number of fish impinged. In the overall assessment of a plant's impact, losses due to impingement are added to equivalent adult, production forgone, and conditional mortality estimates.

5. REDUCING IMPACTS

The most effective way of reducing impacts caused by cooling water withdrawal is to avoid the use of cooling water altogether by initially designing or upgrading a facility to utilize air cooling. However, in many cases, this is cost-prohibitive. Alternatively, closed-cycle cooling costs significantly less than does air-cooling and requires substantially less water than do once-through cooling systems; therefore, it has lower entrainment and impingement impacts. When air cooling or closed-cycle cooling systems are not an option due to design, siting, or cost constraints, power plant owners can reduce entrainment and impingement impacts through low-impact siting of a new CWIS, operational changes, technological upgrades, and/or biological mitigation. The efficacy of each of these methods has been debated within the CWIS permitting process and has been shown to be dependent on the site-specific characteristics of an individual facility and the distribution of organisms around its intake structure(s). Finally, the implementation of new and existing regulations can potentially reduce entrainment and impingement impacts on a regional scale.

5.1 CWIS Siting

When the use of once-through cooling is the only option, one way of minimizing impacts is through the careful siting of new intake structures after consideration of the temporal and spatial distribution of organisms in the source water body. Identification and avoidance of spawning runs, egg-laying sites, hydrodynamically low-energy or sheltered areas where larvae may collect, juvenile nurseries, feeding areas, and overwintering refuges can greatly reduce potential impacts. To achieve this, some intakes may be resited to offshore locations to remove them from the most biologically productive habitats.

Intake structures raised slightly above the bottom will aid in keeping bottom-dwelling organisms from entering the intakes (but it will do little to deter planktonic or swimming organisms). Although the careful siting of intakes outside the most productive habitats will reduce impacts, there will always be some level of impacts due to CWIS unless some physical characteristic of the water (e.g., consistently low dissolved oxygen) prevents organisms from living there.

5.2 Operational Changes

Changes to operational procedures at the facility can also reduce impacts. For example, flow reductions may reduce impacts because entrainment and impingement rates are often directly correlated with flow rates. One way of reducing flow is to use variable-speed pumps (instead of on/off pumps) to reduce water intake during months when biological activity is highest. Another method is to operate in what is called "piggyback" mode, where the discharge from one unit is used to cool another unit. This cooling water recycling measure increases the risks to organisms that are initially entrained (because they may go through the cooling system several times) but decreases the overall amount of new cooling water needed, thereby decreasing impacts. Another operational procedure that can reduce impingement impacts is the continuous rotation of screens in front of the intake. Typically, screens are rotated only when excessive blockage of the screens (by vegetation, debris, or organisms) decreases intake rates beyond the threshold of condenser efficiency. Continuous rotation of screens during months when impingement is known or expected to be highest can reduce the amount of time that impinged organisms spend on the screens, thereby increasing the probability of survival if there is an adequate return sluice.

5.3 Technological Upgrades

In addition to carefully planned CWIS siting and operational protocols, technological modifications and additions provide an opportunity for reducing impacts.

The upgrade to modified traveling screens with a well-designed fish return system can enhance survivorship of many impinged organisms. Improvements to traveling screens and fish return systems to minimize the physical stress on fish before they return to the receiving water body include modified fish buckets on the screens and low-pressure spray washes, variable speed drives for rotating the screens (3–30 feet/min), and separate fish and debris return troughs (Fig. 2). Furthermore, designing return sluices so that they deliver fish back into the receiving water body at all water levels (i.e., not allowing returned fish to drop on the shore at low water levels), and far enough away from the intake so as not to be reimpinged, may also increase survival rates of returned fish.

When biocides are necessary to reduce biofouling on intake screens, the location of biocide injection

can be important to the survival of impinged organisms. Positioning the biocide injectors so that they do not dose impinged organisms (i.e., aiming injectors toward the descending portion of the traveling screen) may help to increase survival rates. Furthermore, using targeted biocides (i.e., those that kill only biofouling organisms and not fish) will also increase the survival of impinged organisms.

Other technological upgrades include physical and behavioral barriers. Filter fabric curtains, fixed panel screens, or wedge wire screens placed in front of the CWIS create a physical barrier between organisms in the water body and the intake structure (Fig. 3) These barriers, if installed and maintained properly, reduce intake velocity and can prevent impingement and reduce entrainment (although the smallest eggs and larvae may still pass through the barrier and into an intake). Other systems that use angled screens or vertical panels placed at 90 degrees to the flow of water create flows that divert fish to a bypass on the outside of the screens that prevents them from entering the cooling system (Fig. 4). These systems have been shown to reduce impingement but not entrainment. In a similar way, localized turbulent flows generated at points near an intake can "sweep" fish away from intakes (Fig. 5). This method has been shown to be successful in preventing impingement of certain species of fish.

Placing the intake structure under gravel or behind a porous cobble dike is another upgrade that can potentially reduce entrainment and impingement if the intake velocity across the gravel or cobble is less than it would be across an unprotected intake. However, the

efficacy of an under-gravel or porous dike barrier may decrease due to clogging by debris and sediment or fouling by colonizing aquatic organisms.

Other methods of impact reduction are behavioral barrier systems. One behavioral system that works on the premise that fish avoid rapid changes in horizontal flow is called a velocity cap. A velocity cap is placed on an offshore vertical intake and converts vertical flow into horizontal flow (Fig. 6). Like the panel and angled screen systems, this device has only been shown to reduce impingement but not entrainment impacts, and it is more effective for some species than for others. Acoustical or optical (strobe light or air bubble) deterrents have also been used as behavioral barriers to keep fish from approaching CWIS, but the efficacy of these techniques has been shown to be limited and species specific.

5.4 Biological Mitigation

An innovative but still unproven method for reducing impacts is biological mitigation. The theory behind biological mitigation is to accept that a certain number of losses will occur at a given facility and that these losses can be balanced by adding more individuals to the affected biological populations.

Some biological mitigation strategies propose to conserve or restore habitat so as to increase the abundance of certain life stages of affected populations. To facilitate this process, the EPA created a "habitat-based replacement cost" method of valuing biological resources lost to entrainment and impingement. This valuation system identifies the costs of habitat restoration required to replace biological resources lost to entrainment and impingement. One of the strengths of this method is that it recognizes that all organisms, and not just those that are recreationally or commercially important, are valuable to an aquatic ecosystem. An intensive search for habitat restoration opportunities for each affected species and a system of prioritizing the options based on their expected benefits to the affected species is required. Once implemented, only intensive, long-term, and carefully controlled studies can determine whether habitat remediation has led to increases in the abundance of species life stages affected by power plants.

Another form of biological mitigation is restocking. In restocking plans, the sum total of equivalent adult fish entrained plus the number of adult fish that have been impinged is replaced by hatchery-raised fish of the same species. One of the challenges with this method is to ensure that the hatchery-raised fish have the same genetic makeup and ecologically important behavioral responses (e.g., habitat selection, prey capture, predator avoidance) as do the fish they are meant to replace. An additional consideration is that restocking often occurs without respect to restocking the same life stages that are experiencing the greatest impacts. For example, juvenile fish grown in a hatchery and released as mitigation for entrainment impacts will not have the same ecological role as will the larvae they are meant to replace.

Biological mitigation is a field that requires more research before its efficacy can be ascertained.

5.5 New Regulations to Reduce Impacts

At the regulatory level, the EPA has established requirements to reduce entrainment and impingement impacts at new facilities using once-through cooling. On December 18, 2001, it issued its "final rule" implementing Section 316(b) of the Clean Water Act for new facilities. The national requirements for new facilities establish a two-track system. Under track I, facilities using more than 10 million gallons of intake water per day must meet capacity, velocity, and capacity- and location-based proportional flow requirements. Facilities using more than 2 million but less than 10 million gallons of intake water per day do not have to meet the capacity limitation but must use technologies to reduce entrainment. More specifically, the track I standards require the following:

- Intake flow must be commensurate with that of a closed-cycle system (although facilities with 2–10 million gallons/day intake flow are exempt).
- The maximum through-screen intake velocity is 0.5 feet per second.
- If an intake is sited in a freshwater river or stream, flow must be less than 5% of the annual mean flow.
- If an intake is sited in a lake or reservoir, withdrawal from a cooling water intake must not disrupt the natural thermal stratification of the source water body.
- If an intake is sited in a tidal river or an estuary, withdrawal can be no greater than 1% of the volume of the water column within the area centered around the intake, with the diameter defined by the distance of one tidal excursion at mean low water.

Under track II, a facility has the option to demonstrate that alternative technologies or operations chosen by the manager of the facility will reduce entrainment and impingement mortality to a level comparable to that required under track I. Also under track II, flow levels are not limited to those commensurate with closed-cycle cooling, and intake velocity does not need to be less than 0.5 feet per second; however, the other withdrawal constraints are the same. In addition, facility operators choosing track II need to undertake a comprehensive biological evaluation demonstrating that the chosen technologies and operations have an adverse environmental impact level commensurate with that achievable under track I. The EPA has been evaluating requirements to reduce entrainment and impingement effects at existing facilities that use cooling water in order to meet the goals of track II.

Glossary

energy Energy is usually defined as the capacity for doing mechanical work—that is, displacing an object from a position to another by means of the application of a force. This textbook definition is sometimes criticized for being reductive and not always easily applicable to processes other than purely physical ones. A broader definition for energy could be the ability to drive a system transformation, which clearly includes all kinds of physical, chemical, and biological transformations.

enthalpy Enthalpy, H, is a thermodynamic property expressing the total energy content of a system. It is defined as $H = U + pV$, where U is the internal energy of the system (any kind of energy form of its molecules) and pV is the system's energy in the form of expansion work (in fact pV, the product of pressure and volume, has the physical dimensions of energy). In a chemical reaction carried out in the atmosphere the pressure remains constant and the enthalpy of reaction (ΔH) is equal to $\Delta H = \Delta U + p\Delta V$. Enthalpy is a state function, because it only depends on the initial and final states of the system, no matter how the process develops.

macroscopic/microscopic Any system is composed of parts. Parts contribute to the functioning of the whole. Matter is composed of molecules, an economy is made up of production sectors and firms, for example. The dynamics of the whole system may be or appear to be different from the behavior of the component parts. A car may be stopping in a parking lot, yet its molecules possess a chaotic motion, which cannot be seen when we look at the car. A national economy may be in good health, on average, yet some sectors or local firms may face a difficult survival. Macroscopic therefore concerns the system's dynamics, considered as a whole, while microscopic applies to the behavior of the lower scale components.

perfect gas A perfect or ideal gas is a gas the molecules of which are infinitely small and exert no force on each other. This means that their motion is completely chaotic and does not depend on any mutual interaction, but only on completely elastic collisions, which cause a transfer of energy from a molecule to another and a change of their direction and velocity.

probability The probability of an event is the ratio of the number of times the event occurs to a large number of trials that take place. The number of trials (all events that may occur, including those different from the ones fitting the request) must be very large for the probability to be reliable. As an example, assume we cast a die. If the die is perfectly constructed, the probability of a five is 1 out of 6 possible different castings. However, in a real case, we must cast it many times to ensure that a five occurs out of the other possible events in a 1:6 ratio.

reversible/irreversible A reversible change in a process is a change that can be reversed by an infinitesimal modification of any driving force acting on the system. The key word infinitesimal sharpens the everyday meaning of the word reversible as something that can change direction. In other words, the state of the system should always be infinitesimally close to the equilibrium state and the process be described as a succession of quasi-equilibrium states. A system is in equilibrium with its surroundings if an infinitesimal change in the conditions in opposite directions results in opposite changes in its state. It can be proved that a system does maximum work when it is working reversibly. Real processes are irreversible, therefore there is always a loss of potential work due to chemical and physical irreversibility.

self-organization All systems in nature self-organize—that is, use the available energy and matter inputs in order to achieve higher levels of structure and functioning under natural selection constraints. In so doing, they may maintain their present level of complexity or become more and more complex by also increasing the number of components, functions, and interactions.

statistic The science dealing with sampling and recording events, which occur in a different way in dependence of a given parameter (time, temperature, etc.). It estimates

events by recording and analyzing a given behavior verified by an appropriately large number of random samplings. The statistical analysis may lead to hypotheses about the behavior of a given set of events.

temperature Temperature is a property of an object that tells us the direction of the flow of heat. If the heat flows from A to B, we can say that the temperature of the body A is higher than that of the body B. In some a way it measures the concentration of heat within matter and can be linked to the average kinetic energy of the molecules in a body. A thermometric scale (centigrade or Celsius scale of temperature) can be defined by dividing by 100 the temperature interval between the temperature of melting ice (0°C) and the temperature of boiling water (100°C) at sea level. Other existing scales depend on the reference parameters chosen as the zero level. A scale of absolute temperatures (Kelvin) defined as described in this article is linked to the Celsius temperature, t, by means of the relationship: $T\ (K) = t\ (^{\circ}C) + 273.15$. A unit absolute degree (K) coincides with a unit centigrade degree (°C).

work The transfer of energy occurring when a force is applied to a body that is moving in such a way that the force has a component in the direction of the body motion. It is equal to the line integral of the force over the path taken by the body, $\int F \times ds$. Its meaning is different from the usual life work, often associated with activities not always involving visible motion. Physical work requires a body motion under the action of the force.

Entropy, a measure of energy and resource degradation, is one of the basic concepts of thermodynamics, widely used in almost all sciences, from pure to applied thermodynamics, from information theory to transmission technology, from ecology to economics. In spite of the mathematical difficulty of its definition and application for the nonspecialists, the word entropy is often used in the everyday life, where it assumes less constrained, looser meanings than in the scientific community, being generally associated to disorder, lack of organization, indefiniteness, and physical and social degradation. In this article, we first give the mathematical definition of entropy and discuss its meaning as a basic thermodynamic function in reversible, ideal processes. The relationship of the entropy concept with real irreversible processes, statistical thermodynamics, information theory, and other sciences is then reviewed.

1. INTRODUCTION

The development of thermodynamics as well as the introduction of the concept of entropy is deeply rooted into the fertile technological ground of the Industrial Revolution, which took place in England between the beginning of the 18th and the second half of the 19th century. The development of steam-powered machines (first used to pump water out of coal mines and then to convert into work the heat generated by coal combustion) amplified both technological and purely scientific research, in an interplay of mutual reinforcement. The "miner's friend," an engine built by Thomas Savery in 1698, had a very low efficiency. Other more efficient engines (such as Newcomen's engine in 1712) opened the way to Watt's steam engine (1765), the efficiency of which was much higher than Newcomen's engine. The Scottish technician James Watt had to solve several technological and theoretical problems before his machine could effectively replace the previous steam engines. However, at the beginning of 19th century, hundreds of Watt's machines were used in Europe and constituted the basis for the significant increase of production that characterized the Industrial Revolution.

The conversion of energy from one form to another, and in particular the conversion of heat into work, has been investigated by many scientists and technicians in order to deeper understand the nature of heat toward increased efficiency. These studies yielded a general framework for energy conversion processes as well as a set of laws, the so-called laws of thermodynamics, describing the main principles underlying any energy transformation. It is worth noting that the investigation about thermal engines and the limits to the conversion of heat to mechanical work (second law, Carnot, 1824, "Réflexions sur la puissance motrice du feu et sur les machines propres à developper catte puissance") preceded the statement of the first law of thermodynamics. This is because heat conversion to mechanical work (steam engine, second half of 18th century) generated first an attention to the existing constraints and then a much clearer understanding of the nature of heat and a quantitative equivalence between heat and mechanical work (middle of the 19th century).

Clausius then provided Carnot's "Réflexions," with a stronger mathematical basis and introduced the concept of entropy, S, in so developing a clear statement of the second law. The entropy concept is perhaps the most complex one in physical science, also because it was gradually charged by many meanings belonging not only to thermodynamics, but also to a variety of other fields and disciplines. A further definition of the entropy concept came from L. Boltzmann (1844–1906) in the second half of the 19th century, by means of the so-called H-theorem,

in which the statistical meaning of entropy was definitely assessed.

2. ENTROPY AS A THERMODYNAMIC STATE FUNCTION

A consequence of the first and second laws of thermodynamics is that the efficiency, η_R, of any reversible machine only depends on the two temperatures, T_1 and T_2, between which the machine operates. In short, after adequately choosing the thermometric scale in order to have $T = t + 273.14$ (t is Celsius temperature), it is

$$Q_2/Q_1 = T_2/T_1 \tag{1}$$

and

$$\eta_R = (T_1 - T_2)/T_1 \tag{2}$$

independently on the fluid or the amount of heat exchanged. The temperature T is called absolute temperature and measured in absolute degrees (or Kelvin degrees, K). Since it does not depend on the particular thermometric substance used, it therefore coincides with the one obtained by using an ideal fluid as the thermometric substance.

Equation (1) can be rewritten as

$$Q_1/T_1 - Q_2/T_2 = 0 \tag{3a}$$

and generalized to the case of n sources in a reversible cycle, as

$$\sum Q_i/T_i = 0, \tag{3b}$$

where Q_i has a positive sign if heat is provided to the fluid and a negative sign if heat is released. Eq. (3b) can be further generalized to the case of infinitesimal amounts of heat δQ exchanged by each source in any reversible process with continuous temperature changes:

$$\int_{\text{cycle}} \delta Q/T = 0. \tag{4a}$$

For any *irreversible* process S, it would be

$$\int_{\text{cycle}} \delta Q/T < 0 \tag{4b}$$

because $\eta_s < \eta_R$

Let us now consider the most general case of a reversible cycle as the one shown in Fig. 1, with continuous temperature changes. It can always be simplified as the succession of two reversible transformations from A to B (along the pathway 1) and vice versa (along the pathway 2).

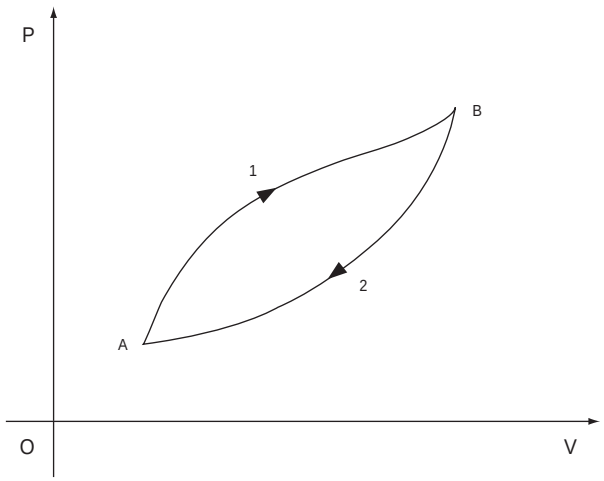

FIGURE 1 Diagram of a reversible cycle, with continuous temperature changes, simplified as the succession of two reversible transformations from A to B (along the pathway 1) and vice versa (along the pathway 2).

According to Eq. (4a), we may write

$$\int_A^B \delta Q/T|_1 + \int_B^A \delta Q/T|_2 = 0, \tag{5}$$

where the subscripts indicate the paths from A to B and vice versa. Due to the reversibility of the two transformations $A \to B$ and $B \to A$, we may also write

$$\int_A^B \delta Q/T|_1 = -\int_B^A \delta Q/T|_2 = \int_A^B \delta Q/T|_2. \tag{6}$$

This result is of paramount importance, because it demonstrates that the integral does not depend on the specific reversible transformation from A to B, but only on the actual states A and B. We are therefore able to define a new function only depending on the system state (such as the internal energy U).

Clausius (1850) called this function entropy, defined as follows:

> *Given an arbitrary initial system state O, an arbitrary final state A and an arbitrary reversible transformation from O to A, the value of the integral*
>
> $$S(A) = \int_O^A \delta Q/T + S(O) \tag{7}$$
>
> *calculated over any reversible transformation $O \to A$ is a function only of the states O and A. This value is called entropy.*

Entropy is measured in cal/K or J/K. It clearly appears that S(A) is defined but for an arbitrary constant S(O), which has no practical utility, because we are always interested in entropy differences between states and not in absolute values. We can

therefore equate this constant to zero. For any reversible transformation from a state A to a further state B, the entropy variation dS will be

$$dS = S(B) - S(A) = \int_A^B \delta Q/T \qquad (8)$$

independent on S(O), the entropy of the arbitrary initial state O. Unlike dS, an exact differential independent on the path, δQ is path dependent and it is therefore indicated by means of the δ symbol. The expression at the right side of Eq. (8) is called the Clausius integral. As a consequence, in order to calculate the variation of entropy between the initial state A and the final state B of a system undergoing a real and irreversible process we must first consider the corresponding reversible transformation of the system between the same two states and calculate dS over this pathway. If we then consider a globally irreversible cycle (Fig. 2), made up with an irreversible transformation from A to B and a reversible transformation from B to A again, it must be according to Eq. (4b) and Eq. (8):

$$\int_A^B \delta Q/T|_{irr} + \int_B^A \delta Q/T|_{rev} < 0 \qquad (9a)$$

$$\int_A^B \delta Q/T|_{irr} + S(A) - S(B) < 0 \qquad (9b)$$

$$S(B) - S(A) > \int_A^B \delta Q/T|_{irr}. \qquad (9c)$$

This famous inequality, due to Clausius and named after him, states that the variation of entropy between two states for an irreversible transformation is always higher than Clausius integral. From Eqs. (8) and (9c) we have that in a generic transformation,

$$S(B) - S(A) \geq \int_A^B \delta Q/T, \qquad (10)$$

where the equality applies only to reversible processes. If a system is isolated (i.e., it has no exchange of energy [or matter] with the surrounding environment), we have

$$S(B) - S(A) \geq 0 \qquad (11a)$$

$$S(B) \geq S(A) \qquad (11b)$$

that is, "If an isolated system undergoes a transformation from an initial state A to a final state B, the entropy of the final state is never lower than the entropy of the initial state." This statement is the so-called entropy law.

Therefore, when an isolated system reaches the state of maximum entropy consistent with the constraints imposed upon it, it cannot undergo any further transformation. The state characterized by the maximum entropy is the most stable equilibrium state for the system. From a strictly thermodynamic point of view, the increase of a system's entropy measures the amount of energy no longer usable to support any further process evolution. When all the energy of a system becomes unusable (degraded heat with no temperature gradients to drive heat flows), no more system transformations are possible. In fact, heat cannot be further transformed into other forms of energy nor can it be transferred from a body to another within the system, because all bodies have the same temperature.

It is important to underline that the law of entropy states in an unequivocal way that in an isolated system all real transformations proceed irreversibly towards the state of maximum entropy. The whole universe is assumed to be an isolated system, and therefore we may expect it to reach the maximum entropy state in which its energy is completely converted into heat at the same temperature and no further transformation can be supported. This state would be the state of maximum equilibrium for the universe and has been defined as its thermal death.

Finally, unlike in classical mechanics, no time symmetry is observed in thermodynamics. While the movement of a point (i.e., a virtual object) may always occur from A to B and vice versa (time symmetry between t and $-t$ over the time axis), a real

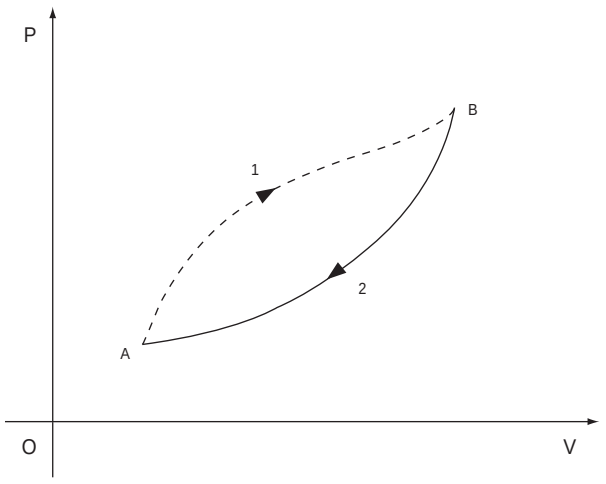

FIGURE 2 Diagram of a globally irreversible cycle, with continuous temperature changes, simplified as the succession of one irreversible transformation from A to B (along the pathway 1, dotted line) and one reversible transformation (along the pathway 2).

process in an isolated system cannot reverse its evolution if this change is not accompanied by an increase of entropy.

In 1906, Nerst demonstrated that the entropy of any thermodynamic system at the absolute temperature of 0 K is equal to zero, whatever is the state of the system (Nerst's theorem). As a consequence of Nerst's statement, also known as the third law of thermodynamics, it is convenient to choose one of these states as the initial state O and to define the entropy of state A (at a temperature $T \neq 0$ K) as

$$S(A) = \int_O^A \delta Q/T, \qquad (12)$$

where the arbitrary constant S(O) of Eq. (7) is equal to 0, in order to be in agreement with Nerst's theorem, and where the integral must be calculated over any reversible transformation from O (at $T = 0$ K) to A (at $T \neq 0$ K).

It is worth noting that, at $T = 0$ K, it is impossible to have a mixture of finely ground substances. In fact, if so, it would be possible to diminish the entropy of the system by separating them out of the mixture. This yields an *equivalent* statement of the third law: The entropy of a pure substance is equal to zero at $T = 0$ K. As a consequence, the substances that are in the mixture will spontaneously separate from each other when their temperature drops in the proximity of $T = 0$ K.

3. STATISTICAL MEANING OF ENTROPY AND BOLTZMANN'S H-THEOREM

Dice players know very well that if we cast two dice it is much easier to get a seven than a twelve. This is because a seven can be obtained as $1+6$, $2+5$, $3+4$, $4+3$, $5+2$, and finally $6+1$, where the first number is the value obtained from the first die, and the second number is the value of the second die. There are therefore six ways to obtain a seven, and only one $(6+6)$ to obtain a twelve. We may state that the macroscopic configuration seven has six microscopic states accomplishing it, and is therefore more probable than the configuration twelve.

A similar result can be achieved if we consider a box divided into two compartments (Fig. 3A). There are several ways of putting four balls in it. We may put four balls in its left compartment leaving the right compartment empty. Or we may do the opposite. The two states are identical from the microscopic and statistical points of view. In fact, if we try to extract one ball from the box, in the dark, we have a 50% probability of putting our hand in the empty part and a 50% probability of putting our hand in the compartment with the four balls. The probability is the same for both compartments, which are therefore perfectly equivalent from a statistical point of view. Therefore, the macroscopic state "four balls in a compartment and no balls in another" can be achieved by means of two microscopic configurations perfectly equivalent.

Things are different if we want to distribute the four balls in both compartments, two in each one of them. We have now six possible ways for distributing our balls, each of them equivalent from a statistical point of view (Fig. 3B). The macroscopic state having two balls per compartment has more ways to occur (more microstates), which means that it is more probable that in Fig. 3A.

It is easy to understand now that a macroscopic configuration having three balls in a compartment and only one in the other is more probable than the two previously considered configurations (Fig. 3C) since it can be achieved by means of eight different microstates, all perfectly equivalent.

Let us now consider a macroscopic state of a perfect gas, defined by given values of the quantities P (pressure), V (volume), and T (temperature). It may result from a given number N of microstates—that is, a given number N of different positions and velocities of the billion molecules which compose it. In each microstate there will be different values of the position and the velocity of each molecule, but the global result of the behavior of all the molecules will be exactly that macrostate characterized by the measured values of P, V, and T. Of course, the larger the number of possible equivalent microstates N, the higher the probability of the corresponding macrostate. We know from the previous section that an isolated perfect gas tends to and will sooner or later achieve the state characterized by the maximum entropy consistent with the energy U of the gas. This state is also the macrostate characterized by the largest number of equivalent microstates. Ludwig Boltzmann (1844–1906) understood the strong link between the thermodynamic and the statistical interpretation of the entropy concept. In 1872 he published a milestone paper in which he introduced the basic equations and concepts of statistical thermodynamics.

As the first step, Boltzmann assumed that all the n molecules constituting the gas had the same velocity and divided the volume V into a very large number of

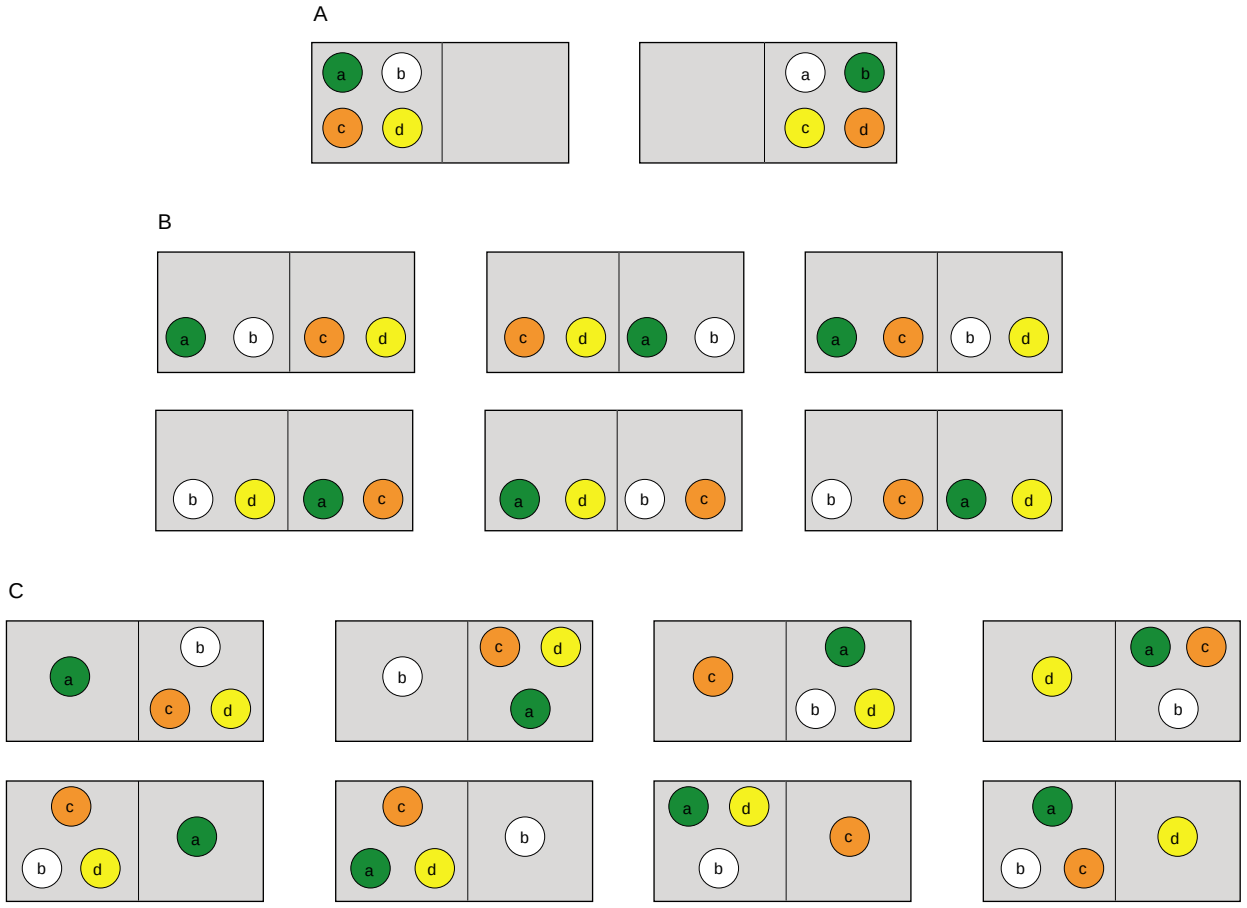

FIGURE 3 Macrostates and microstates in a system made up of four balls in two separated compartments. Each macrostate may correspond to different numbers of equivalent microstates. Figures A, B, and C show the different number of equivalent microstates that may correspond to a given macrostate, characterized by a measurable temperature, pressure, and volume.

cells, M, each having the smallest experimentally measurable size. It is then easy to demonstrate that the number of distinct microstates N corresponding to the macrostate of volume V is

$$\mathrm{N} = \frac{n!}{n1.....n_M!,} \tag{13}$$

where n_i is the number of molecules contained in the i-th cell and $n = \sum_i n_i$ Boltzmann also assumed that the entropy of the state is linked to the number N of microstates by the logarithmic expression

$$\mathrm{S} = k \log N, \tag{14}$$

where $k = 1.38 \times 10^{-23}$ joule/K, the so-called Boltzmann's constant. The logarithm base used is arbitrary, since the conversion from a base to another one would simply require the introduction of a multiplicative constant. For a reason, which will clearly appear in the next section, it is preferable to use the logarithms with base two.

According to Nerst's theorem and to Eq. (14), it must be $N = 1$ when $\mathrm{T} = 0\,\mathrm{K}$, in order to have $\mathrm{S} = 0$—that is, at the absolute temperature $\mathrm{T} = 0\,\mathrm{K}$, a system's state is always composed by only one microstate.

By applying to Eqs. (13) and (14) the properties of natural logarithms and the Stirling formula for the mathematical expansion of $n!$, Boltzmann derived the expressions

$$S = k \log N = k \log\left(\frac{n!}{n_1!.....n_M!}\right) = k\, H \tag{15a}$$

$$H = -\sum_i p_i \log p_i \quad \text{with} \sum_i p_i = 1, \tag{15b}$$

where p_i is the probability to find one molecule in the i-th cell. It is not difficult to show that the maximum entropy state is that state for which all the p_i's have the same value (i.e., that state in which all the cells are occupied by the same number of molecules). It can also be said that this is the most disordered

state, since the distribution of the molecules among the cells is the most uniform and therefore the one showing the lower level of organization.

As the second step, Boltzmann dealt with the most general case in which the positions and velocities of the molecules are all different. He introduced a distribution function, $f(x,y,z; v_x,v_y,v_z)$, to account for the different positions and velocities and expressed the p_i's as functions of $f(x,y,z; v_x,v_y,v_z)$. He also transformed the summation $\sum$ of Eq. (15b) into an integral, due to the very high number of molecules:

$$H = -\int f \log f \, dx \, dy \, dz \, dv_x \, dv_y \, dv_z. \quad (16)$$

Boltzmann finally demonstrated in 1872 his well-known H-theorem—that is, that it must be

$$dH/dt \geq 0. \quad (17)$$

According to the Eq. (17), H (and therefore $S = k\,H$ as well) never decreases over time. Actually Boltzmann defined H without the minus sign in Eq. (16) and then demonstrated that $dH/dt \leq 0$. As a consequence, Eq. (15a) became $S = -k\,H$. We prefer, in agreement with other authors, the introduction of the minus sign in order to have H increasing over time according to Eq. (17). In so doing, H and S show exactly the same trend.

Boltzmann therefore restated by means of statistical considerations the law of entropy in isolated systems—that is, he gave a statistical reading of the second law of thermodynamics and the entropy concept. He also demonstrated that his velocity distribution function f coincided with the one hypothesized by Maxwell in 1859, from which the most probable state corresponding to the maximum entropy could be derived.

Boltzmann's seminal work generated a heated debate about mechanical reversibility and thermodynamic irreversibility. Several critics questioned that thermodynamic irreversibility could be described and explained in terms of mechanical reversibility. It is not the goal of this article to go into the details of this fascinating debate. The latter soon became a philosophical investigation about the mechanistic conception of reality as well as the so-called arrow of time (i.e., the spontaneous direction of natural processes as suggested by their irreversibility).

The most difficult part of this concept is trying to figure out two enormous numbers—that is, the number of molecules constituting the system (the ideal gas or any other) and the number of microstates contributing to a given macrostate of the system. We would like to underline that Boltzmann only stated the statistical irreversibility of the evolution of an isolated system. After a sufficiently (infinitely) long time, the system will certainly achieve the most stable equilibrium state, characterized by the maximum entropy, although among the billion microstates contributing to a given macrostate in any instant, there is a percentually small (but different from zero) number of microstates capable of driving the system to a macrostate at lower entropy. This means that future lower entropy states are not impossible for the system, but only extremely unlikely.

4. ENTROPY AND INFORMATION THEORY

Information theory is relatively recent. It moved its first steps in 1948, when C. E. Shannon published his seminal paper, "A Mathematical Theory of Communication." This paper was the starting point of modern communication technologies, which have so deeply modified all aspects of our life. Shannon's problem was how to measure and transmit a message from a source (transmitter) to a recipient (receiver) through a transmission channel generally characterized by a background noise capable of altering the message itself. We will focus in this paper on the problem of information measure.

First of all, it is important to underline the fact that the concept of message is very broad. However, the set of messages that each source is able to transmit must be specified without any possible ambiguity. A letter of the alphabet, the ring of a bell, a word or a particular gesture are all examples of possible messages. Shannon considered the n elementary messages that a source could transmit (i.e., the basic alphabet of the source itself). He first assumed that these messages were equally probable (i.e., that the probability for each of the n options to be transmitted was $p = 1/n$). If two consecutive elementary messages are transmitted, the possible options (i.e., the number of possible different sequences of two messages out of n available ones) are n^2. In general, if m messages are transmitted in a row, the possible different sequences become $N = n^m$ (i.e., the number of all the possible permutations of the n elementary messages in groups of m elements, also allowing for repetitions). At the same time, the information transmitted (i.e., the events or descriptions that characterize the source and that are not yet known by the recipient) should be twice, three times,…, m times the one transmitted by means of only one elementary message. In any case, this

information should be somehow proportional to the number m of messages that make up the transmitted sequence of messages. Shannon assumed it was proportional to the logarithm of the possible options N, which easily yielded

$$\begin{aligned} \mathrm{I} &= \log N = \log n^m = m \log n \\ &= -m \log 1/n = -m \log p. \end{aligned} \tag{18a}$$

The information conveyed by each elementary message is therefore

$$i = -\log p = \log 1/p. \tag{18b}$$

From Eq. (18b) it appears that the information conveyed by a message is proportional to the log of the reciprocal of its probability. If $p<1$, it is $i>0$. This also means that the less probable the message, the higher the information content transferred from the source to the recipient. If we already know that a given message will be transmitted ($p=1$), it will not carry any additional information. In fact, we would not switch the TV on if we already knew which news are going to be announced. Instead, an unlikely and therefore unexpected message carries a significant piece of information. Finally, no information is carried by a message that cannot be transmitted ($p=0$).

Shannon then generalized his equation to the case of messages showing different transmission probability. He assumed that the source could transmit n elementary messages in groups of m elements, with probabilities p_i, where $i=1,\ldots, n$. If m is large enough, the i-th message with probability p_i will appear $m\ p_i$ times and the total information carried by the sequence of m messages will be

$$\mathrm{I} = -\sum_i m\ p_i \log p_i. \tag{19a}$$

As a consequence, the average information conveyed by each of the m messages will be

$$\mathrm{H} = -\sum_i p_i \log p_i \quad \text{with} \quad \sum_i p_i = 1 \tag{19b}$$

Equation (19b) has the same mathematical form as Eq. (15b), thus indicating a surprising similarity between Boltzmann's entropy and Shannon's information. For this reason, the same symbol H is used and Shannon's expression is very often called entropy of a source. Actually, the entropy of the source should be indicated as in Eq. (15a), where k is Boltzmann's constant and H would be Shannon's expression for the average information of a message. The entropy H of a source, intended as the average information content of a given message, also indicates the recipient's ignorance about the source, or in other words his a priori uncertainty about which message will be transmitted. This fact should not be surprising, since it is exactly by receiving the message that the uncertainty is removed.

In 1971, M. Tribus and E. C. McIrvine provided an interesting anecdote about Shannon, who is reported to have said:

> *My greatest concern was what to call it. I thought of calling it "information," but the word was overly used, so I decided to call it "uncertainty." When I discussed it with John von Neumann, he had a better idea. Von Neumann told me, "You should call it entropy, for two reasons. In the first place your uncertainty function has been used in statistical mechanics under that name, so it already has a name. In the second place, and more important, nobody knows what entropy really is, so in a debate you will always have the advantage."*

True or not, the story points out the links between the two concepts. Equation (19b) also allows the definition of a unit to measure information. Let us assume that the source releases information by means of a binary alphabet—that is, it is able to transmit only two elementary messages, both having a probability $p=\frac{1}{2}$. It is common habit to indicate these messages by means of the two digits, 0 and 1, which therefore become the basis of the so-called digital alphabet and transmissions. The average information carried by an elementary message is, in such a case, from Eq. (19b):

$$\begin{aligned} \mathrm{H}_1 &= -1/2 \log 1/2 - 1/2 \log 1/2 \\ &= -1/2 \log_2 1/2 - 1/2 \log_2 1/2 \\ &= -1/2 \times (0-1) - 1/2 \times (0-1) \\ &= 1/2 + 1/2 = 1. \end{aligned} \tag{20}$$

This unit quantity is called a bit (acronym for binary digit), which indicates a pure number, with no physical dimensions. One bit of information is, by definition, the information carried by each of the two elementary messages released by a binary source with equal probability 1/2. The reason of the choice of logarithms in base two is now evident.

For the sake of completeness, we may also add that another very common unit is the byte (1 byte = 8 bit). Eight bits allow for the construction of $2^8 = 256$ different sets of elementary messages, or different 8-bit strings, to each of which we may for instance assign a given symbol on the keyboard of a personal computer.

4.1 Maxwell's Demon

The link between S and H was deeply investigated soon after the introduction of Shannon's theory. Each isolated system can be considered either a source of information or vice versa. For example, an isolated gas with totally thermal energy and uniform temperature is in a high-entropy, disordered state (from a thermodynamic point of view). It is also in a macrostate to which a high number of microstates may correspond and therefore it is a highly probable state (from a statistical point of view). If so, the uncertainty about the actually occurring microstate is huge and a large number of bits (much information) would be needed to ascertain it (from the point of view of Information theory).

A clear example of the link between entropy and information is the so-called Maxwell's demon, a problem that fascinated scientists for a long time. Assume that we have two rooms at the same temperature, due to the fact that in each room there is the same distribution of molecular velocities and kinetic energies. If we could separate the slowly moving molecules from the fast ones, the temperatures of the two rooms should vary. Maxwell assumed that this task could be performed by a demon quickly opening or closing a frictionless window in the separation wall, in order to pass fast (hot) molecules to a room and slow (cold) molecules to the other one (Fig. 4). The final effect would be the separation of hot from cold molecules and the generation of a temperature gradient (one room would be at higher temperature than the other one), without spending energy from outside, due to the absence of friction in the process. In so doing, the entropy of the system would decrease and the second law would be violated. This paradox was only solved in 1956 by L. Brillouin. He pointed out that the demon needed information about each approaching molecule, in order to decide about opening or not the window. He could, for instance, light them up. The process of generating information would cause an increase of the overall entropy of the system + environment, larger or equal to the entropy decrease of the system only.

From Eq. (15a) and the result of Eq. (20), we have

$$S = k\,H = 1.38 \times 10^{-23}\ \text{joule/K} \times 1\ \text{bit} = 1.38 \times 10^{-23}\ \text{joule/K} \times 1\ \text{bit}. \quad (21)$$

Therefore, 1 bit of information requires an entropy generation equal to 1.38×10^{-23} joule/K. This entropy cost of information is so low, due to the small value of k, that people thought information was free, as for Maxwell's demon. Of course, if H is calculated by means of natural logarithms, then 1 bit corresponds to $k \ln 2$ entropy units.

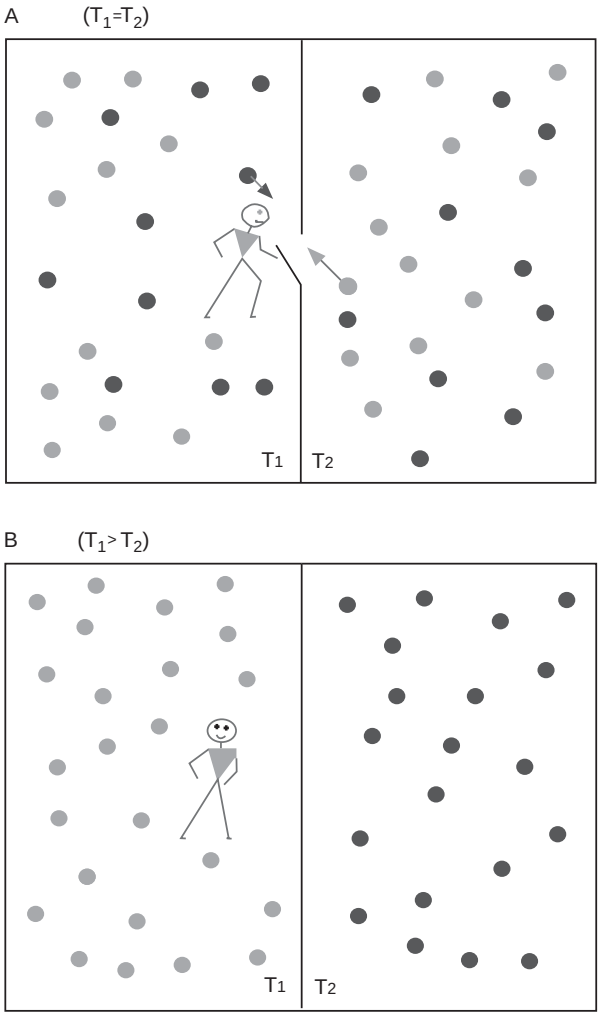

FIGURE 4 Maxwell demon. The demon seems to be able to violate the second law of thermodynamics, by selecting the molecules and sorting the hot (gray) from the cold ones (black). The two compartments are initially at the same temperature (A). After some time, all hot molecules migrated to the left compartment and cold ones to the right compartment. As a consequence of the selection, the temperature of the left side is higher than the temperature of the right side (B).

5. THE FREE-ENERGY CONCEPT

What happens when entropy increases? What does it mean in practical terms? Lots of pages have been written, linking entropy increase with disorder, disorder with less organization, less organization with lower quality, lower quality with lower usefulness.

Sometimes links have been a little arbitrary, because things are different with isolated or open systems. How can we quantify these concepts?

We know from Section 2 that if an isolated system undergoes a transformation from a state A to a state B, its entropy never decreases. The entropy law states in an unequivocal way that in an isolated system all real transformations tend irreversibly towards a state of maximum entropy. This statement applies to any kind of energy conversion, not only to heat-to-work ones. An entropy increase means that a fraction of the energy provided to the system is transformed into degraded heat, no longer usable to support any further process evolution. The energy actually usable is less and less work can be done. Many feel confused by using increasing entropy to mean decreasing ability to do work, because we often look to increasing quantities with positive feelings in our mind. For the entropy concept it is the opposite. The chemist J. W. Gibbs (1839–1903) actually "solved" this problem by introducing a new quantity, which he called available energy, linked to the entropy concept by means of a fundamental equation named after him. Available or free energy was then recognized as being an important property not only in chemistry but also in every energy transformation, in which the dissipation of a gradient (temperature, pressure, altitude, concentration, etc.) yields a product or delivers work as well as releasins some degraded energy or matter.

Several slightly different expressions exist for available energy, so that we will only refer to one of them, the so-called Gibbs energy, or Gibbs free energy, defined for reversible system transformations at constant pressure. This is the most frequent case, because the majority of processes on Earth occur at constant pressure.

5.1 Gibbs Energy

In general, the available energy is that fraction of a system's energy that is actually usable to drive a transformation process. It can be calculated by subtracting from the total system's energy the fraction that becomes unavailable due to the entropy increase. Assuming a process in which heat is transferred at constant pressure p, let us first define the Gibbs-energy function, G, as

$$G = H - TS, \tag{22a}$$

where

$$H = U + pV \tag{22b}$$

is the system's enthalpy, a measure of the total heat content of a system, while

$$U = Q + W \tag{22C}$$

is the well-known expression of the first law of thermodynamics. For a measurable change of the system's state at constant temperature T, from Eq. (22a) we have

$$\begin{aligned} G_f - G_i &= \Delta G = \Delta H - T\Delta S \\ &= (H_f - H_i) - T(S_f - S_i), \end{aligned} \tag{23}$$

which quantifies the amount of the available energy ΔG, after enthalpy and entropy changes have been accounted for. The subscripts i and f indicate the initial and final states.

This result shows the importance of the entropy concept also in practical applications. It indicates that the energy of a system is not always totally available to be transformed into work. Part of this energy is not converted but instead is released as high entropy waste (degraded heat), no longer able to support change of state of the system. The terms available and free can be now understood, as opposed to the bound, unavailable fraction of energy present in the entropy term of Eq. (23).

A process with $\Delta G < 0$ (i.e., a process whose initial state has higher available energy than the final state) may evolve spontaneously towards the latter, and deliver work. This result has a general validity and clearly shows the importance of the entropy-related, free energy concept.

Heat conversion into work and chemical reactions are clear examples of how the second law and the entropy concept work. In both cases we have spontaneous processes: (1) the heat flows from a source at higher temperature to a sink at lower temperature, and (2) the reaction proceeds from the higher to the lower free energy state. In both cases we have a process driven from a gradient of some physical quantity (respectively, a difference between two temperatures and a difference between two free energy states) and some work delivered to the outside at the expenses of the free energy of the system. In general terms, whenever a gradient of some physical quantity (altitude, pressure, temperature, chemical potential, etc.) exists, it can drive a transformation process. The free energy of the system is used whenever these spontaneous processes occur. The result is a lowered gradient, and an increased total entropy of the process + environment system, in addition to the work done.

6. CONCLUSION

The entropy concept is fascinating and rich of significance. At the same time, it appeared scaring and confusing to many. Many focused on the gloomy picture of increasing disorder and thermal death, characteristic of equilibrium thermodynamics and isolated systems. In this regard, entropy is used to point out and measure the decreasing availability of high quality resources (i.e., resources with low entropy and high free energy), the increase of pollution due to the release of waste, chemicals, and heat into the environment, the increase of social disorder due to degraded conditions of life in megacities all around the world, the "collapse" of the economy, and so on.

Others identify entropy as the style of nature: since the biosphere is an open system supported by a constant inflow of solar energy, its structures and life phenomena undergo a continuous process of self-organization. Geologic processes, atmospheric systems, ecosystems, and societies are interconnected through a series of infinitely different and changing relationships, each receiving energy and materials from the other, returning same, and acting through feedback mechanisms to self-organize the whole in a grand interplay of space, time, energy and information. During this self-organization process, entropy is produced and then released towards the outer space. Living structures do not violate the second law, but feed on input sources, which continuously supply low entropy material and energy (free energy) for system development.

While the first point of view calls for increased attention to avoid misuse of resources and prevent degradation of both natural and human environments (i.e., prevent the loss of stored information), the second point of view focuses on the creation of organization and new structures out of disordered materials, thanks to a flow of resources from outside. This point of view calls for adaptation to the style of nature, by recognizing the existence of oscillations (growth and descent) and resource constraints, within which many options and new patterns are however possible. Both points of view are interesting and stimulating and account for the richness of the entropy concept. The latter, first introduced in the field of energy conversion, acquired very soon citizenship in several other fields. We already mentioned the information theory in Section 4, but many other examples can be easily provided.

Environmentally concerned economists focused on the entropy tax—that is, on the fact that the development of economic systems is always dependent on the degradation of natural resources, the amount of which is limited. Some pointed out that the notion of entropy helps "to establish relationships between the economic system and the environmental system," as noted by Faber *et al*. in 1983. In 1971, Nicholas Georgescu-Roegen underlined that "The Entropy Law…emerges as the most economic in nature of all natural laws."

The ecologist Ramon Margalef introduced in 1968 a quantity, called ecological diversity, D, as a measure of the organization level of an ecosystem. This quantity is defined exactly in the same way as entropy, namely,

$$\mathrm{D} = -\sum_i p_i \log p_i \qquad (24)$$

where p_i is the probability for an organism to belong to a given species. The higher the ecological diversity, the lower the production of entropy per unit of biomass, because resources are better utilized and support the growth of the whole spectrum of ecosystem hierarchy. Instead, simplified ecosystems with fewer species (such as agricultural monocultures) do not use available resources and coproducts as effectively, resulting into a higher production of entropy per unit of time and biomass.

Finally, entropic styles have been adopted by several artists to express in their works their desire of novelty and their rejection of previous, static views on life. Some understood and meant entropy alternatively as disorder, indefiniteness, motion, rebellion—the opposite of the ordered and well-defined, Newtonian structures of Renaissance artists. In 1974, Rudolf Arnheim published an interesting assay on disorder and order in arts as well as on the need for complexity, which moves artists toward investigating new forms to express their creativity.

In the end, we would do a disservice to the entropy concept, by limiting its significance to the concept of disorder, which is, however, one of its meanings, or even to the practical application of the concept of free energy. Entropy, a word now very common in the everyday language, may be suggested as the other side on the coin of life itself, with its development, its richness and complexity. Life processes (such as photosynthesis) build organization, add structure, reassemble materials, upgrade energy, and create new information by also degrading input resources. Degraded resources

become again available for new life cycles, ultimately driven by the entropic degradation of solar energy.

Glossary

entropy change The amount of heat absorbed by a material divided by the material's absolute temperature.
isolated system A collection of materials that exchanges neither matter nor energy with its surroundings.
macroeconomics The study of the economy as an aggregated whole, generally ignoring the behavior of individual industries or consumers and instead concentrating on economy-wide magnitudes such as unemployment, inflation, interest rates, the trade deficit, and growth of gross national product.
microeconomics The study of the behavior of one or a few firms, industries, or groups of consumers in an economy.
natural resources Exhaustible resources such as coal, renewable resources such as fish, and ecosystem capacities useful to humans such as the ability to cleanse dirty water.
neoclassical economics The school of economic thought which postulates that consumers act in a way that maximizes their well-being subject to their income and possibly other constraints, that firms act in a way that maximizes their profits subject to the technological constraints of production, and in general that economic agents act in a way that maximizes an objective function that can in principle be rigorously and completely mathematically described, subject to constraints that can also in principle be so described.
second law of thermodynamics Also known as the entropy law, it states that in an isolated system, entropy cannot decrease; it can either rise or remain constant.
neoclassical theory of value The theory that market prices are determined by the intersection of demand curves and supply curves, which in turn arise from the behavior of self-interested atomistic economic agents; these "curves" may be more complicated than simple functions over Euclidian space.

To explain why a capitalist economy produces certain commodities and how the prices of those commodities are determined, a description must be given of consumers' desire and ability to buy the commodity and of how firms produce that commodity. The description of how firms produce a commodity is in many ways a description of the engineering opportunities open to the firm, although describing the allocation and supervision of labor is also important, as is the firm's access to diverse forms of financing. In describing the engineering opportunities open to the firm, economists usually have to work with a simplified version of all the potentially available technologies in order for the problem to be tractable. However, it is important for the simplifications to obey fundamental physical laws, or at least not flagrantly violate them, so economists studying production should have a basic knowledge of those laws. The writers who first emphasized the relevance of the laws of thermodynamics to production economics were Frederick Soddy (the 1921 Nobel laureate in chemistry), Nicholas Georgescu-Roegen, and Herman E. Daly. The second law of thermodynamics, called the entropy law, has been the focus of most of the work in this field.

1. ENTROPY

The first law of thermodynamics states that in an isolated system, energy is neither created nor destroyed. This law cannot explain why an ice cube placed on a sidewalk on a hot summer day always melts, because the first law would permit heat to flow from the ice cube as long as an equal amount of heat

 © 2004 Elsevier Inc. All rights reserved.

flows to the air. Entropy is the concept used to explain why ice cubes on a hot sidewalk melt and in general why heat always flows from hotter objects to colder ones, as well as why spontaneous physical processes are spontaneous.

The definition of entropy is straightforward. Let T stand for absolute temperature, that is, temperature in degrees Kelvin, denoted K. (Kelvin temperature is 273.15 degrees higher than Celsius temperature.) Let Q stand for the flow of heat into a material (or system, which is a collection of materials). The metric unit of heat Q, as well as that work, is the joule, denoted 'J'; the English unit is the calorie or the BTU. Then the change in the entropy S of the material (or system) is defined to be

$$dS = dQ_{\text{rev}}/T, \tag{1}$$

where the subscript rev stands for a reversible process; physicists call a process reversible if it involves no dissipative effects such as friction, viscosity, inelasticity, electrical resistance, or magnetic hysteresis. If a system undergoes an irreversible process between an initial equilibrium state i and a final equilibrium state f, the entropy change of the system is equal to the integral from i to f of dQ/T, taken over any reversible path from i to f. No integral is taken over the original irreversible path.

Suppose one has an isolated system containing two bodies, one hot and one cold, placed in thermal contact. When a given quantity of heat, Q_0, flows from the hotter body to the colder one, the change in entropy of the system is

$$\Delta S = \frac{-Q_0}{T_{\text{hot}}} + \frac{+Q_0}{T_{\text{cold}}}.$$

Since $T_{\text{hot}} > T_{\text{cold}}$, $\Delta S > 0$. If heat were to flow in the opposite direction, away from the colder body and toward the warmer body, then the Q_0 terms in the previous equation would change sign and ΔS would be negative. Because it is the former and not the latter which is always observed, 19th-century physicists postulated that in an isolated system, entropy never decreases. This is one form of the second law of thermodynamics.

2. THE LAWS OF THERMODYNAMICS

The laws of thermodynamics are as follows:

- *Zeroth law*. Two systems that are in thermal equilibrium with a third are in thermal equilibrium with each other.
- *First law*. During a process in which no heat is exchanged with the environment, the work done is only a function of the initial and final states of the system, not of the path. Furthermore, during *any* process, heat flow, Q, is equal to $U_f - U_i + W$ where U_f and U_i are the final and initial internal energies of the system and W is the net work done by the system.
- *Second law, Kelvin-Planck statement*. No process is possible whose *sole* result is the absorption of heat from a reservoir and the conversion of this heat into work.
- *Second law, Clausius statement*. No process is possible whose *sole* result is the transfer of heat from a cooler to a hotter body.
- *Second law, entropy statement*. In an isolated system, entropy is nondecreasing.
- *Third law, unattainability statement*. It is impossible to reach absolute zero by any finite number of processes.
- *Third law, Nerst-Simon statement*. In the limit as temperature goes to zero degrees Kelvin, the entropy change of any reaction is zero.

Proofs that the three statements of the second law are equivalent can be found in standard texts, as can proof that the two statements of the third law are equivalent.

3. ECONOMIC IMPLICATIONS OF ENTROPY TO PRODUCTION THEORY

3.1 Heat Engines

The first application of entropy was to "heat engines"; these are devices, such as internal combustion engines and power-plant steam engines (in both conventional and nuclear power plants), that use temperature differences to do their work. (A car's motor, for example, will not work in a room hotter than the spontaneous ignition temperature of gasoline.) The efficiency of a heat engine is defined to be its work output divided by its heat input. A surprising and important implication of the second law of thermodynamics is that the maximum efficiency of any heat engine operating between the temperatures T_{low} and T_{high} is $1-(T_{\text{low}}/T_{\text{high}})$. This is less than 1 because T_{low} is strictly greater than zero due to the unattainability statement of the third law. A felicitous explanation of the maximum-efficiency

equation appears in Sir Oliver Lodge's *Energy*. Lodge also explains what it has to do with entropy:

> *If the quantity of heat energy Q is lost by a body at temperature T, and gained by a body at temperature T′, then the entropy lost is Q/T, and the [entropy] gained is Q/T′. The gain is greater than the loss, if T′ is less than T. But if some of the heat is utilised,—converted into mechanical or other forms of energy by means of some kind of engine,—so that only Q′ is imparted to the colder body (the work done corresponding to the difference Q−Q′) then it may be that Q/T = Q′/T′; and in that case the entropy of the system remains constant. This is the condition for a perfect engine conducting a reversible operation. Irreversible operations increase entropy or dissipate energy, for the lost availability cannot be recovered. The efficiency of an engine means the ratio between the portion of heat utilised and the heat taken from the source. It is (Q−Q′)/Q; and we see now that in a perfect engine this would be (T−T′)/T, because the Q's and the T's are then proportional. (pp. 39–40)*

Lodge's "perfect" heat engine is called a Carnot engine; on a temperature-versus-entropy diagram, the cycle of this engine traces out a rectangle, called a Carnot cycle.

This second law limit on the maximum efficiency of heat engines is striking because it establishes a boundary beyond which technological progress will never cross. This has the salutary effect of throwing scientific doubt on the predictions of technological Panglossians who believe that technical progress is unbounded and can eventually remedy any problem facing industrial civilization. On the other hand, not all engines are heat engines (fuel cells, for example, are not), and the second law maximum-efficiency limitation only applies to heat engines.

All engines—and indeed all uses of energy—are, however, subject to another limitation due to the entropy law. Lord Kelvin's principle of the degradation of energy states that whenever an irreversible process takes place, the effect on the universe is the same as that which would be produced if a certain quantity of energy were converted from a form in which it was completely available for work into a form in which it is completely unavailable for work. This amount of energy is the temperature of the coldest heat reservoir at hand times the entropy change of the universe brought about by the irreversible process. As a consequence of this principle, it is never desirable to recycle energy (because accomplishing such recycling requires using up more energy than would be regenerated).

3.2 Chemical Processes

To discuss implications of entropy to chemical rather than mechanical processes—for example, if one wished to analyze fuel cells—it is useful to rewrite Eq. (1) as

$$\Delta S = \int_i^f \frac{C_p(T)}{T}\, dT, \tag{2}$$

where i denotes some convenient initial reference state, f denotes the state of interest, and C_p denotes the heat capacity at constant pressure of the chemical substance. (The heat capacity of a substance, also known as its specific heat, is the amount of heat or work needed to raise the temperature of 1g of the substance by 1 degree Kelvin [or Celsius]. A substance's heat capacity changes slightly depending on its initial temperature.) In a laboratory, Eq. (2) can be approximated to any degree of accuracy by replacing the integral with a sum, as in

$$\Delta S \approx \sum_{j=i}^{f} \frac{C_p(T_j)}{T_j}\,(1\mathrm{K}), \tag{3}$$

where the temperature range from T_i to T_f has been broken down into j parts. Using Eq. (3), the entropy of one gram of a substance is experimentally determined in the following way: Start with the substance at a convenient initial temperature and pressure. Measure the heat needed to raise its temperature from T_1 to T_2, then divide this figure by $T_2 - T_1$ to obtain the specific heat (at constant pressure). Divide this specific heat by the initial temperature; this is $C_p(T_1)/T_1$. Next measure the heat needed to raise the temperature from T_2 to T_3, and divide that by $T_3 - T_2$, then divide that by the temperature; this is $C_p(T_2)/T_2$. Continue until T_j is reached. The change in entropy of the substance between the initial and final states is approximately equal to the sum of the $C_p(T_j)/T_j$ terms, times 1 degree Kelvin to adjust the units.

In this way, the entropy change of different materials can be experimentally determined. The results of such experiments are given—for example, in freshmen chemistry textbooks—in tables of entropies for many substances. For instance, the standard entropy of one mole of copper (63 grams) is 33 J/K = 8 cal/K, where "cal" denotes calories, and where standard (or absolute) entropies are defined with an initial condition of 0 K and one atmosphere pressure and a final condition of 300 K and one atmosphere pressure.

Armed with such knowledge, and the second law's principle that entropy in an isolated system never decreases, the equilibrium proportions of different chemicals reacting with each other can be determined merely by calculating, on paper, which proportions maximize the entropy of the mixture. In other words,

once entropy values have been tabulated, the equilibrium direction and extent of any chemical reaction can be determined without further laboratory work. There is a caveat: while the equilibrium direction and extent of any chemical reaction can be determined, not all chemical systems to go equilibrium; some get stuck in a metastable state in which an activation energy barrier blocks their path to the equilibrium. This barrier can be broken by a catalyst, which works by supplying the activation energy, which is then returned in full to the catalyst.

3.3 General Processes

The entropy law thus governs the efficiency of heat engines, the recycling of energy, and the direction and extent of chemical reactions. More generally, it sets the ground rules within which mechanical and chemical systems operate. Even more generally, it constitutes a fundamental principle of irreversibility in the following sense: Imagine a system that is isolated. By the second law, entropy always increases in such a system (it could remain the same, but only if there were no friction, only perfect machines, and so forth). Choose two dates t_1 and t_2 with $t_1 < t_2$. Then the entropy of the system at t_1 (call it S_1) is less than the entropy of the system at t_2 (call it S_2): $S_1 < S_2$. Then it is in principle impossible to reverse all of the changes that have happened in this isolated system between t_1 and t_2—assuming the system remains isolated—because such a reversal would imply a decrease of entropy. This means that perpetual motion machines are impossible. It means that complete recycling of all a process's components is impossible; some fresh inputs will always be needed for the process to occur again. *A fortiori*, the economy will always require natural resource input of some sort from nature. The economy will never be a perpetual motion machine.

Nicholas Georgescu-Roegen wrote that "the Economic Process has a unidirectional irrevocable evolution" (from low to high entropy), and, in fact, all processes have such an evolution. The activities of an isolated mine, factory, or household—activities that ultimately turn valuable inputs into waste products—are all physically irrevocable. As Georgescu-Roegen and Herman Daly have emphasized, this replaces the typical freshman textbook conceptualization of the economy as a circular flow with an alternative conceptualization of the economy as entailing a one-way flow of matter and energy from usefulness to uselessness.

The type of economic growth occurring over the past four centuries has greatly accelerated this flow toward the ultimate maximum-entropy equilibrium from which no change could ever be made. In speeding up this final end, modern economic growth has produced not just more waste but also wonderful dissipative structures, which, as we learn from the work of Ilya Prigogine, can be the vehicles through which entropy is transformed from low to high. Dissipative structures include machines, human beings, and amazing new technologies like R. Dean Astumian's molecular motors, which function precisely because they are not in thermodynamic equilibrium and can use the resulting chaotic turbulence to do work.

Important as the conceptualization of the economy as a one-way process always dependent on fresh inputs from nature is, two caveats are in order. The first is that the word "isolated" is an important qualifier. A farm, for example, is not thermodynamically isolated from the sun. To construct a proper isolated system for agriculture, the sun has to be included as part of the system. The second caveat then comes into play: while a system as a whole cannot be returned to its previous state, a component of the system—such as a farm's soil—can be returned to its previous state as long as some other component of the system (such as the sun) suffers an increase in entropy sufficient to offset the decrease in entropy of the component that has returned to its previous state. In principle, this means it may be possible to perfectly recycle the materials of any production process that involves or could be made to involve the sun (until the sun dies).

Nicholas Georgescu-Roegen believed such perfect matter recycling to be impossible. Since such an impossibility does not follow from any of the scientifically accepted laws of thermodynamics, he proclaimed this impossibility as a new "fourth law of thermodynamics." Ecologists often believe that nutrient recycling in ecosystems is 100% complete and thus dispute the fourth law's validity. By contrast, economics Nobel laureate Paul Samuelson, in a forward to a book about bioeconomics, wrote that Georgescu-Roegen's "Law of Inevitable Dissipation of Useful Concentrated Matter … is good-sense certainty …: only if all useful copper and gold and helium could be 100 per cent recycled would a *perpetuum mobile* be possible. If pigs could fly, if my Aunt Sally were a stagecoach, if … and if …." So the truth of the fourth law remains in dispute.

As an aside, not only does $t_1 < t_2$ in a closed system imply $S_1 \leq S_2$, but $S_1 < S_2$ in a closed system also

implies $t_1 < t_2$. The second statement has been used to explain the direction of time, "time's arrow." For example, it has been proposed that since we live in a universe whose expansion causes the universe's entropy S to change, the reason we perceive time to increase in the direction it does is that that causes us to conclude that the universe's S is increasing, in accordance with the second law of thermodynamics, not decreasing, which would violate the second law.

4. ENTROPY AND NEOCLASSICAL ECONOMIC ANALYSIS

Neoclassical microeconomic theorists have no difficulty incorporating scientific constraints into their work. Indeed, as far back as Tjalling Koopmans' and Gerard Debreu's work of the 1950s, general equilibrium theorists have explicitly incorporated an irreversibility assumption into their work, as well as a more basic assumption that there cannot be outputs without inputs. Unfortunately, general equilibrium analysis is conducted at a level of abstraction that makes it almost useless for policy applications. (For example, applied general equilibrium analysis of trade policy assumes full employment, which begs the question of free trade's effects on employment.)

Neoclassical analysis of long-run economic growth has been conducted, not using microeconomic general equilibrium, but instead using a macroeconomic framework in which aggregate economic output is assumed to be a function $f(L, K)$ of the economy's stock of labor L and physical capital K, or sometimes a function $f(L, K, R)$ including natural resources R. Inspired by the work of Robert U. Ayres, one notices that elementary mass balance (conservation of matter) is lacking in $f(L, K)$—for where does K come from? Surely not from L, and most physical capital nowadays is not alive and able to reproduce itself! — and it is also lacking in $f(L, K, R)$ in the common formulation where K can be maintained at a constant or even increasing level while R goes to zero.

Neoclassical resource economists have constructed a useful body of microeconomic knowledge about how profit-maximizing firms exploit the environment, as well as the implications of different types of government regulation of that activity. However, these results usually do not treat the overall issue of natural resources in long-run growth.

Fundamentally, no economic technique will be able to definitively foretell the abundance and accessibility of particular natural resources far in the future, nor the need for those resources in the future. Educated guesses are possible, but novelty, contingency, and lack of predetermination mean that it is not possible to predict the future. There is no basis to confidently assume that the future will resemble past centuries, in which technological progress made it possible and desirable to exploit vast, hitherto useless stocks of many different materials found in nature.

5. INTERPRETATIONS AND MISINTERPRETATIONS OF ENTROPY

Equations (1), (2), and (3) are completely straightforward in their literal meaning. However, they give no intuitive insight into what entropy is. Other famous formulas in physics, such as $F = ma$ or even $E = mc^2$, deal with concepts we have at least some everyday familiarity with or understanding of, such as force, mass, acceleration, energy, and the speed of light. By contrast, Q/T or C_P/T are remote and hard to grasp. This has led scientists to come up with interpretations or explanations of entropy. Some of these interpretations are extremely valuable to scientific specialists in the field. Others are unfortunate misinterpretations. Neither the useful ones nor the useless ones have much importance to economists, but their continuing great influence on the historical development of the field makes it important to understand them.

5.1 Disorder, Randomness, and Probability

One of the most surprising consequences of Eq. (1) comes from analyzing the mixing of two ideal gases in a container whose walls allow no heat to flow. (An ideal gas has molecules that do not interact with their neighbors.) At first sight, the formula textbooks give for the resulting change of entropy—which is

$$\Delta S = -R\left[n_1 \ln\frac{n_1}{n_1+n_2} + n_2 \ln\frac{n_2}{n_1+n_2}\right], \qquad (4)$$

where n_1 and n_2 are the moles of the gases and R is the universal gas constant (8.31 J/(K · mole)—seems wrong, because since no heat can flow into or out of the container, it seems from Eq. (1) that the system's entropy cannot change. This doubt about Eq. (4)'s validity is incorrect. Entropy change is not $\int_i^f dQ/T$

(which is zero in this case) but rather $\int_i^f dQ/T$ over a reversible path. The mixing of two ideal gases is not reversible. The only way to calculate the entropy change accompanying the mixing of two ideal gases is to replace the original irreversible path linking the states before and after the mixing with a reversible path linking those same states, then performing the integration. Because entropy change is a function of the initial and final states only, entropy change along the new reversible path, which can be calculated using Eq. (1), must be the same as the entropy change along the original irreversible path. Along the reversible path, heat does flow, and the entropy change turns out to be Eq. (4), which is greater than zero.

The remarkable result that mixing two gases increases entropy has led observers to think that there is more to the idea of entropy than expressed by Eq. (1)—that entropy measures increasing mixing, or spatial disorder, or even some general notion of order per se. This is incorrect. Increasing entropy does not mean increasing disorder in any intuitive, layperson sense. For example, the spontaneous (i.e., entropy-increasing) evolution of an oil/water mixture is toward oil on top, water on the bottom, which is hardly increasing disorder according to any intuitive meaning of the word disorder.

Confusing the issue is that while increasing entropy does not mean increasing disorder in any intuitive, layperson sense, it does mean increasing disorder in an abstract, highly technical sense defined by the Boltzmann equation

$$S = k\ln W + S_0, \tag{5}$$

where k is Boltzmann's constant (1.38×10^{-23} J/K), where the constant S_0 is, by tradition but not by necessity, set equal to zero, and where W is defined by Eq. (6), where N is the number of particles in the system and n_i is the number of particles in energy level i:

$$W = \max_{n_0,n_1,\ldots,n_k} \frac{N!}{n_0!n_1!\cdots n_k!} \text{ such that} \tag{6}$$

$$\sum_i n_i = N \text{ and} \tag{7}$$

$$\sum_i n_i \cdot (\text{Energy level } i) = \text{Total system energy.} \tag{8}$$

(Note that $N!/(n_0!\, n_1!\ldots n_k!)$ is the number of ways that N distinguishable objects can be put into groups of n_0, n_1, …, n_k objects.)

While W defined in Eq. (6) is not a random variable and comes from combinatorics not statistics, Boltzmann christened it the thermodynamic probability, which has led observers to incorrectly think that entropy has something to do with randomness. On the other hand, another interpretation of Boltzmann's ideas does involve randomness. In this interpretation, the maximization operator in Eq. (6) is dropped, and W becomes a random variable, which takes on the value $N!/(n_0!n_1!\ldots n_k!)$ with probability

$$\frac{N!/(n_0!n_1!\cdots n_k!)}{\sum_{n_0,n_1,\cdots,n_k} N!/(n_0!n_1!\cdots n_k!)}.$$

The problem with this interpretation is that it allows the second law to be violated with nonzero probability, and such a violation has never been observed.

Boltzmann's ideas have grown into the important science of statistical mechanics, by which the entropies of various substances are explained, from a molecular level; the older classical thermodynamics described how to measure entropy but could not explain why it should take on a particular value for a particular substance. For extremely simple physical systems, statistical mechanics does imply that lower entropy states are those which are intuitively more ordered and less random. Thus, one mole of a substance in the form of a simple solid has lower entropy than if that mole is in the form of a simple liquid, and that in turn has lower entropy than if that mole is in the form of a simple gas. Also, random mixtures of simple substances have higher entropy than if those substances are ordered into unmixed, pure components, as seen in Eq. (4). However, most substances are not simple in the sense necessary for this intuition to be valid, as the oil and water example showed. Treatments that ignore this caveat—such as Erwin Schrödinger's famous 1944 essay "What Is Life"—should be read with the greatest caution.

5.2 Absolute Entropy

Notice that Eq. (1) defines only changes in entropy; absolute amounts of entropy are not defined. It is sometimes asserted that, by contrast, in statistical mechanics absolute entropy is defined—equivalently, that the constant S_0 in Eq. (5) must be zero. Modern treatments of entropy and its physical meaning show that this is not true. This controversy has no bearing on laboratory entropy measurements, which always measure entropy differences anyway.

5.3 Thermal versus Configurational Entropy

Occasionally, scientists find it useful to distinguish the contribution to entropy change represented by Eq. (4)

from other contributions to entropy change. When this is done, the component of the entropy change given by Eq. (4) is called configurational entropy or the entropy of mixing, and the other components of the entropy change are together called thermal entropy. The choice of the term thermal entropy is unfortunate, because it can mislead one into thinking that configurational entropy has nothing to do with thermal changes and hence that configurational entropy has nothing to do with Eq. (1). Configurational entropy is actually just as much a component of Eq. (1) as thermal entropy is.

5.4 Entropy and Free Energy

To calculate the entropy change when an event occurs, the resulting entropy change of the system's surroundings must be added to the entropy change undergone by the system itself. Under conditions of constant pressure and temperature, the former is the energy released by the system into its environment (traditionally represented by $-\Delta H$) times $1/T$, and the latter is ΔS. Adding these two entropy changes together yields a total entropy change of $\Delta H/T - \Delta S = (1/T)(\Delta H - T\Delta S) = (1/T)\Delta G$, where ΔG is known as the Gibbs Free Energy. Tables of Gibbs Free Energies of common substances are readily available, and such a table is all one needs to determine how entropy changes when an event occurs under conditions of constant pressure and temperature. This makes Gibbs Free Energy extremely valuable for chemists, but it should not obscure the fact that entropy is the fundamental physical quantity and that Gibbs Free Energy is a derived quantity of no independent physical importance. Similarly, Helmholtz Free Energy $F = U - TS$ (where U is internal energy) is useful in situations where volume and temperature T are constant, but it is not a fundamental quantity either.

5.5 Information

An equation that looks like Eq. (5) with Eq. (6) appears in the field of information theory, with, of course, entirely different meanings for the symbols. This does not imply any connection between entropy and information, any more than the similarity between the formula for the sum of scores on two student examinations ($e_1 + e_2$) and the formula for the sum of the energy of two hotel elevators ($e_1 + e_2$) implies any connection between student examination scores and hotel elevators. The entropy of information theory, while no doubt quite useful to practitioners of that field, has nothing to do with the second law of thermodynamics.

5.6 Minimum Energy Requirements

Near the end of Section 3.1 it was shown that the amount of energy E degraded during an irreversible process is the temperature of the coldest heat reservoir at hand (call it T_0) times the entropy change of the universe brought about by the irreversible process:

$$E = T_0 \Delta S. \tag{9}$$

Suppose we desire to obtain pure copper from oxide copper ores of the type often found in Africa. Because CuO is thermodynamically stable at room temperatures, breaking up CuO into copper and oxygen would cause an entropy decrease, so it cannot occur spontaneously. Some authors have calculated the amount of the entropy decrease, then used Eq. (9) to assert that T_0 times that amount is a minimum amount of energy necessary to liberate the copper from the CuO. (Their general proposition is that there is a definite theoretical limit to the minimum energy input to a process and that there is no substitute for this minimum energy.) There may be some sense in which this is true, but no amount of an energy commodity (such as coal or electricity) is needed to obtain copper from CuO. What is done is simply to introduce sulfuric acid into the environment of the copper oxide; a typical reaction is $CuO + H_2SO_4 \rightarrow Cu^{++} + SO_4^{--} + H_2O$, which increases entropy and is thus spontaneous. This example shows that there is no minimum "energy commodity" requirement for physical, chemical, and hence industrial processes.

5.7 Entropy and Energy

There is no such thing as low-entropy energy. Entropy is a characteristic of matter, and a substance's entropy changes when the substance reversibly absorbs or emits energy (or when an irreversible process involves the substance and a reversible process linking the same initial and final states would entail the substance's absorption or emission of energy); see Eq. (1).

5.8 Entropy Theory of Value

A glance at a table of standard entropies for different substances will show the error of believing that the lower an object's entropy, the higher its economic value. Similarly, each time one heats a kettle of water

in a kitchen, the water becomes more useful at the same time as its entropy increases. Adding impurities to iron to create steel simultaneously increases the entropy of the metal and increases its economic value. The entropy of oceanic pollutants is decreased by their concentration in the flesh of oysters, but this decrease of entropy makes the oysters unsafe to eat, thus less valuable to humans. So there is no general connection between low entropy and high economic value, nor between high entropy and low economic value. It is true that the process of production and consumption turns valuable inputs into useless waste, with the useless waste having, as a total assembly, higher entropy than the valuable inputs. However, this generalization only applies to assemblies as a whole, not to their component parts.

Furthermore, what is valuable will always be partially determined by psychological, historical, sociological, and in any case nonphysical traits unrelated to entropy; a personal computer made in 1987 was quite valuable then, but would be considered junk now, even if its physical traits are unchanged. Even a simple container of oxygen, whose entropy decreased when it was extracted from air, can be useful and valuable in one situation—helping hospital patients breathe—and be an unwelcome hazard in another situation, such as near a stove.

6. CONCLUSION

The entropy law implies that economic production will never be entirely self-contained or self-replicating, let alone self-expanding. Production will always require fresh inputs from nature, and nature's size, both of terrestrial stocks and of the rate of solar flow, is finite.

Glossary

agro-ecology Crop production as a component of an ecosystem that includes not only the desired species but also, for example, the weeds, water, and nutrient relations; soil characteristics; and human inputs.

cosmogenesis The creation of the whole cosmos in a single event. In some societies it has been seen as an annual renewal of nature.

developed countries Those nation-states with an industrial economy and generally high gross demestic product and commercial energy use per capita, though not necessarily evenly distributed.

extrasomatic Outside the body. In using a bow and arrow, the energy deployed is somatic but the technology used to channel it is extrasomatic.

heterotrophic Nourished from outside—that is, of all organisms incapable of photosynthesis, which constitute most living things except green plants.

intensification Delivery of more product per unit area per unit time, for example, double-cropping of rice or shelling with heavier ordnance.

less developed countries (LDCs) Those nation states with a low level of industrial development and usually a low consumption of commercial energy. Most have high rates of population growth. Sometimes referred to as low-income economies (LIEs).

moa The large flightless herbivorous bird of New Zealand, equivalent to the ostrich, emu, and cassowary. Extinct.

noosphere Concept of Soviet biologist V. I. Vernadsky that there would be a global envelope of thought equivalent to the lithosphere and biosphere.

organochlorine A class of chemical developed in and after World War II with biocidal properties; the most famous is DDT. Without natural breakdown pathways, they have accumulated in ecosystems. Still used in LDCs.

overkill A popular but graphic term for the mass extinction of genera of animals. Originally conceived for late Pleistocene times but extended to the disappearance of the dinosaurs and held in reserve for a "nuclear winter."

pastoralism A mode of life involving herds of domesticated animals pastured over large areas, with seasonal migrations that track the availability of water and animal food.

permanent cultivation The replacement of a preexisting ecosystem with a permanently manipulated agroecology in order to produce crops as frequently as climate and soil conditions allow.

photosynthesis The chemical process of the basis of life, in which the energy of the sun is transformed into the tissues of plants.

precautionary principle A commandment of environmental management in which actions are avoided if there is a probability that they will lead to environmental degradation. Like certain other Commandments, breaches are frequent.

savanna A regional-scale ecosystem of tall grasses with interspersed trees. It usually experiences fire at least once a year and in Africa may well have coevolved with the genus *Homo*.

shifting cultivation Crop production in which the land is allowed to revert to a wilder state once the soil is exhausted or weeding is too onerous. Much derided by colonial administrators but ecologically appropriate in times of low population growth.

teratogenic Of fetuses (usually but not exclusively applied to humans) that are deformed by the mother's ingestion of certain chemicals. Dioxins (of which some are more toxic than others, such as 2,3,4,7,8-TCDD) have been detected as a major cause.

1. HUMAN ACCESS TO ENERGY

plants. So in its 4-million year perspective, human history can be seen as a set of stages of access to energy sources. Early hominids relied on recently captured energy as edible plant and animal material, and at one stage (whose chronology is disputed but may have been as long ago as 0.5 my) gained control of fire at landscape scale. This reliance on solar energy as biomass is also characteristic of preindustrial or solar-based agriculture, but here the concentration of energy is enhanced by making it available in delineated fields or herded animals. Hence, many more people could be fed off a smaller area, especially if water control could be added to the technological repertoire. Once fossil fuels were exploitable for steam generation, solar power could be subsidized by energy from the stored photosynthesis as represented by coal, oil and natural gas. Energy concentration in these fuels was higher than more recent sources, and this trend is continued by the harnessing of the energy content of the nuclei of uranium and hydrogen.

2. CONCEPTUAL FRAMEWORKS

A number of concepts are embedded in this overview of human history. The first is that of a stage of simply garnering the usufruct in the form of plant and animal material that could be gathered, hunted, or scavenged. Most early human societies were probably mobile, so that these early species of the genus *Homo* could be said to have lived in an environmentally determined fashion. Thus, another concept is that of control and the rest of human history can be viewed as a desire to increase the degree of mastery over environmental components, of which energy has been arguably the most important. The first key step was regulation of fire away from the hearth and into the landscape, with the multiple benefits thus brought about, as amplified later in this article. Fire is also at the center of the developments of industrialization, when the combustion of coal released energy that could be controlled via a steam-using technology; its concentration was such that even mobile devices could be pioneered. Direction of the energy of the atomic nucleus has been achieved for fission but for fusion, only the awesome threat of the hydrogen bomb remains available.

Another major concept is that of technology. Apart from eating it as food, humans must access the usefulness of most energy sources via an extrasomatic device. They must learn to preserve and transport fire, for example; crop harvesting is enhanced by the use of an iron blade produced by smelting metal ores with charcoal; the steamship carried goods, ideas, and troops from one end of the earth to the other. The energy made available to growing populations in the 19th century from the potato comes not only from the carbohydrates inherent in the tubers but from its better growth when encouraged by bagged fertilizers. Electricity is a flexible carrier of energy that has facilitated all kinds of environmental change, not least in the transmission of ideas about how to control the environment. In all these devices, the hope is that the group will improve their net energy yield—that is, the ratio of usable energy harvested to energy invested as labor, draft animals' food and the making of the technology itself. The major stages in human access to energy before the 20th century and the quantitative results are summarized in Table I.

Technology, however, is not simply a set of inventions. It is the product of, and embedded within, human societies. This means that the strict rationality and "scientific" qualities associated with it are not necessarily found in every application. To begin with, much technology was prescientific, in the sense that it was the product of practical-minded men (sic?), who happened on a better way of doing things. Only after the 17th century did the theory precede the technology in truly scientific procedures. (It has been argued that the steam engine, for example, was pioneered by practical men with no knowledge of the theories of physics.) Certain possibilities follow: it is feasible to reject technology on religious, economic or simply prejudicial grounds, as medieval Islam is said to have regarded the wheel

and sensible nations have regarded atomic weapons. Hence the distribution of energy technologies is likely to be uneven, as is shown by the access to commercial energy today, or by the way in which the adoption of fossil-fuel based technologies took off in the West after ca. 1750 AD but not elsewhere. So access to, and use of, energy in any society is mediated by technologies that are themselves subject to the organization of that society, with all its potentials for, especially, inequalities of distribution.

The relationship of all these kinds of energy use to environment has of course varied according to the intensity of available energy and the number (and density) of people, but a few historical generalizations can be made. The first is that the environment is a source of energy that may be altered as the energy is garnered. An animal population severely depleted by intensive hunting is an obvious example. A savanna fired frequently to drive out game will undergo species' shift as fire-intolerant plants are extirpated. A strip mine changes the ecology in a radius measured in tens of kilometers. Second, while many of these changes may be deliberate and desired by a society, there may well be side effects which are undesired and degradatory. The smoke from unregulated coal burning has been the source of much human ill health in cities since the 13th century, for instance; the fallout from the nuclear accident at Chernobyl in 1986 sterilized large areas of formerly productive land. The possibility of negative consequences of human actions in matters of energy access and use was pointed out in the myth of Prometheus, which retains a certain resonance today.

3. HISTORICAL STAGES OF ACCESS TO ENERGY

None of these stages, with exception of the last, can be given precise dates. Thus the chronology must be read as having wide margins for different places. Agriculture, to quote an obvious example, may have been dominant in southwest Asia by 8000 BCE but only arrived in Australia with European colonization in the 19th century. Coal was used to console Roman soldiers on Hadrian's Wall but is only a significant global influence from about 1800 AD/CE.

3.1 Hunters and Gatherers (4 MY–8000 BCE)

This stage encompasses (1) human biological evolution in the transitions from early African forms of *Homo* to the anatomically modern human of *Homo sapiens* at *ca* 35 ky with a worldwide distribution and (2) cultural development through the various levels of the Palaeolithic and Mesolithic to hunter-gatherers described at and after European contact, usually described as near-recent groups. There are a few remaining groups but a way of life that comprised 100% of the human population in 10,000 BCE now accounts for something less than 0.001% and is shrinking. The term "hunting and gathering" also includes fishing and scavenging; it may also be written in the reverse to suggest the dominance of plant material in most of their life ways.

The environmental relations of hunter-gatherers are dominated by the practice of food collection rather then food production. This is not to say that there is no environmental manipulation in the cause of gaining nutrition or status, but that it is practiced in a context where there is (1) a low population density, (2) no conscious attempt to manipulate the genetics of biota with the exception of the dog, and (3) a mythological context of nonseparation from the natural world and of annual cosmogenesis. For many years, academic interpretation of these relationships postulated a "child of nature" construction in which hunter-gatherers lived in complete harmony with the natural world, taking little from it and exhibiting complete reverence. Yet the development of an ever more efficient technology was characteristic of that age, as it is of industrial and post-industrial times. Devices such as the bow, spear thrower, and blowpipe harnessed the energy of a group of human muscles to direct a missile down a narrow channel. Net energy returns were of the order of 1:5-15 and might rise to 1:40. Controlled fire seems to have been used event in wet places like the lowland tropical forests,!QJ; the Californian Coast redwoods, and the moorlands of England and Wales.

Some examples of hunter-gatherer life indeed fitted a Golden Age view. Work in the 1950s and 1960s on groups like the !Kung San Bushmen of the Kalahari seemed to show that with relatively little effort, a well-nourished population could persist even in an unforgiving environment. It is certainly true that given a large and preferably diverse territory, an abundant staple food (the case of some of the !Kung it was the mongongo nut), and a slow rate of population growth, hunter-gatherers could exert relatively little effect on their environment. Some indeed adopted conservationist attitudes to their resources. Nevertheless,

many historical examples have been shown to have brought about considerable environmental changes.

The most thoroughgoing of such manipulations has been the discovery that the introduction of humans into regions hitherto lacking their presence has resulted in the extinction of large groups of animals, with an emphasis on the loss of large (>50 kg adult body weight) herbivore mammals and flightless birds. The initial scene for this revelation was the High Plains of North America in the late Pleistocene (12-11 ky) but the same phenomenon has been detected in islands in the Pacific and Indian Oceans at later dates, such as New Zealand/Aotearoa (900 CE), Hawaii (600 CE), and Madagascar (700 CE). By contrast, no such overkill phases have been noted for Africa, where humans evolved and spread gradually. Another relationship between hunters and animals sees massive kills but no long-term effects on the populations of the latter since they are so massive (or so rapid at reproduction) that humans at hunter-gatherer densities cannot bring about extinction. This seems to have been the case before European contact on the High Plains of North America. Here, as in the northern forests of Canada, such equilibria did not survive contact with the more energy-intensive economies, whether these were basically agricultural as with the Hudson's Bay Company and its fur traders or the railroads with their hungry and bored laborers. Such interrelationships have been found in recent food-collecting societies: the BaMbuti of the Zaire Basin have traded meat outside their forests to the detriment of duiker populations, for example. Some groups have internalized industrial technology, as with the Inuit, the rifle, and the snowmobile, for example, leading to controversy about their access to traditional prey such as the bowhead whale. Interestingly, no such contentions seems to have arisen over plant life, suggesting that the mythic role of dead animal flesh is deeply rooted in human societies: an aspect of control, perhaps.

At an early stage, hominid energy use must have been totally metabolic in nature, confined to that needed for growth, movement, and reproduction. As cultures became more complex, demands for additional energy grew, with any orientation toward meat consumption likely to cause more impacts than reliance on plant material. Notable technological developments seem oriented to the procurement of meat rather than plants, and in the great artistic monuments of the Upper Palaeolithic in the caves of France and Spain there are no paintings of roots and berries.

3.2 Pre-Industrial or Solar-Powered Agriculture (8000 BCE–1750 CE)

In energy terms, agriculture represents an *intensification* of access. To collect enough energy for survival, an average food collector needed some 26 km^2 of territory as a support system. Subsistence farmers with adequate water supplies can manage on 0.1 ha per head and achieve net energy returns of 1:20. Environmentally, this is achieved by breeding plants and animals in cultural images, by altering ecosystems so as to direct their energy flows at human societies and by coping with the unforeseen consequences of these alterations of the previous patterns. The actual biological channels through which these new patterns were directed varied in time and space. In southwest Asia in 9000 to 8000 BCE, wheat, barley, sheep, and goats were central; in southeast Asia at the same time it was rice above all; in the Americas somewhat later, the potato, tomato, maize, and llama were key elements. Yet the energetics had much in common, as had the environmental consequences.

Compared with hunter-gatherers, the energy is garnered closer to home. There is usually a permanent settlement and the food energy is produced so as to minimize expenditure on travel—hence the development of the field, where a crop is kept within bounds so that its maintenance and yield is under the eye of the farmer, be it wheat or cattle. Energy has to be invested in sowing, weeding, fencing, predator control, storage, and myriad other tasks so that the nearer at hand, the greater the probability of a positive energy balance at dinnertime. The domestication of animals meant that a seasonal round of tapping plants not edible by humans and turning them into milk, meat, blood, and skins could develop on the arid or mountainous fringes of cultivable areas.

Not surprisingly, humans enlisted help in the new diversity of tasks required by the novel economy. Draft animals are not really energy efficient in the sense that they consume food even when not working but they can deliver concentrated power at key times, such as spring ploughing or carrying metal ores to the smelter. They relieve humans of wearisome tasks and may furnish symbols of status. Equally important ameliorations of work came with the harnessing of solar energy in the forms of water and wind power. Perhaps the most important was the realization that precipitation (itself a consequence of solar energy distributions) could be stored and then released at times critical for crop growth or animal watering. Coupled with energy investment in, for

example, terracing, crop production was not only intensified but made more reliable. Since storage and distribution often meant that water had to be lifted, the application of wind power to the chore was another gain. The transformation of energy in wind and falling water to rotary motion also facilitated the technologies of the mill, useful for grinding corn and metal ores as well as lifting water. So as with the bow and arrow in the Upper Palaeolithic, a whole range of extrasomatic technology is brought into action to achieve both survival and wider cultural aims.

Food production is thus the core of preindustrial agriculture and at times of Malthusian pressure, virtually any environmental manipulation becomes acceptable in order to increase the quantity of crop. There are three main types of agroecology: shifting cultivation, permanent cultivation, and pastoralism. The first of these, sometimes regarded as a primitive system, is improved by conversion to permanence, but this is probably a colonialist view of a sophisticated piece of adaptation to forest and savanna environments. Its ecology focuses on the clearance of a patch of near-natural vegetation and the take-up of the nutrient capital into crops. Cleared vegetation may be burned to add to the available stock of nutrients. As fertility falls or weeds become tiresomely prevalent, the patch is abandoned and another opening replaces it. Revegetation then builds up the nutrient stock and smothers the weeds. The crop plants in fact much less efficient at energy capture than the original vegetation, but that loss is traded for the cultural acceptability of the food, herb, spice, and medicinal plants that replace it. Moreover, a cleared patch in a matrix of near-natural vegetation does not readily leak nutrients to runoff, so energy expenditure on adding manure or other sources of nutrients is limited compared with permanently cleared areas. The system is not easily intensified, however, and has to be transformed when population growth necessitates a return to a cultivable patch before the vegetation has restored the nutrient levels. Though generally thought of as a tropical system (especially in forests and savannas), it was used in the deciduous forests of Europe in the Neolithic (7000–5500 BCE) and as late as the early 19th century CE in the Boreal forests of Finland.

The historical energetics of food production are without doubt dominated by systems of permanent cultivation, found all over the world except in polar and subpolar regions. Along with sedentary settlement, they represent one of the truly revolutionary shifts in human-environment relations and the energy relationships reflect the new conditions. The basic agroecology is that of the permanent replacement of the preexisting ecology with crop plants and animals and of progressive intensification of output as populations grow. The energy flow of the land is directed toward the crop biota and all else is labeled as weeds or pests and if possible killed or driven away. As with shifting cultivation, maintenance of nutrient levels is at the heart of the system, and both energy and materials have to be used in their upkeep. Cropping is, of course, a major factor in nutrient loss from the fields, but bare soil is vulnerable to losses from runoff and many systems have adopted strategies for minimizing such losses: cover plants are one such, but the most universal is the terrace, found in a broad belt from the equator to about 55°N and the equivalent southern latitudes.

To harvest the energy in a crop, there has to be considerable energy investment. At some time, there has to be breeding of the best strains of plants and animals for local conditions, with no necessary guarantee of success in prescientific times. More obviously, consider the average field in a preindustrial society. The soil has to be turned over for a start. A spade or digging stick may suffice, or draft animals may be harnessed to a plough with a wooden or metal-tipped ploughshare. The energy pathways can be immediately seen: human energy in the first and animal energy in the second. The animals have to be fed and may thus form part of the energy flows taken by the post-harvest crop. Or indeed they may compete for energy with the human population by needing special croplands: "horses eat people" was a proverb in early modern Hungary. If metal is used then there is an ancillary need for energy in smelting and working the iron. Sowing and weeding need investment, as does the fencing, which keeps the wrong animals out of the crop or the wolves from the sheep at night. Children are very useful for shepherding and bird scaring but have to be fed. Harvesting of plants is generally labor intensive, and only careful built storage will keep at least some of the rats out. Water management also requires energy investment, whether the problem is too much of it or too little. Lastly, many plant foods require cooking since the ability of the human gut to digest cellulose is restricted. Our species is better at processing animal tissues, but the thermodynamics of conversion of plant material to animal tissue ensure that meat in preindustrial societies is a luxury. Yet in many parts of the world, such systems were stable environmentally, nutritionally adequate and even provided surpluses.

On the fringes of settled areas, environments not conducive to permanent agriculture were often

found. Characteristically, these were semiarid in nature, with long periods without rainfall and no permanent surface drainage. Mountains form another category. These could nevertheless be tapped for human use via flocks of domesticated animals in the system known as pastoralism. The fundamental agroecology was the cropping of cellulose in plants inedible to humans by domesticates such as sheep, goats, and llamas (and many more species adapted to particular environments, such as the yak), whose sustainable products could be stored for later consumption and trade. Many dairy products have their origin in such systems and surplus animals might be sold off for meat (and skins) though eaten only rarely by the pastoral communities themselves, who, however, sometimes tapped blood from the live beasts as a source of protein. The energetics of this system are more like hunting and gathering than permanent cultivation in the sense that there has to be continual movement, in this case so as not to overcrop the vegetation. One form of the life way involves the movement up mountains in the summer. This transhumance was common in Europe until the 19th century, and a form of it persisted among people of Basque origin in Nevada until very recently. The energy flow of this system is generally completed by the selling off of most of the embedded energy in the animals and their products to sedentary societies, and there is no investment in nutrient levels. Once the pastures are visited often, then the photosynthetic efficiency declines as the species' mix shifts toward the arid tolerant and more bare ground is seen.

Fishing was often an efficient method of garnering energy since the investment came more or less free as river water, lakes, or wind in sails. Energy investment in construction of boats, weirs, and traps was generally long lasting: only nets required frequent renewal. Yet fish were usually an adjunct to diets: only in a very few places were agricultural societies dominated by their consumption, though as an addition to the palate of flavors they have long been popular.

One outcome of these systems was that they could often provide a surplus. This could be used to fuel, so to speak, population growth in the producing society. Alternatively, it could be mulcted off to feed a superior class who did not have to toil in order that they might eat. Instead they might effect environmental change in other directions. One direction might be that of developing certain nonagricultural skills full time: itinerant metalsmiths are postulated for prehistoric Europe, and presumably the astronomers of ancient Babylon did not grow their own barley. Likewise, the management of forests could become a specialized occupation, with a society recognizing that the maintenance of its chief energy source apart from food was a key element in its survival. This was especially so in the great ages of empire building and trade in wooden ships, when ship timber became a key instrument of national policy for countries such as Great Britain and France. At a less material level, philosophers and university faculties might not have to bake their own bread, though interestingly monastic houses and rural clergy were usually required to be self-sufficient to some degree, even though the latter might be entitled to a tithe of local crops. The most visible product of diverting energy into the hands of an aristocracy (who in a fascinating piece of etymology in English wielded "power") was pleasure and conquest. The latter came by feeding large numbers of soldiers, usually by local communities and on an involuntary basis, diverting the energy stored after the last harvest into the army's day-to-day maintenance. The former can be seen in landscape relics such as hunting parks and gardens. Many a European city park was once the playground of the King or the Archbishop: St. James's and Hyde Parks in London had such a royal origin. The gardens of the Alhambra Palace in Granada were the work of the governors of the moorish province of Andalucia. Lastly, energy might be invested in the afterlife: only very productive irrigated cereal-growing provided enough surplus to feed the laborers who built the Giza pyramids in Egypt.

Above all, perhaps, surpluses made possible the city. Although small by today's standards, they represented concentrations of stored energy in the form of structures. They lived heterotrophically off imported energy as food and fuel, which they transformed into all kinds of wastes. (The basic ecology of today's cities is not very different.) Though gardens might produce food and water mills some energy, their citizens were mostly dependent on their hinterlands, for which a certain nostalgic reverence turns up as early as classical Rome. Some of the energy and matter was however turned into knowledge and stored not only in people's heads but in writing. It is difficult to see how the growth of abstract thought could have taken place without the concentrations made possible by the energy surpluses allowed by well-conducted agriculture. Even before the steamship, the control of wind power allowed the improvement of food production by its facilitation of transferring new crops to new places. The role of the potato in industrializing Europe followed on from its earlier spread out of South America, for example; the penetration of all kinds of European practices into

the Americas can scarcely be contemplated without the horse. So good energy trappers were taken around the world. It might be arguable that the major takeoff of human population growth usually dated to about 1650 ce was in part fuelled by improved energy capture and that better crops of all kinds were implicated in the improved nutrition. (It can be added that in some countries the use of energy to boil water to make tea and coffee has been suggested as a health-producing measure that added to survival rates. Maybe).

The theme of surplus energy produced by preindustrial agriculture has one apogee: it fed the people who conceived and built the pyramids, the Gothic cathedrals, Angkor Wat, and the Ryoan-ji. Somewhat imperfectly, it must be admitted, Mozart got fed as a result.

3.3 Industrialism (1750–1950 CE)

This is sometimes called the age of fossil fuels. Without doubting the accuracy of the label, note should be made of the exploitation of these energy sources in the years before their full flowering. Natural gas, for example, was piped in hollow bamboos from natural seepages into Chinese towns in medieval times and lit the streets. Coal exports from the port of Newcastle in northeast England fuelled breweries and laundries in London in the 14th century CE. But all this was as nothing compared with the explosion of coal use (followed by oil in the late 19th century and natural gas in the mid-20th century) once the potential for combustion of these fuels to produce steam, kinetic energy of all kinds, heat, and electricity had been realized. Further, once past the mid-18th century, the technology might follow a science in that hypothesis testing and theory building preceded the construction of the machines.

The concentrated energy content of mineralized photosynthesis is central to the idea of surpluses. The environmental relations are characterized by the impacts of getting the fuels and then of using them via, as before, the mediation of technology. The key change from the previous era is the highly positive ratio of energy investment to energy yield at, for example, the pit head and the well head, with ratios of 1:20–30. Even when postextraction processing is complex, as with oil (though not with coal, the earliest fuel of this kind to be used on a massive scale), the ratio is still highly favorable. Only with the large heat losses encountered in the generation of electricity in conventional power stations do the ratios begin to drop toward preindustrial magnitudes.

The energy-environment story of the 18th and 19th centuries is that of the adoption of fossil fuels as the basis of transport, communications, and manufacturing in a set of regions that became what are now called the developed countries (or sometimes the north or the high-income economies [HIEs] or simply the rich) and the failure of other parts of the world to undergo the same transitions. They became the less developed countries (euphemized as the developing countries, or sometimes referred to as the south, the low-income economies [LIEs], or the poor). The reasons for both are complex and outside the scope of this work. The energy available in classical Greece, in 17th century Europe, and China in 1880 CE was about the same but the adoption of fossil fuels brought about radical change. The core areas in, say 1850 CE, were western and central Europe together with eastern North America. Soon to be added were eastern Europe and western Russia, Japan, a few parts of the northern shore of the Mediterranean, and other patches of North America. On the map, the sign of the times was the railroad. Those heartlands are still significant in the sense that they acted as core areas for whole nations to adopt enough of the new technologies to ensure their future access to fossil energy supplies, so the present-day situation in which access to energy (usually measured as per capita consumption of commercial energy) replicates roughly the precedence established in the 19th century. Though wood as a fuel has declined greatly in relative terms (its energy content is about 14 MJ kg, compared with hard coal at 29 MJ kg), in absolute terms its use is still rising due to population growth in the LIEs (Fig. 1).

The myriad ways in which these fuels are extracted and utilized exert considerable environmental impacts, and many books have been written about each of them. There is a basic ecology common to all in which the hydrocarbons are lifted from the earth, processed, and stored, and then transformed into their end uses. These latter may be direct (as heat, for example, to power boilers) or as embedded energy as in fertilizers and biocides. All kinds of machines mediate at every stage and millions of different items are manufactured. The environmental impact of some is obvious and direct: the bulldozer is a good instance. Others are more subtle: stored electricity makes possible battery-operated TVs in remote Asian forests whose people are then able to see HIE consumerism at work, or indeed at play or at prayer. The bulldozer is the culmination of earth-moving equipment that started with the steam crane; microelectronics carry on the tradition of the electric telegraph. In that sense,

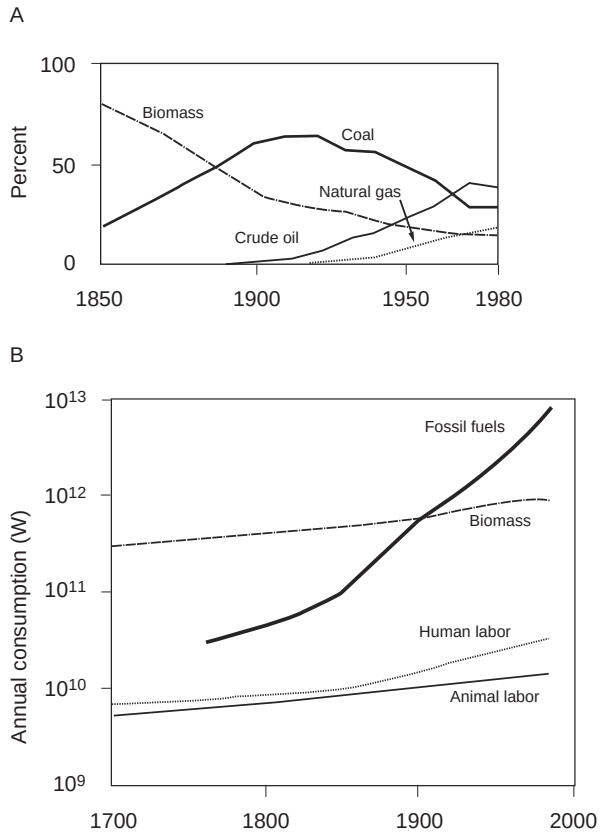

FIGURE 1 The transitions to fossil fuels. (A) shows the global proportions of primary energy for the period 1850–1980 CE and (B) the absolute amounts over a longer time period. Though biomass has declined in relative terms, the rising populations of LDCs (especially in Africa and Asia) have increased actual demand for wood fuel. From V. Smil (1991), "General Energetics." the latter exemplifies the way in which energy as electricity above all carries ideas, which include those devoted alike to changing and protecting the environment. It has without doubt made possible the global coalescence of ideas which have on the one hand allowed corporations quickly to find states willing to accept GM crops but on the other hand pioneered agreements like the Kyoto protocols, which all civilized nations have agreed to ratify.

The historical effects of industrialization on food production are seen in many environmental changes in the 19th century. Many temperate grasslands were ploughed to grown cereals for export to the rapidly growing populations of industrializing regions. The demand for meat also allowed vegetation change in other grasslands as grazing densities increased. All such changes were facilitated by the takeover of areas previously used by preindustrial people (nowadays labeled as "indigenous"), whether officially colonized (as in South Asia where "empty" lands were converted to tea and coffee by British colonial authorities) or internally reallocated, as on the High Plains of the United States. In the case of meat, the technology of refrigeration was critical, as was the reliable transport offered by railroad and steamship. Although to be more a feature of the post-1950 period, the disappearance of the seasons in the rich world began, as asparagus, strawberries, and flowers consumed transportation energy in their journeys from the warm and sunny to the still-emerging-from-winter shops of London, Paris, and New York. The loss of the local, as energy for transport plummeted in price, has its origins in the 19th century, though clearly not confined to that period. One short-lived counter-trend came about in the 1890s in Paris, where there was enough horse-dung to fertilize and heat an export trade in winter salad crops within the city boundaries.

The theme of increased material production can be carried beyond that of food. One result of immense environmental significance was the burgeoning appetite for material possessions, leading to environmental manipulations of all kinds. This was exacerbated by the craving for the new, so that reuse and recycling (a feature of poor societies everywhere) became far less common. Again, the introduction of electricity (as late as the post-1945 in many rural parts of Europe) impelled many authorities to speed up hydropower development, with its many environmental consequences. This is just one of many environmental outcomes of the extraction of energy sources: huge open-cast coal mines in central Europe and oil wells in Mesopotamian deserts were all visible before 1950. The overall impression is of self-amplifying systems in which the extraction of energy is followed by the development of technology to use it and this in turn spawns further environmental change. The motor vehicle is a case in point, where impacts include not only the emissions to the atmosphere but also the paving over of soils, with implications for runoff rates and flood levels on lower ground. Hence, all industrial societies are replete with embedded energy: obvious in the Chicago coal yards but less visible in the suit from Jermyn Street.

As in the previous energy era, opportunities for pleasure were increased. The form of travel now called tourism was made possible by the steamship and the railroad: before the 19th century, a pleasure visit from western Europe to Egypt was too great an

undertaking for almost everybody except the aristocracy. After about 1860, Britons might holiday in Switzerland, beginning a love-affair with the mountains denied them in their own small-scale islands, one which took them to the summit of Everest in 1953. (Actually it was a New Zealander and a Nepalese who first reached it, but imperial attitudes were still strong. The relevance of industrialization is in the specialized gear now used, and the fact that an expedition has had to be mounted to clear up the "litter" from such climbers including some bodies.) The ability to travel to relatively remote places led to conflicts over environmental change: the U.S. National Parks post-1945 slogan of "parks are for people" led to developments that people of later worldviews have found difficult to demolish, in all senses of the word. In a secondary frame, urban electricity made possible all kinds of entertainment, which may well help to inculcate environmental attitudes, whether these be of the exploitive or the conservative kind. Think of oil company advertisements on television or of documentaries on whales.

Only recently has the application of industrial energy to warfare been examined in an environmental context. At one level, there is the way in which calorie production must be stepped up, for soldiers need feeding well, as do the industrial workers who make their munitions. Horses, too, consume cereals and were important as late as 1945. So many grasslands are ploughed up to make way for wheat, oats, and rye crops, with downstream aftermaths for wildflower populations and soil losses. The opposite happens when relict landmines prevent land being used for agriculture: a World War II problem in Poland to this day. But the main impact of industrial warfare before 1950 was seen on the Western Front in World War I. This was in effect a huge concentration of energy use in the form of soldiers, horses, shells, and bullets. The environmental alterations were profound and almost total, as can be sensed from the paintings of John Nash, for example. Yet the land was quite quickly retransformed to agricultural use, and only a few consciously preserved remnants of trench systems are left, though the whole of them can be seen from the air at the end of summer like an archaeological crop mark. The less static warfare of 1939 through 1945 left fewer long-tern environmental changes in Europe but transformed the vegetation, soils, and indeed landforms of some Pacific islands.

If some summative expression of industrialization and environment is sought, then two phenomena stand out. The first is that enough carbon was emitted into the global atmosphere to start the rise in concentration of (especially) carbon dioxide, which underpins today's concerns about climatic change. The mid-18 c is usually taken as the base-level of 280 ppm, to compare with recent values of 360 ppm. The second is the explosion of the city, parasitic on the rest of the world for energy in all forms and for oxygen. The carbon loading has been mostly caused by the rich, but the city's ecology is shared by LIE and HIE alike.

3.4 Post-Industrial Economies (post–1950 CE)

After 1950, most of the indicators of environmental change start to rise in magnitude. Graphs such as those in B.L. Turner's 1990 compilation show sharp upward trends in resource use, waste production, emissions to air and water, and land use transformations. The increases are seen in Table II, where some shift toward an increased proportion being devoted simply to movement can be detected. Most of these are outworkings of increased use of oil, whose ascendancy over coal in this period is unchallenged. So post-industrial economies are in large measure the old fossil-fuel-powered systems writ large in many ways (not least in the geopolitics of oil) but in some of its energy-environment relationships there is something different about the post-1950 world.

For once it is possible to date the genesis of the new world quite accurately: 2.30 p.m. on December 2, 1942, in Chicago, where Enrico Fermi conducted the

first controlled fission of atomic nuclei and thus made possible both military and civilian nuclear power. (The energy content of pure ^{235}U is 5.8×10^5 MJ kg, compared with oil at 43 MJ kg.) The military applications have had some environmental effects, most notably in the fallout of radioactive material from atmospheric weapons testing before the ban in 1963. Levels of long-lived radionuclides (such as ^{137}Cs and ^{90}Sr) built up in high latitudes and have accumulated in the bodies of, for example, the Saami people. The potency of thermonuclear weapons was such that in the 1970s scientists constructed scenarios for a 5000 MT exchange that would produce at least 12 months of virtual darkness in the Northern Hemisphere ("nuclear winter"). This knowledge is sometimes credited with helping to bring about the end of the Cold War. The potency of radionuclides to affect human tissues on all timescales from the immediate to the 240,000-year half-life of ^{240}Pu has accompanied the development of civilian nuclear power where very strict international agreements control the discharges to air and water. In spite of these, nations like Norway and Ireland object vociferously to the marine releases of the UK plant at Sellafield on the coast of Cumbria. Of greater concern, however, is the possibility of accidents resulting in the meltdown of the core of a reactor, as has happened at Sellafield in 1957, at Three Mile Island (United States) in 1979 and at Chernobyl (Ukraine) in 1986. Only the latter was truly disastrous environmentally and to human health but the memory is very vivid all over Europe. Yet of even more extensive importance is the fate of high-level radioactive wastes. Nobody yet knows really what to do with them since they must be sequestered from the environment for about one-quarter million years, a commitment rather like that of the Netherlands in keeping out the sea. One further long-term consequence of this era has been the formulation of chemicals with long-term toxicities, which can accumulate in food chains. The organochlorine pesticides and dioxin are the best known examples with the former causing high avian mortality and the latter implicated in teratogenic fetuses after its distribution in Vietnam as a contaminant of herbicides used in the war of liberation in the 1960s and 1970s.

The adoption of nuclear power in HIEs has mostly been motivated by a fear that fossil fuels might run out, either physically, economically, or politically. The HIE lifestyle is now dependent on relatively cheap and totally constant energy supplies: to interrupt gasoline flow at the pumps for a couple of days is virtually to bring about insurrection, whereas a coal miners' strike for 3 months has virtually no effect. In a similar vein, it takes little imagination to fashion scenarios of a western world without constant electricity. Since capital formation is now a matter of colored numbers on screens, then all kinds of projects to alter the environment might come to a standstill, and the standing of the small screen as a major source of authority in western society (especially if it shows a man (*sic*) in a white coat) would be greatly diminished—no more documentaries about global warming for a while at least.

Unlike the fossil fuel era, it is difficult to designate any particular piece of technology with direct environmental effects as characteristic only of the post-1950 period. In more ways, there has been more indirect effects through capital accumulation in ways that have spun off into environmental projects like the very large dams of the late 20th century planned for China, India, and possibly Turkey. One of the diagnostic features of the post-industrial society, however, is its appellation as a knowledge economy, and there is no quibbling with the fact that the environment is a big absorber of space on hard disks the world over. Cheap and ubiquitous energy makes possible the gathering of environmental data, its storage, and even its transmission in windowless, air-conditioned classrooms.

The present is always impossible to assess in historically oriented accounts and it may well be that the post-1950 phases is not really a new era but simply an intensification of the one that started in 1750. It could equally be the start of a transition to something totally new, in which case the energy-environment linkages would be a central feature along with one of their outgrowths already in place: the creation of a truly global network of instant communication (a noosphere in fact, as envisaged by Vernadsky in 1945) such as there has never been.

4. OVERVIEW FROM TODAY'S PERSPECTIVES

In the perspective of the last 10 ky, access to energy can be seen as having produced tensions in a world where access is highly differential (Table III). In a positive view, many developments have been facilitated, without which today's humans would not even be able to aspire to the cultural richness and diversity that have evolved. By contrast, access to energy has allowed impacts that if foreseen by some omniscient world power imbued with the precautionary principle would likely have been prohibited.

Looked at positively, access to energy has been one consequence of agriculture, which has brought about the possibility of adequate nutrition even for human populations of more than 6 billion: if they do not get it, then the causes are political, not to do with energy capture. In the wake of the shifts to more intensive sources of food than offered by hunting and gathering, a quite wonderful diversity of human cultures came about. (It is interesting that the more up-market the tourism, the further back along this spectrum people want to go, albeit only on vacation.) There are still elites who think that imperialism was a positive outcome of energy made available by gunpowder, the breech-loading rifle, the steamship, and by their latter-day equivalents. Travel has been one further outreach into which energy can be channeled. For humans, there is tourism and space travel (think of the rocket as an updated blowpipe), for instruments gathering data there is the satellite and the remote weather station on a buoy in the Pacific. To sum it all up, there is the city and its urbanized fringes, where the CBD stacks the decision makers in high towers (always a visible emblem of power, i.e., of personal access to energy: recollect as well the personal jet and the LDC leaders' Mercedes) and the suburbs spread out the expenditure of energy and money.

But change inevitably brings loss. Most of these have been irreversible, like the diminution of biodiversity caused by habitat change as, for example, agricultural intensification works toward monoculture or the demand for wood products devastates forests. In the period 1700–1980, forests and woodlands decreased globally by about 19%, grassland and pasture by about 1%, but croplands increased by 466%. Industrialized warfare is better at destruction of all kinds, including life in all its forms, than a few armies raging seasonally across selected terrain. The chemical industry has produced many quality-enhancing pharmaceuticals but has also thoughtlessly allowed out persistent substances that have engendered problems for wild species, crops, and human health alike. One effect has also been to introduce uncertainty: models of climate change are in the end models and can be disregarded on those grounds by those wanting to emulate the moa rather than the ostrich. Though the multiplicity of environmental changes that are problematic for somebody or something is bewildering, the main two for humans can probably be summed up as meat and motors. The energy going into both produces all kinds of patterns that could be rearrayed to the greater good of many more inhabitants of the planet.

If, though, there is only one allowable view of the history of energy and environment, it must be that access to the energy flows and stores of the planet, especially after the 18th century, has allowed the growth of the human population—from about 720 million in 1750 to 6.1 billion of the early 21st century. Whether regarded historically, culturally, technologically, or politically, that view fills the lens.

abundance Number of a species found per area.
distribution Range of occurrence, as in brook trout are distributed in the Appalachian Mountains from Maine to Georgia.
gradient A gradual change in some condition from low to high. For example, there is a gradient in temperatures in the Luquillo Mountains of Puerto Rico from 22° at the top of the mountain to 30° at the bottom.
opportunity cost When an organism uses some of its surplus energy for one activity that energy is no longer available for some other activity.
population dynamics Changes in species' population abundance over time.
succession More or less orderly replacement of one species by another over time in an ecosystem following the relaxation of a disturbance.

The examination of an organism's energy costs and gains along environmental gradients, such as temperatures varying over a terrain, can help establish a central issue for all levels of ecology, which is what determines the distribution and abundance of species and populations.

1. INTRODUCTION

Population ecology is concerned with the distribution of individuals of a particular species over space and time, community ecology examines the distribution of species congregations over space and time, and ecosystem science considers materials transfer and other processes which in turn influences the collective distribution and abundance of organisms within defined environments over time. These issues are equally important to plant and animal ecologists, as well as to those who study behavior and other interactions.

1.1 Observed Patterns in the Distribution and Abundance of Biota

How are species distributed over space and time? There are several important generalities. Usually individuals of a species are more abundant near the middle of their geographic range and become progressively rarer toward the edges, a pattern that approaches a normal curve, or sometimes a skewed normal curve. This generality relates to the assumption that distribution and abundance of a species reflects the probability density distribution of the species' required environmental resources and biotic interactions. A corollary is that populations of species are often found in a greater variety of habitat types near the middle of their geographic range compared to the edges. A second major pattern is that in any given environment some species are relatively abundant, but most are relatively rare. Furthermore, species that are abundant in the center of their range tend to have widespread distributions, and the rarer species may be rare everywhere. Relative abundance also is influenced by differential survival and reproduction, although factors that

cause those differences are often not readily apparent and are rarely quantified.

A third important generality is that species or population abundances usually do not follow repeatable patterns over long time periods in a given environment, even though the number of species may persist. While examples of relatively constant populations certainly exist, such as Spartina grass in many coastal environments and brown trout in small streams, most populations that have been studied over long time periods seem to fluctuate widely in abundance, even when plotted on a log scale. The dynamics of populations tend to be, or at least appear, stochastic and should not be described or modeled by a deterministic or logistic equation. In most environments, populations are almost continually reduced by random environmental disturbances of the many abiotic (e.g., temperature, moisture, light, nutrients) and biotic (e.g., predation, competition, parasitism, dispersal) factors that influence population dynamics.

1.2 The Need for an Integrative Approach

Many investigators have remarked on the general lack of an integrative approach to assessing the many potentially important factors effecting organismal distribution and abundance, as well as the need for more comprehensive approaches of understanding the impact of more than one resource or factor. In fact, many studies have shown that all factors examined were clearly important in determining the distribution and abundance of the populations in question. However, the difficulties and costs associated with measurement of multiple factors in ecological studies are great, especially over the long time periods required to demonstrate interannual variation, which may be essential to inferences. The lack of multifactor empiricism in ecology is also rooted in the lack of a general, unifying theory that (1) integrates the myriad of biotic and abiotic factors that influence species distributions and abundances and (2) provides a mechanism for explaining how organisms or species identify resources and evaluate (or trade off) the costs associated with either obtaining them or adapting to alternatives.

1.3 Multiple Factors and Tradeoffs

Maguire examined the growth response of a phytoplankter as a function of two (or, in theory, more) environmental gradients (e.g., variability in temperature and a nutrient). Maguire then examined how these resources changed over time as the season progressed and temperatures warmed while nutrients were reduced. By integrating the environmental changes in relation to concommittant changes in growth of that species over the year, or between years, he was able to show how abundances and distributions changed as environmental conditions waxed and waned. This seems substantially superior to assuming a constant rate of growth and a fixed carrying capacity, as is the case in the more generally used logistic models.

Many other studies have identified the tradeoffs associated with different resources or adaptations in relation to biotic distributions and abundances. Some very good examples pertain to plant life history strategies, where investments in chemical defense versus growth, fixation of carbon versus nitrogen, efficiency of water use versus carbon uptake, or growth rate versus structural integrity have been quantified. A particularly interesting example is one pertaining to nitrogen concentration of leaves. There is a remarkably linear relation between leaf nitrogen concentration and growth rates of plants. Aspen *(Populus tremuloides)* and other plants with high nitrogen concentrations have high growth rates, probably due to the presence of high levels of carbon fixation enzymes. However, leaves high in nitrogen are also more desirable food for many heterotrophs, from microbes to moose. But this means that high growth rates may also be associated with high loss rates through herbivory, and high rates of herbivory can induce plants to produce chemical defenses. Our point is that approaches emphasizing tradeoffs are important when trying to understand biotic distributions and population dynamics because essentially every resource can be obtained only at the expense of other resources. Smith and Huston proposed a general theory linking vegetation patterns to species-specific physiological and life history traits in relation to energetic constraints on the capture and use of resources. Their approach emphasized fundamental tradeoffs facing plants, such as CO_2 uptake versus water retention (at the level of stomates as well as the whole plant), root versus shoot allocations in relation to the costs of acquiring water or nutrients versus sunlight, and allocation of photosynthate to leaves versus the whole plant. Plants are very plastic with respect to these tradeoffs, both among and within species, by virtue of adaptations.

Any holistic scheme that attempts to provide a comprehensive approach must satisfy at least three

criteria. First, it must analyze, and give procedures for assessing, the tradeoffs that exist among more than two or three factors. Second, explicit explanations must be given as to why these tradeoffs should exist or of the mechanisms by which they operate relative to the observed distribution and abundance of a population or species. Third, they must start from first principles, an approach that tends to work well in other disciplines. Energy is the common currency of ecology and is necessary for any biophysical process to occur. Thus, energy should be fundamental in the development of an ecological theory that attempts to explain the distribution and abundance of animals and plants in relation to the myriad of ecological factors that impinge on all populations.

2. AN INTEGRATIVE APPROACH BASED ON BIOENERGETICS AND FIVE IMPORTANT PRINCIPLES ABOUT ENERGY AND ECOLOGY

The essence of the approach developed here is to integrate energy costs and gains along all appropriate environmental gradients to yield net energy gain in the form of biomass elaboration and reproduction. In this way, the observed distribution and abundance relationship may be explained in terms of the net energy balance or budget of the organism, population, or species. Our central tenet is that a sufficient, positive energy balance must be sustained through time and space such that a significant number of individuals reproduce effectively. If this does not occur, then eventually the population and ultimately the species will decline toward extinction or, through the process of natural selection, adapt some other energy strategy that will permit survival.

It is necessary first to identify five important principles about energy and ecology. First, as identified in many review articles, energy contributes to survival and reproduction of organisms in accordance with our contemporary understanding of basic evolutionary. We believe that the most appropriate way to express this relationship is energy per time, or power, as developed in many publications by Howard Odum and also others. In the words of Ware, "Optimal life history is concerned with power allocation." Energy is vital to organisms in that, other things being equal, the more energy an organism can sequester per unit time, the larger its energy reserves will be to help meet stress and contingencies. Therefore, if an organism can maximize energy intake, it is more likely to reach age of reproduction rapidly and maximize the number of propagules it can propel into the future to perpetuate its genome. Orians and Solbrig summarize this view: "a plant capable of increasing photosynthesis within the constraints of its available resources and the physical environment should gain advantages in competition with other plants, defenses against herbivores, and should have more energy to devote to reproduction."

Second, an examination of an organism's ongoing energy balance allows a less circular definition of fitness than is possible through the more commonly used criteria of reproduction itself. Although at various times in an organism's life its ability to accumulate energy can be satiated, in nature this is very rare. This is especially true with respect to high-quality food items, whose availability is usually limited.

Third, energy balance is important from the perspective of how much energy an organism must divert from growth and reproduction to overcoming contingencies such as adverse environmental conditions. In general, organisms reproduce only from the energy surplus after meeting other contingencies in their life, including growth to a reproductive size. However, when conditions become so extreme that the organism itself has a high probability of death, all available resources often are put into reproduction.

Fourth, the importance of energy as it effects organisms encompasses far more than just the environmentally available or stored (i.e., trophic or elaborated) energy that is usually emphasized. It includes, among other things, metabolic energy drains imposed on organisms by nonoptimal environmental conditions or added stresses, thermal energy gained or lost by behavioral modifications and biotic interactions as discussed later. Most important, however, it includes the energy costs of respirational requirements as well as energy required for an organism to live in and to exploit particular environments, especially suboptimal environments. For example, a rainbow trout is isotonic to water of about one-quarter the salt content of seawater. In fresh or saltwater, that fish must use at least 30% more energy for basal metabolism simply for osmotic adjustments. This is probably one reason that estuaries are such important fish nurseries. Fish can grow better in environments where their basal metabolism is lower. Fifth, in order to grow and ultimately reproduce, organisms require resources and must invest stored energy reserves to get them.

Moreover, all resources vary in quantity and quality. The most important point about energy and its relation to other resources is not that everything can be reduced to energy (which is false) but rather that every material (and most nonmaterial) resource has an associated acquisition energy cost. Most resources become limiting in part because their acquisition may require too great an energy investment on the part of the organism. Thus, high-quality resources are often those that require less energy expenditure per unit of resource obtained. However, with sufficient energy reserves and as constrained by its genome, an organism can divert energy to the acquisition or mobilization of essentially whatever other resources are in short supply, even when their quality is low. Likewise, quality also reflects the value of the energy per kcal of heat content so that, for example, a kcal of food has more utility to an animal than a kcal of incident solar energy and food with a high nitrogen content may be much more useful. We define high-quality resources as those of highest utility that are available to the organism with relatively low energy investment.

Bioenergetics can provide a comprehensive and explicitly testable set of mechanisms for predicting where species will be found and for determining why they are not found in other locations, although it cannot account for conveyance of propugules to new sites. While it is true that organisms need resources other than energy—for example, various nutrients—these other resources can be examined from the perspective of their acquisition energy cost.

2.1 Net Energy Balance: The Elusive Integrator

Each factor that impinges on an organism has energy costs and, in many cases, potential energy gains. The life history strategy (phenology) of an organism is the outward expression of the genetic codification of past successful trials of an organism's energy return on investment. At each point in an organism's life it must invest energy for obtaining more energy while decreasing energy drains and converting tradeoffs about which contingency is most deserving of whatever energy reserves might be available. Tradeoffs occur because most energy gains are obtained only by increasing energy costs—that is, by increasing energy investments. Energy investments by plants to grow leaves versus roots is one obvious example. Another is the energy investment by animals in motility for the purpose of optimizing energy intake from food resources.

Life is a continuous balance of energy investments, each with potential gains but also real and potential costs. As one simple example, plants have energetic tradeoffs whereby the advantage gained by early reproduction tends to be at the cost of future reproduction. For another example, longer-lived but slower growing trees often put large energy investments into energy-intensive structural fibers that generally allow them to survive storms and other contingencies, but at the cost of reduced growth and reproduction. Similarly large, long-lived trees that are easy for insects to find tend to be more heavily defended with secondary compounds that operate to discourage insect feeding. Generally, plants that are exposed to high levels of infestations increase their investments in secondary compounds in subsequent years. In summary, this energy balance perspective derives from the fundamental energetics ideas of earlier investigators as detailed at the end of this entry and involves examination and integration of all pertinent energy costs and gains throughout the life history of the organism. Populations (or species) may be examined in the same context, if one accepts that the net energy balance of the population results from the cumulative energy balance of individuals within the population (or species). This gives a less circular and more mechanistic set of tools to assess tradeoffs facing an organism or population, and ultimately the relative success of its genome, than by using fitness (potential reproductive output) as a direct function of multiple environmental gradients. Ideally both approaches would give similar answers to the same question.

2.2 Energy Costs and Gains in Relation to Environmental Gradients

As noted, population densities tend to be higher in the middle of the species' geographic range, and we can extend that idea to say it is because physical, chemical, and biotic resource gradients are optimal there, which allow maximal energy profits. For plants, light, water, and nutrients are clearly important in this context, and for animals, food derived from photosynthate and (generally) oxygen are essential. For both, temperature, often considered the master regulator, is critical. The concept and data of gradient analysis, as developed initially by Ramensky, Gleason, and Whittaker, demonstrate this fundamental ecological pattern. In terms of our energy balance approach, individuals of a species will be distributed over space and time in a way that may

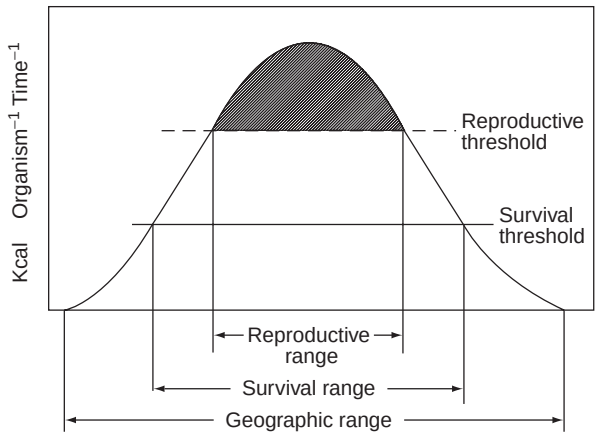

FIGURE 1 Net energy balance of a species over its geographic range. The horizontal solid line represents zero net energy gain for the species (survival threshold)—that is, conditions where energy gain is just sufficient to compensate for basal metabolic energy, plus the energy required to capture food and overcome stress. Below that line, organisms can exist only by consuming their own energy resources. The broken line indicates the larger amount of energy intake needed to generate sufficient energy surplus for reproduction (reproductive threshold). The hatched area of the curve is the only part of the range in which the species can exist in the long term. From Hall, C. A. S., Stanford, J., and Hauer, R. (1992). The distribution and abundance of organisms as a consequence of energy balances along multiple environmental gradients. *Oikos* **65**, 377–390. Used with permission.

be idealized as a more or less normal curve representing energy return on investment along a gradient (Fig. 1). Two important points derive from Fig. 1. First, individuals near the center of the collective distribution enjoy a high energy profit, which allows a large net gain of energy, growth, and either numerous offspring per effort or frequent reproduction. Individuals on the margins of their physiological, territorial, or nutritional range with respect to the gradient are unable to generate a sufficient energy profit to produce population growth. Competition may also be more important at the margins of the range because it raises the cost of resource acquisition and creates more of an impact on individual energy gain in locations on the gradient where the net gain is already small. Hence, if the gradient is favorable and temporally stable, the species will be abundant and widespread, which is consistent with the first generality of observed patterns of distribution discussed earlier. The second point is that rare species are those whose particular morphologies and behaviors do not allow them to be abundant anywhere because they never make a sufficient energy profit. This is consistent with the second generality of observed patterns of distribution discussed previously.

This approach emphasizes that all abiotic variables that may be important for bioproduction of any species may be examined in the context of the energy costs and gains to that species. This is regardless of whether resource limitation is examined in the context of availability of the resource or the ability of the species to obtain the resource. For example, at very low nutrient concentrations, such as the 1 ug/l of bioavailable phosphorus that commonly occurs in oligotrophic lakes (where phytoplankton production is often phosphorus limited), a 10 um plankton cell is surrounded by roughly 100 atoms of phosphorus in the 10 ul of water adjacent to the cell. Even though it may seem that phosphorus atoms are relatively abundant, bioavailability of phosphorus atoms is more influenced by the large concentration gradient that exists between the inside and the outside of the cell membrane. Uptake of phosphorus by the cell to mediate growth requires energy expenditure (active transport). Therefore, nutrient uptake at low concentrations is influenced critically by light. A low concentration of nutrients acts as an energy drain to the phytoplankter, which in turn reduces the reproductive output of the plant and contributes to their low concentrations found where nutrients are low.

Finally, various biotic interactions may also be considered as gradients in our energy balance context. For example, natural selection operates to optimize the risks of predation versus the benefits of exposure to predators in such a way that net energy gains are optimized. Thus, it is possible to view predation energetically from a "Lloyd's of London view." In the old days of sailing ships, Lloyd's knew that a certain proportion of the ships they insured would founder in any given year; but the company management also knew that if no ships left port, no profits would be forthcoming to the shipping industry (or to Lloyd's). On the other hand, captains who loaded too much sail trying to maximize profits usually foundered (or otherwise lost more than they gained) and were selected against. As an analogous example, Gilliam and Fraser found that the risk taken by minnows could be manipulated by changing the energetic return of a foray into predator-infested waters, and that the behavior of minnows in accepting risk was predictable from an energetic model of energy gains and costs. Likewise, it costs energy to avoid predation, including both the direct costs of avoiding food rich areas that contain predators or of manufacturing defenses; there are also the indirect costs of decreased motive efficiency. Using similar reasoning, competition (both inter- and

intraspecific) usually reduces the availability of a resource for one or both of the competitors, and hence may reduce the range or move the optimum location of an organism along the resource gradient. Hence, competition for resources may reduce the net energy profits, unless the organism is a very good competitor, in which case net gains may indeed be enhanced.

2.3 Some Examples of Energy Tradeoffs in Response to Resource Gradients

An important aspect of any analysis of energy balance in relation to resource gradients is that there are opportunity costs to being a particular species or genome. This simply refers to the fact that energy investment in life history strategies that produce prosperity at one place along an environmental gradient (opportunity costs) precludes adaptation to other conditions. Thus, inherent in the concept of phenological energy balance in response to an environmental gradient is the concept of tradeoffs. At any given time, the energy available to adjust to contingencies or to reproduce effectively usually is limited and must be invested wisely.

Often the relations defining costs and gains (tradeoffs) along a gradient are nonlinear. Such nonlinearities, at least in principle, can produce many of the classic hump-shaped growth curves along a gradient found in the literature. In the case of the growth of a particular aquatic insect or fish as a function of temperature, foraging rates increase, often linearly at least up to a point. But respiration increases more rapidly as temperature rises, because of its Q10-type response (Fig. 2A). More complicated relations can exist, especially at the extremes of the gradient, but even so the maximum net gain is normally near the middle of the gradient, even for homeotherms including humans. The net energy return to an organism is the difference between energy gains and energy costs. Thus, the observed growth curve versus temperature relation can be explained as the difference between energy gains and costs along a temperature gradient (Fig. 2). A clear tradeoff exists between temperature and growth for many organisms. Vannote and Sweeney elegantly showed how this idea applied to distribution and fecundity of different species of mayflies.

Bunce and his colleagues measured photosynthesis and respiration of eight plant species that had different distributions over the elevational gradient of moisture on a mountain in Arizona and calculated

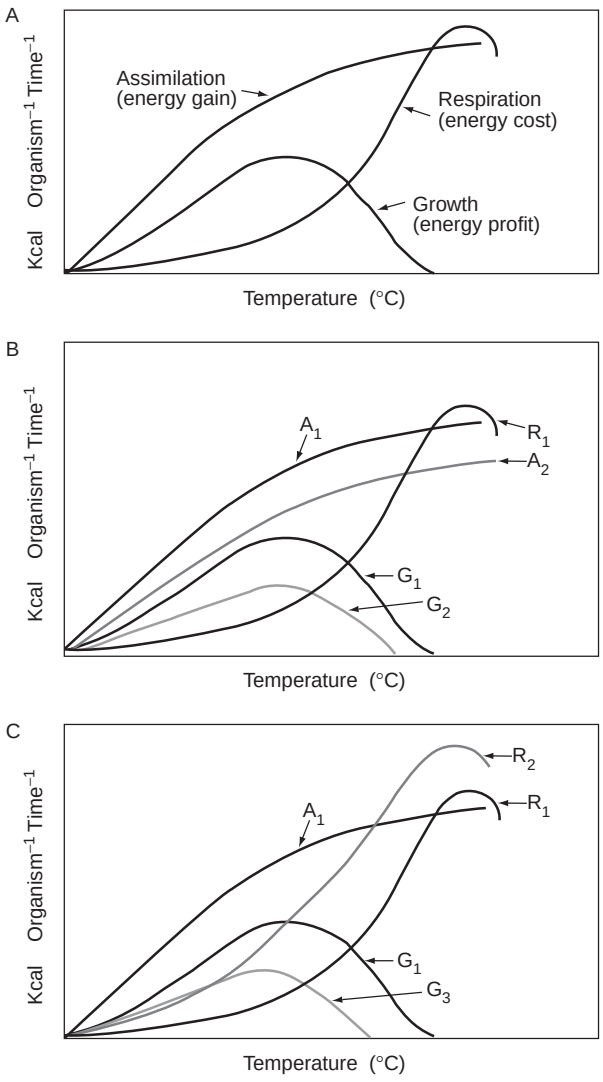

FIGURE 2 (A) Growth of a poikilotherm in response to an environmental gradient (in this case temperature). We hypothesize that net energy profit, which equals growth plus reproduction, is the result of changing energy costs and gains along the gradient. The commonly observed bell-shaped growth curve is the net difference between metabolic energy expenditures (respiration) and gains (assimilation), realized as individual growth (energy profit). (B) Factors that reduce energy assimilation (curve A_1 changes to curve A_2) will result in a decrease in individual growth rate (G_1 to G_2). Decreased quantity or quality of food assimilated may be the result of abiotic factors (e.g., nutrient availability, disturbance) or biotic factors (e.g., competition or predation pressure). (C) Factors that result in increased respiration (R_1 increases to R_2) will also decrease individual growth rate (G_1 to G_2). Increased respiration may be the result of changing abiotic conditions (e.g., caused by disturbance) or manifestation of biotic interactions (e.g., increased search time for food due to competition, increased activity caused by predation pressure). From Hall, C. A. S., Stanford, J., and Hauer, R. (1992). *Oikos* **65**, 377–390. Used with permission.

the carbon balance of each species as a function of moisture and hence elevation. They found that the lower limit of each of the species was approximately 200 m above the zero carbon balance elevation predicted from their field measurements. In other words, each species would not be able to make a significant carbon, and hence energy, profit very much beyond the measured limits of their range. The actual mechanisms for drought tolerance or avoidance were complex, but the net effect was well predicted by their model. Thus, tradeoffs along the moisture gradient were apparent between species. Some had mechanisms, such as a relatively large area of open stomates, favoring high carbon gain caused by high rates of photosynthesis, but they were also prone to high water losses. Other species were more conserving of water but had lower carbon gains.

Trout in a river are principally drift feeders. If they are able to maintain position in rapidly flowing water, the current brings more food to them, but the energy costs of swimming rapidly to maintain position may be too great to maintain a positive energy balance in the long term. Bachman developed a general theory of the energy costs and gains of trout feeding in waters of different velocities. Dominant or fastest-growing fish were found approximately where the difference between the costs and gains were greatest. Thus, dominant trout grew faster where the current was optimal relative to food delivery (energy gains), swimming speed, and duration (energy costs). Young steelhead trout were also distributed along the velocity gradient of a stream approximately as predicted from this model. Brook trout change the area they defend, and their antagonistic displays, as a function of changes in water velocity in a way that maximized the energy efficiency with which they defended their territories. The same kind of result held for pelagic fish and their swimming speeds. Young bleak (a British minnow) voluntarily swam at velocities ($107\,\mathrm{mm\,s^{-1}}$), similar to velocities that theoretically optimized their net energy gains ($111\,\mathrm{m\,s^{-1}}$). In a more general sense, organisms that defend larger territories get more food for their young but must expend more energy in that defense, resulting in a bell-shaped net return curve.

2.4 Molecular and Cellular Tradeoffs

While it is not difficult to find organisms responding to gradients, there is not a well-developed or recognized procedure for *why* organisms should do well at certain parts of gradients and not well at others, or for why this should affect energy gains and costs. There are probably many reasons, depending on the gradient considered, but an important point is that many enzymes controlling growth, maturation, and reproduction tend to have great specificity. Moreover, this specificity is greatly influenced by the environment, especially temperature. Enzymes exhibit thermal optima that correspond closely to body temperatures in the case of homeotherms or to the preferred habitat temperatures in poikilotherms. Organisms tend to seek temperatures where their particular enzyme variants are most effective; therefore, the distributions of closely related species may be explained by variable enzymatic responses within an environmental gradient. At temperatures below the thermal optima, enzymes function slowly. This is due partially to low levels of kinetic energy and partially to the constraints on flexibility because of the specificity of temperature-mediated activities, such as folding, at the active site. Above the thermal optima, the weak chemical bonds that are responsible for formation of transition state structures, and ultimately catalysis, are weakened and break. Various physiological mechanisms have evolved to broaden the functional range of temperatures and lower Q10 values. Clearly, however, there are limits to the functional range of a given protein molecule. In addition, the number of isozymes with different thermal optima available to an organism necessarily is limited to the number of alleles for that enzyme, a maximum of two in the case of diploids (assuming no genetic duplication). There are exceptions. Rainbow trout (*Oncorhynchus mykiss*), a fish with a relatively broad thermal tolerance among salmonids, are tetraploid. As a consequence they have twice as many alleles to generate enzymes as other trouts. Presumably this allows various races of the rainbow to be adapted more specifically to warm or cool water.

It is probably efficient for organisms to have enzymes with a relatively narrow temperature range for metabolic activity, because enzymes that operate well at a given temperature appear to operate less well at other temperatures. This has been demonstrated empirically for different subpopulations of the killifish *(Fundulus heteroclitus)*. Each subpopulation of the fish had an optimal operating temperature where metabolic efficiency was maximized. Moreover, an associated optimal temperature for maximum kinetic performance of lactate dehydrogenase B was observed, which related to swimming efficiency and hatching success. Such tradeoffs along gradients are also important for the structural

components of cells. Membrane lipids, for example, are subject to functional alteration at different temperatures.

2.5 Extension to *N* Gradients

Not all the gradients affect an organism's welfare equally, because some, such as temperature and food quantity and quality, have a large effect on metabolism whereas others, such trace metals, often have minimal effect. But the cumulative effects will be reflected in the organism's integrated net energy balance in relation to each relevant gradient. For example, a tree species may grow progressively well or poorly from the bottom of a mountain to the top, due to differences in temperature. Likewise, it may do well or poorly as a function of sunlight or moisture gradients from one side of the mountain to the other. Shelford introduced and Hutchinson developed the idea that the realized niche of an organism could be determined empirically by plotting the boundaries of that organism's existence as a function of the *N* factors that influenced the distribution of the organism. The resulting *N*-dimensional hyperspace is the definition of the range (and sometimes niche) of that organism. A species is the aggregate genetic code, and its phenotype is the organism that can generate a sufficient energy profit to reproduce at some place along each possible environmental gradient. Since it apparently does not pay to exist along the entirety of each environmental gradient, natural selection of each species is focused on the part of each gradient that allows a sufficient profit for the species to survive and reproduce. This may be a strong factor favoring speciation. Widespread species are those that have evolved mechanisms for making significant energy profits within a large portion of the hyperspace created by all gradients that impinge on the phenology of the species.

Hutchinson's concept of *n*-dimensional hyperspace can be extended such that all relevant resource gradients, and the energy costs and gains for an organism to live along each of those gradients are integrated graphically and mathematically (Fig. 3). The well-being, growth, and eventual reproductive success of the organism is defined by the interpretation of energy costs and gains on all gradients that influence the organism's phenology. For purposes of illustration, these energy profit gradients can be envisioned as a Chinese egg set of *N* dimensions, with the exterior egg representing the limits of the organism's range. Where individuals

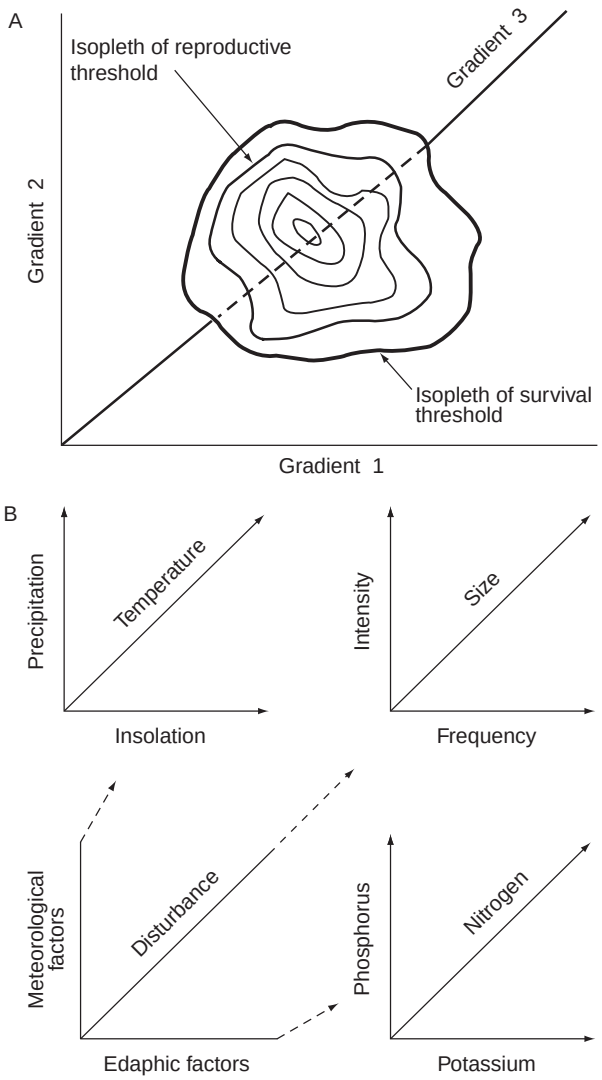

FIGURE 3 (A) Isopleths of net energy profits, defined as energy gains minus costs, of a species as a function of three environmental gradients. Net energy profits and, hence, species distribution and abundance respond to the influence of each environmental gradient involved in the energy balance of the species. Smaller energy profits therefore are shown as isopleths occurring successively outward from the point of optimum profit in relation to these three gradients. Although drawn hypothetically here in just three dimensions, in reality energy profits are influenced by many (*N*) environmental gradients and should be visualized in the context of an *N*-dimensional hyperspace (see text). (B) One way to display the effects of more than three gradients simultaneously. In this case, the figure is showing nine gradients (three each: edaphic, disturbance, and meteorological) thought to influence the distribution and growth of plants and animals in the Luquillo Mountains of Puerto Rico. Edaphic gradients include soil nutrient (e.g., N, P, K) concentrations, disturbance gradients include intensity, size, and duration of hurricanes, landslides, and tree-falls, and meteorological gradients include the relation between precipitation, temperature, and solar insolation at different altitudes in the mountains. From Hall, C. A. S., Stanford, J., and Hauer, R. (1992). *Oikos* **65**, 377–390. Used with permission.

of a species range beyond where they can survive for long periods, the next interior egg represents the survival range, and so on. Reproduction takes place within some interior egg, which represents an even greater optimization within the hyperspace. Maximum reproduction takes place at a center of gravity representing simultaneously the midrange of all impinging gradients. Thus, many gradients can be represented and analyzed as in Fig. 3.

2.6 Niches, Succession, and Competition

In the context of this energy balance perspective, a Gaussian niche is the volume of all possible energy profits for a species within the hyperspace of all gradients to which the organism might be exposed. A Hutchinsonian niche is the volume of all realized energy profits for a species and is at least partly dependent on the geographical history of the species. Succession, then, may be caused in large part by the changing energy profit regimes of the environment in response to the presence or absence of various species and the changes produced on that site by various species over time. It is not clear whether species generally affect other species by any other mechanism than by changing the quality and hence energy cost of resources. For example, trees influence understory plants by shading or lowering available nutrients. The conditions favoring a positive energy balance for particular species change over successional time.

Competition often has been invoked as the principal mechanism that causes the distribution patterns of organisms, but that view seems to be increasingly called into question. The data of Whittaker, for example, show plant species distributed along elevational gradients in more or less random patterns, rather than in avoidance patterns that would be more consistent with competition. This indicates that the species are not causing each other to move "away" from one another on the gradient. Although few ecologists would argue with the existence of competition in nature, there is a very large difference between establishing its presence and attributing to this one factor the fundamental role in structuring communities. Where competition is demonstrated to be operational, it can be factored easily into the energy balance analysis promoted herein. As noted earlier, exploitive or interference competition can alter the availability of a resource and impact the energy balance of the competitors. For example, light-intolerant shrubs are aided by the shading of other plants (exploitation) or one species may produce a substance that is toxic or stressful to another (interference). Such influences can be treated as additional gradients (axes) that impinge on the organism's energy balance. If enough axes are examined, the concept of competition may not be as relevant in explaining the displacement of different species along resource gradients. Each species simply does not have the morphological, behavioral, or, especially, physiological (biochemical) wherewithal to provide an energy balance that allows it to exist along the full length of all important gradients.

3. METHODOLOGY FOR MEASURING ENERGY BALANCE WITHIN N GRADIENTS

Species-specific responses of individuals at locations within many environmental gradients result in a complex pattern of energy costs and gains. This seemingly intractable pattern can be analyzed and predicted by using simulation modeling, if the basic input data for each gradient exist. First, an appropriate time loop is generated. Then, the environmental gradients are established mathematically according to historical or simulated patterns. Geographical specificity can be included; for example, procedures have been developed for projecting meteorological information from a single station to a montane landscape. Next, the individuals are located mathematically along each relevant environmental gradient for each time unit (month or day or hour) as a function of the species' known preferences or behavior in response to each gradient. Data on the energy costs and gains are needed for each gradient as per Fig. 2. Then, all costs and gains are summed across gradients for the time period of interest or as the various state variables (gradients) are changed.

4. ENERGY BALANCE AND POPULATION DYNAMICS

A final point is that the multifactorial energy balance approach given here should be useful in attempting to understand population dynamics. Very simply, the net energy balance of a species changes as environmental conditions change. Temporal variations are inherent in resource gradients, and phonological energy balances will likewise vary. Therefore,

populations will be dynamic in relation to net energy profits invested in offspring and the energy balance of those offspring as environmental conditions become more or less favorable over space and time (Fig. 4). This replaces the dogma that survival is the only determinant of future population levels and leads to mechanistic, explicitly testable hypotheses that can be applied to any individual or population. One good example of where the energy balance approach might be useful in producing a more realistic explanation of year-to-year variation in abundance of a species is in regard to recruitment variability and the dynamics of commercial marine fisheries. For years, fisheries managers have focused harvest goals on density-dependent (logistic) responses in considering controls on stock-recruitment dynamics. However, in the multispecies, environmentally complex world of most exploited marine fisheries, the implications of the analysis in Fig. 4 seems to be much more appropriate based on the rationale of this paper.

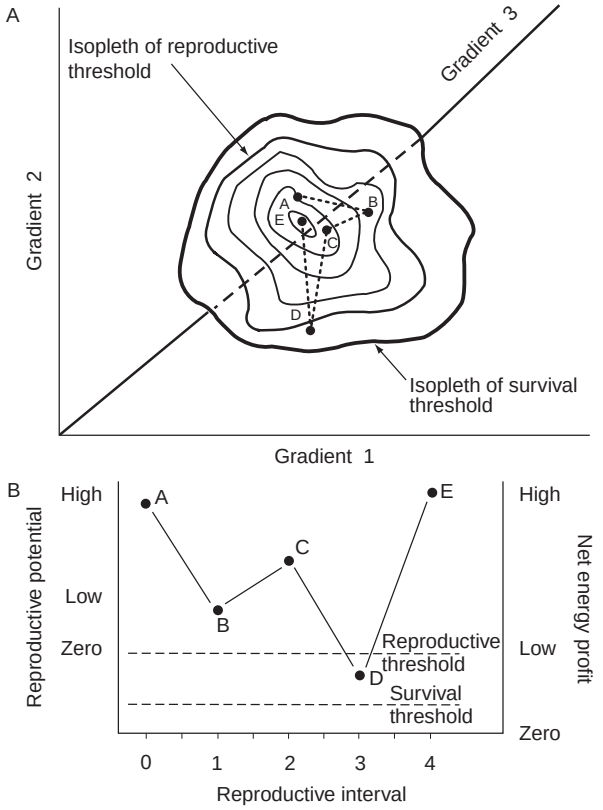

FIGURE 4 (A) Net energy balance (isopleths) of a population existing at A–E different positions within the *N*-(in this case three dimensional) hyperspace determined by important ecological gradients that influence growth throughout the life history. (B) Temporal reproductive potential of the population represented in Fig. 4A. In this example, the cumulative energy gains of individuals exceed losses and the population survives, although investments in reproduction are variable over time. For genomes that die after a single reproductive effort and do not have multiple cohorts (e.g., many insects), population extinction would occur at D. For organisms that live many years (e.g., most commercially important fishes), such year-to-year fluctuations in reproduction and similar changes in death rates lead to the population dynamics that we observe. 5. SUMMARY

This article began with a discussion of generally observed patterns of biotic distributions. It concludes that these patterns can be explained as a consequence of energy balance along multiple environmental gradients due to species-specific energy costs and gains (energy balance) in response to the many (Hutchinsonian *N*-dimensional) environmental or resource gradients. Competition, predation, and other biotic interactions operate principally by increasing energy costs to the species and can be included in our energy balance methodology as additional environmental gradients of energy costs. Persistence of a population and, ultimately, the species in a given locality will occur only where energy return on investment allows a significant energy profit in the form of propugules. At any given time, energy investment in physiological, behavioral, or morphological adaptations that optimize abundance at one point within the *N*-dimensional hyperspace of environmental gradients precludes the investment of the same energy elsewhere. Within the spatial and temporal range where the species can reproduce, abundance is related to the stochastic nature of the important environmental forcing functions because energy balance is ultimately controlled by the sum of organismal responses to all environmental influences. Populations tend to be most abundant where their genome allows the optimization of energy profits. Therefore, population dynamics reflect the cumulative effect of environmentally induced shifts in organismal energy balance.

Holistic energy perspectives in the past have been complicated and controversial and often based on very theoretical considerations. But when an energy perspective is integrated with the vast bulk of appropriate physiological and ecological analysis, as done here, the energy approach can generate an elegant and powerful syntheses. The goal here is to

show that energy analysis can be used to integrate formerly disparate components of ecology using an approach that is straightforward enough to require little in the way of going beyond most traditional views in biology. If the energy balance theory presented here is robust, it has the potential of synthesizing ecology at many levels.

Glossary

biomass fuels Any plant or animal matter used as fuel, including animal dung, crop residues, wood, charcoal, or peat.

respirable particulates Airborne particles with diameter less than 10 microns.

vectorborne disease A disease that affects more than one host species and that is transmitted by one host (the vector) to other host species. Many vectors are insects or arthropods; mosquitoes, for example, are the vector that transmits malaria.

working level (WL) One WL is defined as any combination of radon progeny in one liter of air that ultimately releases 1.3×10^5 MeV of potential alpha energy.

working level month (WLM) One WLM is equal to 170 WLs (that is, exposure to an average of 1 WL for a working month of 170 hours).

The energy sector relies on a broad range of facilities to extract and distribute resources, produce energy, and handle wastes. All these facilities benefit those who use the energy produced. But many facilities also create environmental pollution and have negative impacts on human health—impacts that may fall on populations who do not benefit from the energy produced. In some cases the environmental exposures or health impacts of energy facilities, like those of other industrial facilities, fall disproportionately on certain geographic regions or nations, due to the concentration of resources or facilities in certain locations. In other situations, disproportionate burdens may fall on particular subpopulations, including disenfranchised groups such as low-socioeconomic status communities, communities or workers of color, less developed nations, women or men (male workers, for example), children or other age groups, future generations, or susceptible populations. This article describes such environmental injustices, or inequities, associated with energy facilities. It begins with energy production activities related to fossil fuels (coal and oil) and electric power generated from these fuels, and then the article considers in turn the nuclear fuel cycle, large hydroelectric dams, and home use of biomass fuels. International statistics on energy production and consumption are taken from the World Energy Council.

1. COAL AND COKE PRODUCTION

Nearly all the world's coal production—and its environmental and health consequences—is concentrated in Europe, North America, and Asia. Asia accounted for 38% of 1999 global production (China 24%, India 7%). The United States and Europe each produced 23% of the world's coal. The global distribution of coal consumption mirrors that of production rather closely.

1.1 Environmental Impacts of Underground and Surface Mining of Coal

Coal mining traditionally took place underground, with men and equipment following seams of coal deep within mountains. Since the 1960s, surface mining methods have become more common, and today they account for more than half of the coal

 © 2004 Elsevier Inc. All rights reserved.

produced in the United States. In this approach, also known as strip mining, oversized bulldozers remove the land surface until coal is exposed, producing large amounts of waste rock—and dust—in the process.

Historically, destruction of forests often accompanied underground coal mining in the United States. The usual practice in the 1800s was to cut down all trees with commercial value on the overlying land before beginning to mine. Much of the timber was used for props in the coal mine shafts and for railroad ties as track was laid to carry away the coal.

Both underground mining and surface mining of coal cause acid mine drainage. This problem occurs when the mineral iron disulfide is exposed to water and air, leading to the formation of sulfuric acid. Large volumes of acidic liquid drain into local streams, killing fish as well as aquatic plants.

An extreme form of strip mining now being practiced in the Appalachian region of the United States is known as mountaintop removal. As the name suggests, several hundred feet are sheared off the tops of mountains that are close to one another, exposing the coal, which is removed. The waste rock is dumped into valleys so that a set of neighboring mountains in effect become a single plateau. The resulting valley fill buries streams and may become unstable as it becomes saturated with water; its impacts on local groundwater transport are unknown.

1.2 Community Burdens of Coal Mining

Coal production in the United States is highly concentrated in the Appalachian region. The leading coal-producing states, West Virginia and Kentucky, together accounted for 43% of the value of U.S. coal produced in 1997, as reported by the U.S. Economic Census. Pennsylvania and Virginia together accounted for an additional 17%, bringing the total for the Appalachian region to 61% of the value of U.S. coal production. Wyoming, Colorado, and Alabama together account for another 16%. The leading coal states, West Virginia and Kentucky, are also two of the poorest states in the United States, ranking 50th and 44th, respectively, on median household income in 1999, and 4th and 7th on the proportion of their population who lived in poverty (18% and 16%).

In Appalachian communities where mountaintop removal is under way, residents endure dynamite blasts, falling rock, and dust. Property values decline, and many residents move away. Studies of communities near ordinary surface mining in the United Kingdom indicate that particulate concentrations in air are somewhat elevated in these areas, and children in mining communities make somewhat more visits to their doctors for respiratory symptoms such as wheezing and coughing.

On a global scale, community impacts of coal mining in less developed nations are likely to be more pronounced than in the United States and the United Kingdom, which can afford more stringent regulatory controls. For example, the study of surface mining of coal in the United Kingdom reported mean concentrations of respirable particulates (particulates less than 10 microns in diameter, known as PM_{10}) ranging from 14.4 to 22.3 $\mu g/m^3$ (micrograms particulates per cubic meter of air) in nearby communities. A study of surface mining of coal in one of India's major coal fields reported concentrations of respirable particulates of roughly 70 $\mu g/m^3$ in nearby residential areas, as well as concentrations of total suspended particulates (i.e., including larger particulates) of 200 to 500 $\mu g/m^3$ in these areas.

1.3 Impacts to Workers

Communities also bear the burden of disease that occurs among their workers. Coal miners, traditionally men, are at high risk of physical injury from machinery and from strenuous, sometimes repetitive, physical labor. Many coal miners suffer hearing loss from the noise of machinery. Coal workers' pneumoconiosis, also known as black lung disease, is a chronic lung disease caused by exposure to coal dust. As the lungs become progressively scarred with continuing exposure, they become stiffer and lung function is impaired. There is no cure, and the disease is sometimes fatal.

Some coal is converted to coke for use as fuel in blast furnaces in the steel industry. Coke itself is made in a coke oven, where gaseous components of the coal are driven off using extreme heat, leaving the coke as a residue. Coke oven workers, especially those working in undesirable jobs at the top of the oven where fumes are strongest, are exposed to high levels of chemicals known as coal tar pitch volatiles.

A classic 1975 occupational health study by Mazumdar and colleagues, which focused on lung cancer risk to coke oven workers, gives a window onto historical racial inequities in this work setting. The study estimated the men's cumulative exposures to coal tar pitch volatiles based on their tenure in various job categories. As shown in Fig. 1, the proportion of nonwhite workers increases steadily from lower to higher categories of cumulative exposure. This pattern reflects the historical practice

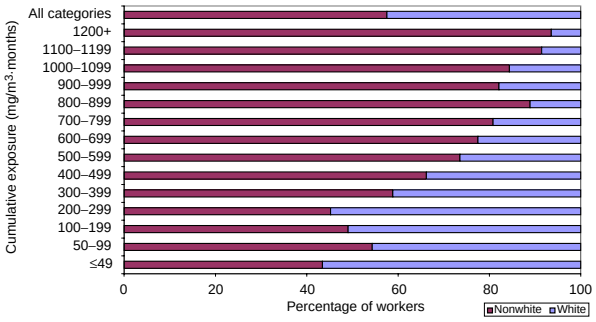

FIGURE 1 White and nonwhite coke oven workers, by exposure category. From Mazumdar *et al.* (1975).

of differentially assigning African-American workers to the high-risk "topside" jobs, while white workers were more likely to be assigned safer positions away from the top of the coke oven.

2. PETROLEUM PRODUCTION

The regions that consume the largest share of the world's petroleum production are not those that produce the largest shares. North America is the largest consumer (30% of global consumption) and is a major producing region (19%), but not the foremost. Similarly, proportional consumption outstrips production in Asia and Europe. The Middle East, by contrast, produced 30% of the world's oil and natural gas in 1999 but consumed a mere 9%.

The environmental and health impacts of oil production can be substantial; the compensating benefits that accrue to producing regions are not only access to the energy produced, but also financial gain from oil sales and political power gained through controlling resources and production.

Where foreign interests control oil production, the host country may bear the environmental health impacts while a multinational corporation realizes the financial gain. Such a situation now exists in Nigeria, which produced about 30% of Africa's oil in 1999. British and U.S. oil companies, in joint ventures with the Nigerian state oil company, have done most of the oil exploration and extraction in the country. Regional populations within Nigeria have bitterly protested the exploitation of local oil resources, with profits departing from the region and environmental contamination left behind.

2.1 Oil Refineries

Most chemical releases from oil refineries are to air. In the U.S. Environmental Protection Agency's (EPA's) Toxic Release Inventory data for 2000, ammonia and sulfuric acid were released in the largest amounts; also prominent were volatile aromatic hydrocarbons that are found in both crude oil and petroleum products (e.g., benzene, toluene, xylene), as well as *n*-hexane and the gasoline additive methyl *tert*-butyl ether.

Like crude oil resources, oil refineries are geographically concentrated, so their environmental and health impacts fall on local populations. Within the United States, the 1997 U.S. Economic Census identifies 244 petroleum refineries nationwide (excluding small establishments). Three states—Texas, California, and Louisiana—host more than 40% of those refineries, representing more than half the total value of U.S. petroleum shipments (Table I).

Petroleum facilities may also be highly concentrated on a more local scale. In Louisiana, for example, data from the U.S. EPA's Toxics Release Inventory show that the 29 reporting petroleum facilities are located in just 19 of the state's 525 five-digit zip codes—mostly near Baton Rouge, in Calcasieu and Caddo parishes on the Texas border, and in parishes near New Orleans. Of all the chemical releases from these facilities, half are from a single ExxonMobil refinery in East Baton Rouge, whose releases are almost five times greater than those of the second-ranking refinery. As shown in Table II, this immense refinery is located in a zip code whose population is 89% nonwhite—about three times higher than the state average. The third-ranked refinery in Louisiana, located in Caddo parish, is in a zip code whose population is 90% nonwhite. The stretch of the Mississippi River from Baton Rouge to New Orleans, known locally as "cancer alley," is home not only to several refineries but also to a much larger number of petrochemical factories. Activists have long protested the concentration of these petrochemical industries in poor, nonwhite communities.

2.2 Oil Storage Facilities

The U.S. EPA's Toxics Release Inventory reported releases from 474 petroleum bulk terminals in 2000. Not surprisingly, some of the largest of these transport hubs are located at ports. For example, five facilities, representing 7% of releases nationwide, are coastal facilities in Greater Boston, and five facilities, representing 4% of releases nationwide, are located in Los Angeles County. The chemicals released in the largest amounts by weight are some of the same volatile organic chemicals released by oil refineries, though the total releases from bulk terminals amount to only about 5% of those from refineries.

Petroleum bulk terminals, as large industrial installations, are often located in lower income neighborhoods. Four of the five Boston-area "tank farms," for example, are located in some of the most poverty-stricken communities in the eastern part of the state. In addition to routine chemical releases and the potential for spills or attacks, communities that host petroleum bulk facilities endure the exhaust, noise, and accident hazards of the many trucks that roll through their neighborhoods each day.

3. COAL- AND OIL-FIRED ELECTRIC POWER PLANTS

Inequitable environmental impacts of burning fossi fuels in electric power plants include local air pollution burdens on disadvantaged populations, regional and international effects of acid deposition, and climate change on a worldwide scale.

3.1 Disparate Impacts of Local Air Pollution

Coal- and oil-fired electric power plants contribute to local air pollution, especially particulates, sulfur dioxide, and nitrogen oxides. In the United States, industrial sources of air pollution tend to be located in lower-income urban areas, and so local impacts often fall most heavily on poor and minority populations. The prevalence of asthma, which may be exacerbated by exposure to air pollutants, has been rising in the United States in recent decades and is particularly elevated among inner-city children.

3.2 Transboundary Acid Deposition

Through a series of complex chemical reactions in the atmosphere, sulfur dioxide and nitrogen oxides emitted from coal- and oil-fired power plants may be converted to sulfuric acid and nitric acid, respectively. These chemicals may be transported hundreds of miles by wind and ultimately be dissolved in precipitation—rain, snow, or fog—and deposited far from their point of origin. Such long-distance transport was brought about by the installation of tall smokestacks in the 1970s; intended to alleviate local pollution, the tall stacks placed air pollution within reach of higher level air currents.

As a result, acid deposition as an environmental impact is very often inequitable, since the receiving area is typically far from the source of the pollution.

For example, acid deposition in the northeastern United States and parts of eastern Canada is due largely to sources in the Midwestern United States. Similarly, burning of fossil fuels in Germany and the United Kingdom contributes to acid deposition in Scandinavia, and coal-fired plants in China were the original source of acid deposition in Japan. Acid deposition can acidify drinking water sources, potentially mobilizing toxic metals such as lead from the sediments of drinking water reservoirs or from drinking water distribution pipes. Acid deposition also harms aquatic life and damages buildings and statues.

3.3 Inequities Related to Global Climate Change

The very designation of "developed" and "less developed" nations identifies an enormous disparity in material security and public health status between these groups of countries. It is inherently unfair that much of the economic growth in the developed nations occurred before the impacts of carbon fuels on global climate were appreciated, whereas the less developed nations must take account of these impacts as they seek economic growth. The dilemma of defining an equitable approach to controlling emissions will not easily be resolved.

Some of the anticipated impacts of global climate change are expected to fall more heavily on less developed countries simply as a matter of geography. For example, warming climates will increase the ranges of mosquitoes and other vectors of infectious disease, and this impact will be felt most strongly in parts of the globe where these diseases, such as malaria, are already endemic. Similarly, much larger numbers of people in the developing world live in low-lying areas that will be threatened by rising sea levels. Small island nations from the Pacific to the Caribbean are experiencing increased temperatures and are uniquely vulnerable to a rising sea level.

The Intergovernmental Panel on Climate Change (IPCC) in its report *Climate Change 2001: Impacts, Adaptation, and Vulnerability* projects that many areas in the developing world are more vulnerable to the effects of global climate change, whereas impacts will generally be more moderate, or more mixed, in North America and Europe. In the more arid regions of Africa, for example, global climate change is expected to exacerbate water scarcity and increase desertification. Food insecurity, already a problem in much of the continent, is expected to worsen due to water stress in agricultural areas and impacts of climate change on fisheries. Increases in temperature and rainfall will increase the range of vector-borne diseases and will also make it more difficult to maintain sanitation, with a resulting increase in waterborne illness. Increased food insecurity and infectious disease are also projected for areas in Asia. In parts of Asia that are already vulnerable to typhoons or cyclones, droughts, and floods, such extreme weather events are projected to increase. IPCC projects that with a 100 cm rise in sea level, 5763 km^2 in India would be submerged, putting a population of 7.1 million at risk. Under the same scenario, Bangladesh could lose 29,846 km^2 of land area, putting 14.8 million people at risk (13.5% of the country's population). Even a sea-level rise of 45 cm is projected to displace 5.5 million in Bangladesh.

The IPCC projects that global climate change will bring more difficult conditions for the southern and Arctic areas of Europe than for other areas of the continent. Pressures on water supply will increase. Crop yields in northern Europe are projected to increase somewhat, though yields in southern Europe are likely to be somewhat reduced. The major direct risks to human health are anticipated from episodes of extreme heat, especially in urban areas, from some increase in vector-borne disease, and from flooding. For North America, a mix of positive and negative impacts is projected. More extreme weather events are anticipated, such as episodes of extreme heat or cold, storm surges, and floods. Overall agricultural production is not threatened under moderate climate change scenarios, though some regions will gain and others will lose in agricultural productivity, and greater warming could cause more disruption of farming. Some increase in vector-borne diseases is also projected. The strong social, economic, and public health infrastructures in Europe and North America are expected to mitigate effects somewhat.

In addition to placing an inequitable burden on developing nations that are less responsible for the problem and less able to manage its impacts, climate change will differentially affect future generations in all regions of the world. More than any other environmental health problem, climate change is global in the scale of its impacts and uncertain in the scope and nature of its intergenerational effects.

4. THE NUCLEAR FUEL CYCLE

Like other energy resources, uranium reserves are unevenly distributed around the globe. The United

States and Canada have produced the most uranium over the long term. U.S. production has fallen off dramatically since the 1980s, but Canada remains the leading producer of recent years. Historically South Africa and Germany have also been major producers of uranium; today Australia, Niger, Namibia, and several countries of the former Soviet Union are producing increasing shares of global uranium output. In contrast, about half of the world's nuclear generating capacity is currently concentrated in Europe and about one-third in North America (mostly in the United States); Japan is the largest user of nuclear power in Asia.

4.1 Environmental Health Hazards of the Nuclear Fuel Cycle

The nuclear fuel cycle, with its unusual suite of environmental health hazards, raises issues of environmental inequity distinct from those of fossil fuels. Nuclear power plants do not produce air pollution in the normal sense of the term, nor do they contribute to global climate change. The hazards associated with nuclear power are those of ionizing radiation, and include the potential for catastrophic reactor failure as well as the unique challenges of disposing of wastes that remain radioactive for thousands or millions of years. Until the emergence of global climate change as a threat to human health, nuclear power was unique in shifting to future generations much of the burden of health risk associated with today's energy production.

Short-term exposure to high levels of ionizing radiation, as in a nuclear accident, may be rapidly fatal or may cause radiation sickness—a syndrome that includes effects on the blood-forming system, the gastrointestinal system, and the central nervous system. Exposure to lower levels of ionizing radiation over a period of time leads to an increased risk of leukemia and of other cancers including cancers of the thyroid, bone, lung, and breast. Birth defects including microcephaly, growth retardation, and mental retardation have also been associated with low-level exposure to ionizing radiation *in utero*.

4.2 Distribution of Nuclear Energy's Benefits and Risks

The distribution of benefits and public health risks associated with nuclear power is inherently inequitable, simply in geographic terms. The "front end" of the nuclear fuel cycle (uranium mining and milling, and fabrication of reactor fuel) offers no benefit to local populations, other than employment, and workers in uranium mines and mills are exposed to elevated concentrations of radon gas. When radon gas is inhaled, exposure to its radioactive breakdown products, known as radon progeny or radon daughters, increases lung cancer risk. People living in nearby communities are also exposed to radioactive dust from the freestanding piles of waste rock (called tailings) left near mines and mills. In some communities, tailings have been used as construction materials for roads or even homes, resulting in higher radiation exposures to residents.

The hazards associated with mining and milling are usually located far from the people who benefit from the electric power produced by a nuclear reactor. Those populations, often in densely populated areas, do, however, bear the uncertain risks associated with routine low-level radioactive emissions and would be hardest hit in the event of a severe accident—though the incident at Chernobyl demonstrated how geographically widespread such impacts can be. At the "back end" of the nuclear fuel cycle, specially constructed waste repositories are ideally located in isolated areas, which would typically be far from the beneficiaries of the power plants that produced the wastes. This strategy reduces the size of the population at risk, but shifts the burden of risk to people who got no benefit from nuclear power. In the absence of such a repository, spent fuel may be held for long periods at the power plants, as currently in the United States, or disposed of in a less secure manner.

In the United States, most uranium mines and mills are in the West—predominantly in Arizona, Colorado, New Mexico, Utah, and Wyoming. The 103 nuclear power plants operating in the United States in 2003, by contrast, are mostly located east of Kansas and Nebraska. Indeed, if a map of uranium mill tailings piles were overlaid on a map of nuclear power plants, the tailings piles would drop neatly into an area not served by nuclear power. Yucca Mountain, in the southernmost corner of Nevada, is the long-planned site for permanent disposal of U.S. nuclear power plant wastes. The wastes are to reach this remote location by rail lines that crisscross densely populated areas that benefit from nuclear power, regions with no nuclear activities at all, and areas already heavily affected by uranium mining and milling.

4.3 Profile: Differential Impacts on Native Americans of the Nuclear Fuel Cycle in the United States

4.3.1 Early Uranium Mining in the United States

The Four Corners region—where Colorado, New Mexico, Arizona, and Utah meet at right angles—is home to rich reserves of carnotite, an ore containing oxides of both uranium and vanadium. The Navajo Nation is here, located mostly in Arizona but extending into New Mexico and Utah. Carnotite was first mined on a small scale in the early 1900s for the orange color it gave to ceramic pottery glazes. During World War I, radium was in demand for painting instrument dials, and between the world wars vanadium—used to harden steel—was much sought after. But uranium mining began in earnest in the early 1940s with the start of the Manhattan Project and the loss of Czechoslovakian uranium reserves to the Nazi invasion of that country. It became a true boom industry in the late 1940s when the U.S. Atomic Energy Commission (AEC) began to ratchet up development of atomic bombs. For national security reasons, the AEC was at this time the sole buyer of the area's uranium, though mining operations were run by private companies. The AEC would soon begin to press the development of nuclear power as well, further increasing the demand for uranium.

When the mining peaked in 1955–1956, there were hundreds of active uranium mines on the Navajo reservation, as well as several mills where the ore was crushed and the uranium extracted. Jobs were scarce on the reservation, and by the time the boom ended, some 2500 to 3000 Navajos had worked in the mines, either on the reservation or in nearby areas. Smaller numbers of Hispanic men and non-Hispanic white men also worked in the mines. These early mines were known for their poor working conditions. Until the early 1960s, there was no ventilation and no protective gear. Large-scale uranium mining in the region ceased in the late 1960s.

Miners' exposure to radon progeny, which emit radiation as alpha particles, is measured in units called working levels (WL). The WL is a measure of the concentration of potential alpha particles in air. (One WL is defined as any combination of radon progeny in one liter of air that ultimately releases 1.3×10^5 MeV of potential alpha energy.) A working level month (WLM) is equal to 170 WLs (that is, exposure to an average of 1 WL for a working month of 170 hours). The federal exposure limit for miners was set in 1971 at 4 WLMs per year.

4.3.2 Evolving Understanding of the Health Risks of Uranium Mining

As early as 1879, a lung disease called *Bergkrankheit* ("mountain illness") was described in uranium miners in the Erz Mountains in Europe. By the time of World War I, lung cancer had been identified as an important cause of death in these miners. Uranium ore had been known for some time to be radioactive, and radon gas had also been identified. However, scientific confusion over whether and how radon might cause lung cancer continued until the role of radon progeny was elucidated in the early 1950s. Still, the link between occupation and illness was clear, and both Czechoslovakia and Germany had begun to compensate lung cancer in uranium miners as an occupational disease by the early 1930s.

The U.S. Public Health Service (PHS) undertook the first study of radon exposure and lung disease in U.S. uranium miners, many of whom were Navajo, through medical surveys during the 1950s. Both the health agency (the PHS) and the regulatory body (the AEC) have been strongly criticized for failing to obtain informed consent from the miners before using them as research subjects and for recording miners' exposures and health outcomes without providing ventilation and protective gear to reduce exposures already known to be harmful.

More than four decades of published research now documents the experience of the early U.S. uranium miners as this cohort has aged, accumulating illnesses and deaths. Exposure to radon progeny has been found to be associated with increased risk of both malignant and nonmalignant lung disease. Further, because the ore in this region is found in formations of quartz sandstone, workers are exposed to silica dust and are at risk for silicosis. Smoking enhances the lung cancer risk of radon exposure—that is, the lung cancer risk of smoking and radon exposure combined is greater than the sum of their separate risks.

In 1990, Congress passed the Radiation Exposure Compensation Act (RECA). Miners who worked during the years that the U.S. government was the sole purchaser of uranium (1942–1971) may qualify for one-time compensation in the amount of $100,000 for primary lung cancer and certain nonmalignant respiratory diseases including pulmonary fibrosis, pneumoconiosis, and silicosis. To qualify, a miner (or his survivors) must provide documentation of a designated medical condition and must also be able to document a certain total radon exposure.

4.3.3 Differential Impacts of Uranium Mining on Navajo Miners

Because most U.S. uranium mines were located on or near the Navajo Nation, the Navajos were vastly overrepresented among the miners, compared to their representation in the U.S. population as a whole. Navajos were more likely to work underground than other miners, partly because they were less likely to hold supervisory positions. It appears that in some small Navajo-run mines, working conditions were even worse than in the larger corporate mines. Some Navajos did not speak English, inhibiting their access to any health information that might have been available to the miners. Thus the burden of the government's ongoing failure to regulate working conditions in mines, and of its conduct of research violating accepted ethical standards, fell heavily on the Navajo.

Although early publications on the U.S. uranium mining cohort included some data on mortality among Navajos, a full analysis of the lung cancer risk among Navajo uranium miners was not published until 1984. This landmark study, led by Jonathan Samet of the New Mexico Tumor Registry, identified all cases of lung cancer among Navajo men in New Mexico that had been identified by the tumor registry and compared the men's work histories to those of a control group of Navajo men not diagnosed with lung cancer. Because every Navajo with lung cancer had a history of uranium mining, it was not possible to calculate the relative risk for this exposure (with a zero denominator, the relative risk is infinity), but the lower bound risk was statistically estimated to be a 14-fold increase. That is, the study found that a history of uranium mining carried at least a 14-fold increased risk of lung cancer, and probably a much higher risk.

A second milestone in documenting the differential impacts of the uranium era on Navajo miners came in a 1997 publication by Douglas Mapel and others at the University of New Mexico comparing the *non*malignant lung disease experience of Native American, Hispanic, and non-Hispanic white uranium miners. The study clearly documented some expected contextual patterns. Nearly two-thirds of the miners (63.4%) were Native American, 24.7% were Hispanic, and 11.9% were non-Hispanic white. A higher proportion of Native American miners had worked only in *under*ground uranium mining (84.3% versus 59.4% Hispanic and 62.4% non-Hispanic white), and a lower proportion of Native American miners had worked only in *above*ground uranium mining (3.7% versus 7.5% Hispanic and 9.3% non-Hispanic white). The study group reflected the well-known differences in smoking patterns—a much larger percentage of Navajos in the study had never smoked (72.9% versus 34.6% Hispanic and 22.2% non-Hispanic white). Further, those Navajos who did smoke had smoked a much smaller number of cigarettes (Hispanic and non-Hispanic white miners had accumulated more than five times as many "pack-years" of cigarettes smoked). Statistical analysis revealed that this difference in smoking behavior had an important consequence: although all three groups of miners experienced obstructive lung disease, among Hispanic and non-Hispanic white miners this condition was largely attributable to smoking, whereas among the Navajo (most of whom had never smoked), obstructive disease was mostly attributable to uranium mining. Other research has documented a similar effect for lung cancer, identifying a situation—perhaps unique in the annals of public health—in which most of the lung cancer in a population is attributable to a single occupational exposure.

To receive compensation under RECA for nonmalignant lung conditions, such as obstructive pulmonary disease or restrictive pulmonary disease, miners must meet certain diagnostic criteria—for example, lung function must be reduced by a certain percentage below normal on a standard lung function test. RECA specified the standards to be used, and they were based on the general U.S. population of non-Hispanic whites. Mapel and colleagues showed that 24% of Navajo miners who would be classified as having restrictive lung disease on the basis of a Native American-specific formula were excluded using the RECA standard. That is, some Navajo miners have been denied compensation under RECA although ethnic-specific criteria indicated that they were sufficiently impaired to warrant compensation. Amendments to the RECA in 2000 adjusted some eligibility criteria.

4.3.4 Differential Impacts of Uranium Mining on Navajo Communities

The risks of large-scale uranium mining were also brought to the Navajo at home, because much of the uranium ore so highly valued by the broader U.S. society was located within the boundaries of the Navajo Nation. The U.S. government, which held reservation lands in trust for Native Americans, freely exploited those resources, with profound impacts to the natural environment and risks to the health of local populations. Especially in the early decades, uranium was mined disproportionately on

native lands. The sense of injustice felt by Native Americans from this experience is reflected in the use of terms such as "internal colonialism," to describe U.S. government exploitation of uranium resources on Native American lands, and "national sacrifice area," to describe the environmental devastation that resulted.

Because groundwater seeped into both underground shaft mines and the deeper open-pit mines, the water had to be continuously pumped out so that operations could continue. This "dewatering" released large volumes of water. A single site might dump tens of thousands of gallons of water per day into local streams—water contaminated with radionuclides and heavy metals. Uranium mills, many located on or near reservation land, left behind enormous piles of tailings, an estimated 140 million tons altogether in seven western states. These heaps of pulverized waste rock are an ongoing source of radioactive dust. In 1979, an earthen dam collapsed, releasing more than 1000 tons of tailings sludge and almost 100 million gallons of water that were carried downstream into a Navajo community. Even the introduction of vents in mines sometimes resulted in community exposures, if vents were placed in populated areas above mines. All these burdens fell on communities that already lived with more poverty, poorer health, and a lower life expectancy than the general U.S. population.

4.3.5 Potential Siting of Nuclear Waste Facilities on Native American Lands

Since the 1980s, the federal government has planned to build a permanent repository for high-level radioactive wastes from nuclear power plants at Yucca Mountain, Nevada, but the expected opening year for the facility has receded steadily to 2010. As the permanent repository has been delayed, pressure has built for an interim storage facility (known as monitored retrievable storage, or MRS), so that spent fuel can be moved from storage sites at power plants. During the 1990s, the U.S. Department of Energy actively sought communities and Native American tribes to host such an MRS facility. The department worked to create an interactive process through which safety provisions and financial or social benefits would be negotiated such that the community would be satisfied that the potential negative impacts of the site had been offset. Though dozens of communities and tribes began the process, extended negotiations were held only with Native American constituencies—the Mescalero Apache of New Mexico and the Skull Valley Band of the Goshute in Utah. Both negotiations ultimately foundered. The Skull Valley Band has since entered negotiations with a private utility to host an MRS, resulting in legal battles that are not yet resolved. Although these Native American groups have participated voluntarily in siting negotiations, the process has nevertheless raised the question of an environmental injustice against disadvantaged populations whose economic need made them vulnerable.

5. LARGE HYDROELECTRIC DAMS

Although hydropower is a renewable energy technology and is often seen as relatively benign in terms of pollution, its facilities may have very different impacts on different populations.

5.1 Hydropower and Environmental Equity

Hydropower is a well-developed technology that is relatively accessible to developing nations. At present, five nations—the United States, Canada, China, Brazil, and the Russian Federation in that order—are global leaders in hydropower capacity, together representing almost 40% of the world's operating capacity. Dam projects now under construction worldwide, including the massive Three Gorges Dam in China, are expected to increase current global operating capacity by 16%. Taking account of capacity currently under construction or in the planning stages, China and Brazil are expected in coming years to push the United States and Canada to the third and fourth ranks, and India is expected to move up into sixth place behind the Russian Federation.

Thus, at a global scale, hydropower is becoming more equitably distributed between richer and poorer nations. On the smallest scale, too, when the benefits and burdens of small dams are shared by the same people, hydropower's impacts may be equitable. But to a great extent the very large dam projects that emerged in the latter 20th century and continue into the 21st deliver benefits and burdens to different populations, creating persistent inequities.

Hydropower is a relatively inexpensive form of electric power after the initial investment in construction, so the principal benefit of a large dam is cheap electricity for some population. Large dams may offer other benefits related to management of a waterway, such as flood control, improved navigation, or increased opportunities for irrigation. On the

other hand, new reservoirs may displace large numbers of people, often disenfranchised populations, and there may be detrimental downstream effects on fishing or farming. Finally, those located downstream of a dam are at risk in the event of a catastrophic failure, though this is generally considered an unlikely event.

Although this discussion focuses on the outward environmental impacts of hydropower facilities on different demographic groups, a historical episode from the occupational setting deserves mention. In 1930–1931, the 3-mile Hawk's Nest Tunnel was bored through a mountain in West Virginia to divert water from its natural riverbed to a hydropower plant being built for an industrial facility. The rock was high in silica, and dust was thick in the tunnel, but no measurements were taken, and attempts to ventilate the tunnel or damp down the dust were minimal. Although chronic silicosis was a recognized occupational illness in miners at the time, it was the fast-paced construction of the Hawk's Nest Tunnel that revealed *acute* silicosis, an illness that killed many workers within months of their tunnel labors. The workers, many of whom were brought in from outside the county for the tunnel project, were about two-thirds African American. Of the white laborers, 44% worked inside the tunnel at any time, and 22% worked *only* inside the tunnel (Fig. 2). By contrast, among the African-American laborers, fully 70% worked at some point inside the tunnel, and 35% worked *only* inside the tunnel. Thus the episode is noteworthy not only for revealing the acute form of silicosis but also for the striking racial inequities in workforce exposures to the silica-laden dust of the tunnel.

5.2 Profile: The Three Gorges Dam on the Yangtze River in China

The Three Gorges Dam now being built in Hubei province in China will be the largest dam ever constructed. The high dam is to create a narrow reservoir 600 kilometers (370 miles) long filling the Qutang, Wu, and Xiling Gorges of the Yangtze River. Construction began in 1994; by 1997 a diversion dam was completed so that work could begin on the main dam. Flooding and power generation began in 2003, and the project is to be completed in 2010.

5.2.1 Benefits

The dam is expected to produce 18,000 MW of electric power, and some 15 million people in five provinces in Central China will get inexpensive electricity from the project. By replacing coal-burning power plants, the dam is also expected to result in cleaner air in the Yangtze Valley.

In addition to its energy benefits, the dam is intended to control flooding, a major problem on the Yangtze River—although many tributaries enter the river below the dam site. It is also expected to smooth navigation of the river above the dam, though critics argue that locks needed to carry ships around the dam may stall river traffic.

5.2.2 Displacement of Residents

The Three Gorges Dam will flood nearly 20 cities, hundreds of towns, and more than a thousand villages. Estimates of the number of people to be displaced by the dam range from 1.3 million to 1.9 million. To date, more than 600,000 have been moved from their homes. Some 30,000 hectares (74,000 acres) of farmland will be flooded, and perhaps half of the people who will ultimately be displaced are farmers.

Because so many people must be moved within such a short time, the competition for resources is intense. Many of the displaced face hunger or food insecurity, occurring in the context of a disrupted social fabric. Although the government has compensated those displaced by the dam project, the compensation has been inadequate and many of the displaced become migrants. Resentment against the government is widespread, as is resentment against the displaced populations in the areas that receive them.

Because the Three Gorges Dam is such a high-profile project, institutional pressure to continue with it is intense, despite any problems or challenges that may occur. In this context, the large-scale removal and resettlement of people creates troubling

potential for human rights abuses, including punishment of those who refuse to leave—or who leave but later return to their homes.

A survey of displaced persons by Li Heming and colleagues gave insight into the experience of the dispossessed. The resettling of farmers offers special challenges because of their intense attachment to the land. Many of those who have refused to leave, or who have returned, are farmers. For the most part, the resettlement program has sought to move rural residents to other rural locations not too far distant from their original homes. But farmers have been given less land than they owned in the area to be flooded, and land of lower quality—for example, with poor soil on a steep slope—or suited for growing different crops from the ones they are familiar with.

Other displaced residents, urban and rural, have been moved to urban settings far away from the Three Gorges Area. Here housing costs often outstrip the compensation provided. Some of the displaced are not given jobs in their new locations, and some of those who are given jobs lose them. The resistance to living in a distant location is strong. The most successful relocations appear to take place when elderly persons, who are no longer working, move in with relatives. Many displaced persons believe that the project has been tainted by corruption.

5.2.3 Other Detrimental Impacts

The Three Gorges Dam will destroy the habitat of a number of indigenous species, including some found only in China and a species of sturgeon found only in the Yangtze river. The dam will flood three gorges famous for their natural beauty, along with the many antiquities located there. Some critics of the project have suggested that upstream pollution sources will degrade the quality of the water in the reservoir. Downstream concerns include a loss of fertility in farmlands that are no longer regularly flooded by the river and loss of wells because groundwater will not be replenished.

Finally, there is some concern about a catastrophic failure of the dam in the event of an earthquake, especially if engineering decisions or construction quality have been compromised. Some critics even fear that the sheer weight of the reservoir could trigger an earthquake along a fault line that lies under it.

6. HOME USE OF BIOMASS FUELS

A total of 1.4 billion tons of fuelwood was produced worldwide in 1999, and a roughly equal amount is consumed. Global production and use of fuelwood is concentrated in Asia (46%) and Africa (30%). India alone accounts for 14% of global fuelwood production; India, China, and Indonesia together account for almost one-third of the world's production.

The use of wood for fuel declined rapidly in the developed world with the increasing availability of oil and natural gas after World War II. In the United States, wood was used to heat almost one-quarter of all homes in 1940, but only 1% in 1970 (Fig. 3). Wood heat enjoyed something of a resurgence in the 1970s and 1980s, especially among middle- to upper-income households in New England and in the Northwest, but fell off again in the 1990s.

Global peat production amounted to only about 1% by weight of fuelwood production in 1999. Peat remains predominantly a fuel of Europe, where 95% of the world's peat was produced. Finland accounts for 37% of the world's peat production, Belarus and the Russian Federation 15% each, and Ireland 14%.

6.1 Health Effects of Domestic Woodsmoke in Developed Countries

Woodsmoke's constituents form a profile of products of combustion, including respirable particulates less than 10 microns in diameter (PM_{10}), carbon monoxide, nitrogen oxides, and sulfur oxides, polycyclic aromatic hydrocarbons (PAHs), formaldehyde, and various volatile organic compounds (VOCs). Exposure to woodsmoke or to its constituent respiratory irritants (e.g., particulate matter, nitrogen dioxide, sulfur dioxide) has been associated with inhibition of the cilia that line the respiratory tract and sweep foreign objects up and out; constriction of airways due to swelling of the membranes that line them

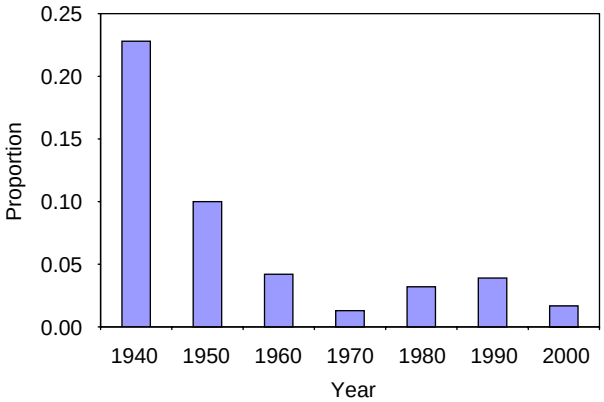

FIGURE 3 Proportion of U.S. housing units using wood for heart, 1940–2000. Data from 2000 U.S. Census.

(chronic airway resistance); a decrease in the volume of air that can be deliberately expelled from the lungs after inhaling (vital capacity); an increase in such respiratory symptoms as coughing, wheezing, and shortness of breath; and increased risk of infectious respiratory disease in children. Formaldehyde is a respiratory irritant that exacerbates asthma and causes headaches; in addition, chronic exposure is associated with increased risk of nasal cancer. Some PAHs have also been shown to be carcinogenic or to have immunosuppressive effects.

6.2 Profile: Effects of Home Heating and Cooking in Developing Nations

It is estimated that approximately half of the world's population—around 3 billion people—use biomass fuels to heat their homes and cook their foods. In rural locations in developing countries, the great majority of households use biomass fuels to meet domestic needs. Biomass fuels are derived from plants or animals, including not only wood and peat, but also animal dung and crop residues. Among these fuels, animal dung and crop residues are the dirtiest to burn but also least expensive; wood and charcoal burn somewhat more cleanly but cost more. Oil, gas, and electricity are the cleanest and most expensive fuels, out of reach of much of the world's population.

Biomass fuels are typically burned in primitive stoves with very incomplete combustion, in an open fire, or even using more than one stove, or some combination of open fire and stove. Depending on the time of year, the type of fuel and stove being used, and the nature of the structure, pollutant concentrations in indoor air may be many times those found in homes in the developed world. The U.S. EPA sets a standard for respirable particulates (particulate matter less than 10 microns in diameter, or PM_{10}) of 50 $\mu g/m^3$ as an annual average and 150 $\mu g/m^3$ as a daily average. (These small particles penetrate deeply into the lung; in fact, particles less than 2.5 microns in diameter penetrate more deeply still.) In a recent study of health impacts of wood stoves in Quebec, Canada, 9% of the homes examined had 24-hour average concentrations greater than 50 $\mu g/m^3$; 67% had 24-hour average concentrations less than 11 $\mu g/m^3$. These measurements contrast sharply with those taken in homes in developing countries where biomass fuels are used for heating and cooking. Here, researchers report typical 24-hour average concentrations in homes ranging from 200 to 5000 $\mu g/m^3$; and peak concentrations of more than 50,000 $\mu g/m^3$ recorded near stoves.

6.2.1 Assessing Exposures to Domestic Biomass Fuels

An individual's cumulative exposure to the products of combustion depends on a number of factors in addition to the type of fuel and the combustion efficiency of the stove. For example, the fire may be burning brightly or smoldering. The use of the stove is affected by season and time of day. The degree to which pollutants are evenly dispersed through the house is affected by whether the cooking and living areas are in the same room or are separate from one another. Ventilation varies widely across homes.

However, research by Majid Ezzati and others has shown that individual patterns of behavior are the most important determinants of exposure. How much time is spent in the cooking area? How much time is spent bending over the stove or fire, adjusting the fuel or stirring the food? Studies have shown that women aged 16 to 50 and girls aged 6 to 15 spend more time in the cooking area, and more time engaged in high-exposure activities related to cooking, than do men or boys in the same age groups. As a result, women's cumulative exposures to indoor air pollution are higher than men's, and the proportion of their exposure that comes from cooking is also higher. Similar gender differences in exposure are not documented for children under 6, who have not yet taken on many household duties. However, young children's exposures are higher than those of older boys or of men aged 16 to 50, reflecting time spent in their mother's company.

6.2.2 The Global Burden of Disease from Domestic Use of Biomass Fuels

Exposure to indoor air pollution in developing countries has been most clearly associated with increased risk of acute lower respiratory infection, middle ear infection (otitis media), and chronic obstructive pulmonary disease. An estimated 1.5 to 2 million deaths each year in developing countries are due to indoor air pollution from the burning of biomass fuels, with perhaps 1 million of these due to acute lower respiratory infections in children under age 5. In sum, the burden of disease from domestic burning of biomass fuels rests most heavily on disenfranchised groups: the world's poorest countries, lower income populations within those countries, women, and young children.

Glossary

cointegration Classical regression analysis assumes that the error term in a regression is normally and independently distributed. An extreme violation of this condition is when the error term is a random walk. Such a regression is termed a spurious regression and the results are not reliable. It usually indicates that a required variable with random walk behavior has been omitted from the model or that the variables in the model follow random walks and are not related to each other.

consistent estimation May show bias and inefficiency, but both are reduced toward zero as the sample size increases.

developed economies Countries with high income levels; typically have an income per capita greater than U.S. $10,000, life expectancy greater than 70 years, and literacy rates greater than 95%.

developing economies Countries with low- and middle-income levels; equivalent to the term "Third World."

econometrics The specialized branch of mathematical statistics applied to the analysis of economic data.

economic growth An increase in economy-wide economic production usually measured by an increase in gross domestic product; also, the process of the economy growing over time.

environmental degradation Any human-caused deterioration in environmental quality.

externality When a production or consumption activity has unintended damaging effects, such as pollution, on other firms or individuals and no compensation is paid by the producer or consumer to the affected parties (negative externality); when activities have beneficial effects for others, such as freely available research results, and the recipients do not pay the generator of the effect (positive externality).

heteroskedasticity When the variance of the error term in a regression model varies systematically across observations or cases.

income elasticity The percentage increase in some variable when income increases by 1%.

income per capita Usually computed as the gross national product of a country for one year divided by the total population.

integrated variable A random walk is an integrated variable—the current value is equal to the previous period's value plus a random shock. This means that the effect of these shocks on the future does not decline over time. Rather, the current value of the variable is an integration of all past shocks.

The environmental Kuznets curve is a hypothesized relationship among various indicators of environmental degradation and income per capita. During the early stages of economic growth, degradation and pollution increase, but beyond some level of income per capita (which will vary for different indicators) the trend reverses, so that at high income levels economic growth leads to environmental improvement. This implies that the environmental

impact indicator is an inverted U-shaped function of income per capita. Typically, the logarithm of the indicator is modeled as a quadratic function of the logarithm of income.

1. INTRODUCTION

An example of an estimated environmental Kuznets curve (EKC) is shown in Fig. 1. The EKC is named for Simon Kuznets, who hypothesized that income inequality first rises and then falls as economic development proceeds. Emissions of various pollutants, such as carbon dioxide, sulfur, and nitrogen oxides, are tightly coupled to the use of energy. Hence, the EKC is a model of the relationship among energy use, economic growth, and the environment.

The EKC is an essentially empirical phenomenon, but most of the EKC literature is statistically weak. It is very easy to do bad econometrics, and the history of the EKC exemplifies what can go wrong. The EKC idea rose to prominence because few paid sufficient attention to the relevant diagnostic statistics. Little or no attention has been paid to the statistical properties of the data used such as serial dependence and random walk trends in time series, and few tests of model adequacy have been carried out or presented. However, one of the main purposes of doing econometrics is to test which apparent relationships are valid and which are spurious correlations.

When we do take such statistics into account and use appropriate techniques, we find that the EKC does not exist. Instead, we get a more realistic view of the effect of economic growth and technological changes on environmental quality. It seems that most indicators of environmental degradation are monotonically rising in income, although the "income elasticity" is less than 1.0 and is not a simple function of income alone. Time-related effects, intended to model technological change common to all countries, reduce environmental impacts in countries at all levels of income. However, in rapidly growing middle-income countries, the scale effect, which increases pollution and other degradation, overwhelms the time effect. In wealthy countries, growth is slower and pollution reduction efforts can overcome the scale effect. This is the origin of the apparent EKC effect.

The econometric results are supported by recent evidence that, in fact, pollution problems are being addressed and remedied in developing economies.

This article follows the development of the EKC concept in approximately chronological order. Sections II and III review in more detail the theory behind the EKC and the econometric methods used in EKC studies. Sections IV to VI review some EKC analyses and their critiques. Section VII discusses the recent evidence from Dasgupta and colleagues and others that has changed the way in which we view the EKC. The final two sections discuss an alternative approach, decomposition of emissions, and summarize the findings.

2. THEORETICAL BACKGROUND

The EKC concept emerged during the early 1990s with Grossman and Krueger's pathbreaking study of the potential impacts of the North American Free Trade Agreement (NAFTA) and Shafik and Bandyopadhyay's background study for the *World Development Report 1992*. However, the idea that economic growth is necessary for environmental quality to be maintained or improved is an essential part of the sustainable development argument promulgated by the World Commission on Environment and Development in *Our Common Future*.

The EKC theme was popularized by the International Bank for Reconstruction and Development's (IBRD) *World Development Report 1992,* which argued that "the view that greater economic activity inevitably hurts the environment is based on static assumptions about technology, tastes, and environmental investments" and that "as incomes rise, the demand for improvements in environmental quality will increase, as will the resources available for investment." Others have expounded this position even more forcefully, with Beckerman claiming that "there is clear evidence that, although economic

growth usually leads to environmental degradation in the early stages of the process, in the end the best—and probably the only—way to attain a decent environment in most countries is to become rich." However, the EKC has never been shown to apply to all pollutants or environmental impacts, and recent evidence challenges the notion of the EKC in general. The remainder of this section discusses the economic factors that drive changes in environmental impacts and that may be responsible for rising or declining environmental degradation over the course of economic development.

If there were no change in the structure or technology of the economy, pure growth in the scale of the economy would result in a proportional growth in pollution and other environmental impacts. This is called the scale effect. The traditional view that economic development and environmental quality are conflicting goals reflects the scale effect alone. Panayotou, a proponent of the EKC hypothesis, argued,

> *At higher levels of development, structural change towards information-intensive industries and services, coupled with increased environmental awareness, enforcement of environmental regulations, better technology, and higher environmental expenditures, result in leveling off and gradual decline of environmental degradation.*

Therefore, at one level, the EKC is explained by the following "proximate factors":

1. Scale of production implies expanding production, with the mix of products produced, the mix of production inputs used, and the state of technology all held constant.
2. Different industries have different pollution intensities, and the output mix typically changes over the course of economic development.
3. Changes in input mix involve the substitution of less environmentally damaging inputs to production for more damaging inputs and vice versa.
4. Improvements in the state of technology involve changes in both (a) production efficiency in terms of using less, *ceteris paribus,* of the polluting inputs per unit of output and (b) emissions-specific changes in process that result in less pollutant being emitted per unit of input.

These proximate variables may, in turn, be driven by changes in underlying variables such as environmental regulation, awareness, and education. A number of articles have developed theoretical models about how preferences and technology might interact to result in different time paths of environmental quality. The various studies make different simplifying assumptions about the economy. Most of these studies can generate an inverted U-shape curve of pollution intensity, but there is no inevitability about this. The result depends on the assumptions made and the value of particular parameters. It seems fairly easy to develop models that generate EKCs under appropriate assumptions, but none of these theoretical models has been empirically tested. Furthermore, if in fact the EKC for emissions is monotonic as recent evidence suggests, the ability of a model to produce an inverted U-shaped curve is not necessarily a desirable property.

3. ECONOMETRIC FRAMEWORK

The earliest EKCs were simple quadratic functions of the levels of income. However, economic activity inevitably implies the use of resources, and by the laws of thermodynamics, use of resources inevitably implies the production of waste. Regressions that allow levels of indicators to become zero or negative are inappropriate except in the case of deforestation where afforestation can occur. This restriction can be applied by using a logarithmic dependent variable. The standard EKC regression model is

$$\ln(E/P)_{it} = \alpha_i + \gamma_t + \beta_1 \ln(\mathrm{GDP}/P)_{it} + \beta_2[\ln(\mathrm{GDP}/P)]^2_{it} + \varepsilon_{it}, \quad (1)$$

where E is emissions, P is population, GDP is gross domestic product, ε is a random error term, and ln indicates natural logarithms. The first two terms on the right-hand side are intercept parameters that vary across countries or regions i and years t. The assumption is that although the level of emissions per capita may differ over countries at any particular income level, the income elasticity is the same in all countries at a given income level. The time-specific intercepts are intended to account for time-varying omitted variables and stochastic shocks that are common to all countries.

The "turning point" level of income, where emissions or concentrations are at a maximum, can be found using the following formula:

$$\tau = \exp[-\beta_1/(2\beta_2)]. \quad (2)$$

The model is usually estimated with panel data. Most studies attempt to estimate both the fixed effects and random effects models. The fixed effects model treats the α_i and γ_t as regression parameters, whereas the random effects model treats them as components of the random disturbance. If the effects

α_i and γ_t and the explanatory variables are correlated, the random effects model cannot be estimated consistently. Only the fixed effects model can be estimated consistently. A Hausman test can be used to test for inconsistency in the random effects estimate by comparing the fixed effects and random effects slope parameters. A significant difference indicates that the random effects model is estimated inconsistently due to correlation between the explanatory variables and the error components. Assuming that there are no other statistical problems, the fixed effects model can be estimated consistently, but the estimated parameters are conditional on the country and time effects in the selected sample of data. Therefore, they cannot be used to extrapolate to other samples of data. This means that an EKC estimated with fixed effects using only developed country data might say little about the future behavior of developing countries. Many studies compute the Hausman statistic and, finding that the random effects model cannot be estimated consistently, estimate the fixed effects model. But few have pondered the deeper implications of the failure of this test.

Tests for integrated variables designed for use with panel data find that sulfur and carbon emissions and GDP per capita are integrated variables. This means that we can rely only on regression results that exhibit the cointegration property. If EKC regressions do not cointegrate, the estimates will be spurious. Very few studies have reported any diagnostic statistics for integration of the variables or cointegration of the regressions, and so it is unclear what we can infer from the majority of EKC studies.

4. RESULTS OF EKC STUDIES

The key features differentiating the broad variety of EKC studies can be displayed by reviewing a few of the early studies and examining a single indicator (sulfur) in more detail. This section also discusses EKCs for total energy use, seen by some as a proxy indicator for all environmental impacts.

The early EKC studies appeared to indicate that local pollutants, such as smoke and sulfur emissions, were more likely to display an inverted U-shaped relation with income than were global impacts such as carbon dioxide. This picture fits environmental economics theory; local impacts are internalized in a single economy or region and are likely to give rise to environmental policies to correct the externalities on pollutees before such policies are applied to globally externalized problems.

Grossman and Krueger produced the first EKC study as part of a study of the potential environmental impacts of NAFTA. They estimated EKCs for SO_2, dark matter (fine smoke), and suspended particles (SPM) using the GEMS data set. This data set is a panel of ambient measurements from a number of locations in cities around the world. Each regression involved a cubic function in levels (not logarithms) of purchasing power parity adjusted (PPP) per capita GDP and various site-related variables, a time trend, and a trade intensity variable. The turning points for SO_2 and dark matter are at approximately \$4000 to \$5000, whereas the concentration of suspended particles appeared to decline even at low income levels.

Shafik and Bandyopadhyay's study was particularly influential in that the results were used in the *World Development Report 1992*. They estimated EKCs for 10 different indicators using three different functional forms. Lack of clean water and lack of urban sanitation were found to decline uniformly with increasing income and over time. Deforestation regressions showed no relation between income and deforestation. River quality tended to worsen with increasing income. However, local air pollutant concentrations conformed to the EKC hypothesis, with turning points between \$3000 and \$4000. Finally, both municipal waste and carbon emissions per capita increased unambiguously with rising income.

Selden and Song estimated EKCs for four emissions series—SO_2, NO_x, SPM, and CO—using longitudinal data from World Resources. The data were primarily from developed countries. The estimated turning points all were very high compared with those in the two earlier studies. For the fixed effects version of their model, the estimated turning points were as follows (converted to 1990 U.S. dollars using the U.S. GDP implicit price deflator): SO_2, \$10,391; NO_x, \$13,383; SPM, \$12,275; and CO, \$7,114. This study showed that the turning point for emissions was likely to be higher than that for ambient concentrations. During the initial stages of economic development, urban and industrial development tends to become more concentrated in a smaller number of cities that also have rising central population densities, with the reverse happening during the later stages of development. So, it is possible for peak ambient pollution concentrations to fall as income rises, even if total national emissions are rising.

Table I summarizes several studies of sulfur emissions and concentrations, listed in order of estimated

income turning points. On the whole, the emissions-based studies have higher turning points than do the concentrations-based studies. Among the emissions-based estimates, both Selden and Song and Cole and colleagues used databases that are dominated by, or consist solely of, emissions from Organization for Economic and Cooperative Development (OECD) countries. Their estimated turning points were $10,391 and $8,232, respectively. List and Gallet used data for 1929 to 1994 for the 50 U.S. states. Their estimated turning point is the second highest in Table I. Income per capita in their sample ranged from $1,162 to $22,462 (in 1987 U.S. dollars). This is a wider range of income levels than was found in the OECD-based panels for recent decades. This suggests that including more low-income data points in the sample might yield a higher turning point. Stern and Common estimated the turning point at more

than $100,000. They used an emissions database produced for the U.S. Department of Energy by ASL that covers a greater range of income levels and includes more data points than do any of the other sulfur EKC studies.

The recent studies that use more representative samples of data found that there is a monotonic relation between sulfur emissions and income, just as there is between carbon dioxide and income. Interestingly, an estimate of a carbon EKC for a panel data set of OECD countries found an inverted U-shaped EKC in the sample as a whole. The turning point was at only 54% of maximal GDP in the sample. A study using a spline regression implied a within-sample turning point for carbon for high-income countries. All of these studies suggest that the differences in turning points that have been found for various pollutants may be due, at least in part, to the different samples used.

In an attempt to capture all environmental impacts of whatever type, a number of researchers estimated EKCs for total energy use. In each case, they found that energy use per capita increases monotonically with income per capita. This result does not preclude the possibility that energy intensity (i.e., energy used per dollar of GDP produced) declines with rising income or even follows an inverted U-shaped path.

A number of studies built on the basic EKC model by introducing additional explanatory variables intended to model underlying or proximate factors such as "political freedom," output structure, and trade. On the whole, the included variables turned out to be significant at traditional significance levels. However, testing different variables individually is subject to the problem of potential omitted variables bias. Furthermore, these studies did not report cointegration statistics that might indicate whether omitted variables bias was likely to be a problem or not. Therefore, it is not really clear what can be inferred from this body of work.

The only robust conclusions from the EKC literature appear to be that concentrations of pollutants may decline from middle-income levels and that emissions tend to be monotonic in income. Emissions may decline over time in countries at many different levels of development. Given the likely poor statistical properties of most EKC models, it is hard to come to any conclusions about the roles of other additional variables such as trade. Too few quality studies of other indicators apart from air pollution have been conducted to come to any firm conclusions about those impacts as well.

5. THEORETICAL CRITIQUE OF THE EKC

A number of critical surveys of the EKC literature have been published. This section discusses the criticisms that were made of the EKC on theoretical, rather than methodological, grounds.

The key criticism of Arrow and colleagues and others was that the EKC model, as presented in the *World Development Report 1992* and elsewhere, assumes that there is no feedback from environmental damage to economic production given that income is assumed to be an exogenous variable. The assumption is that environmental damage does not reduce economic activity sufficiently to stop the growth process and that any irreversibility is not severe enough to reduce the level of income in the future. In other words, there is an assumption that the economy is sustainable. However, if higher levels of economic activity are not sustainable, attempting to grow fast during the early stages of development, when environmental degradation is rising, may prove to be counterproductive.

It is clear that the levels of many pollutants per unit of output in specific processes have declined in developed countries over time with technological innovations and increasingly stringent environmental regulations. However, the mix of effluent has shifted from sulfur and nitrogen oxides to carbon dioxide and solid waste, so that aggregate waste is still high and per capita waste might not have declined. Economic activity is inevitably environmentally disruptive in some way. Satisfying the material needs of people requires the use and disturbance of energy flows and materials. Therefore, an effort to reduce some environmental impacts might just aggravate other problems. Estimation of EKCs for total energy use is an attempt to capture environmental impact regardless of its nature.

Various critics argued that if there was an EKC-type relationship, it might be partly or largely a result of the effects of trade on the distribution of polluting industries. The Hecksher–Ohlin trade theory, the central theory of trade in modern economics, suggests that, under free trade, developing countries would specialize in the production of goods that are intensive in the production inputs they are endowed with in relative abundance: labor and natural resources. The developed countries would specialize in human capital and manufactured capital-intensive activities. Part of the reductions in environmental degradation levels in developed countries and part of the increases in environmental degradation levels in

middle-income countries may reflect this specialization. Environmental regulation in developed countries might further encourage polluting activities to gravitate toward developing countries.

These effects would exaggerate any apparent decline in pollution intensity with rising income along the EKC. In our finite world, the poor countries of today would be unable to find other countries from which to import resource-intensive products as they themselves become wealthy. When the poorer countries apply similar levels of environmental regulation, they would face the more difficult task of abating these activities rather than outsourcing them to other countries. There are no clear solutions to the impact of trade on pollution from the empirical EKC literature.

Some early EKC studies showed that a number of indicators—SO_2 emissions, NO_x, and deforestation—peak at income levels around the current world mean per capita income. A cursory glance at the available econometric estimates might have led one to believe that, given likely future levels of mean income per capita, environmental degradation should decline from this point onward. However, income is not normally distributed but rather very skewed, with much larger numbers of people below mean income per capita than above it. Therefore, it is median income, rather than mean income, that is the relevant variable. Both Selden and Song and Stern and colleagues performed simulations that, assuming that the EKC relationship is valid, showed that global environmental degradation was set to rise for a long time to come. More recent estimates showed that the turning point is higher; therefore, there should be no room for confusion on this issue.

6. ECONOMETRIC CRITIQUE OF THE EKC

Econometric criticisms of the EKC concern four main issues: heteroskedasticity, simultaneity, omitted variables bias, and cointegration issues.

Heteroskedasticity may be important in the context of cross-sectional regressions of grouped data. Data for a country are a sum or mean of observations for all of the regions, firms, or households within that country. Smaller residuals may be associated with countries with higher total GDPs and populations. Taking heteroskedasticity into account in the estimation stage seems to significantly improve the goodness of fit of globally aggregated fitted emissions to actual emissions.

Simultaneity may arise because increasing energy use drives increasing income, but increasing income may also increase the demand for energy in consumption activities. In addition, if environmental degradation is sufficiently severe, it may reduce national income, whereas the scale effect implies that increased income causes increased environmental degradation. A Hausman-type statistical test for regressor exogeneity can be used to directly address the simultaneity issue. No evidence of simultaneity has been found using such a test. In any case, simultaneity bias is less serious in models involving integrated variables than in the traditional stationary econometric model. The Granger causality test can be used to test the direction of causality between two variables. In tests of causality between CO_2 emissions and income in various individual countries and regions, the overall pattern that emerges is that causality runs from income to emissions or that there is no significant relationship in developing countries, whereas causality runs from emissions to income in developed countries. However, in each case, the relationship is positive, so that there is no EKC-type effect.

Three lines of evidence suggest that the EKC is an incomplete model and that estimates of the EKC in levels can suffer from significant omitted variables bias: (1) differences between the parameters of the random effects and fixed effects models tested using the Hausman test, (2) differences between the estimated coefficients in different subsamples, and (3) tests for serial correlation. Hausman-type test statistics show a significant difference in the parameter estimates for estimated random effects and fixed effects models in the majority of EKC studies. This indicates that the regressors—the level and square of the logarithm of income per capita—are correlated with the country effects and time effects, indicating that the regressors are likely correlated with omitted variables and that the regression coefficients are biased. As expected, given the Hausman test results, parameter estimates turn out to be dependent on the sample used, with the global and developing country estimates of emissions EKCs for sulfur and carbon showing a turning point at extremely high income levels and the developed country estimates showing a within-sample turning point. In the cases where serial correlation in the residuals was tested, a very high level was found, indicating misspecification in terms of either omitted variables or missing dynamics.

Tests for integrated variables designed for use with panel data indicate that sulfur emissions per capita, carbon emissions per capita, and GDP per capita are

integrated. This means that we can rely only on regression results that exhibit the cointegration property. Results for cointegration are less clear-cut than those for integration in the individual time series. For sulfur emissions in 74 countries from 1960 to 1990, approximately half of the individual country EKC regressions cointegrate, but many of these have parameters with "incorrect signs." Some panel cointegration tests indicate cointegration in all countries, and some accept the non-cointegration hypothesis. But even when cointegration is found, the forms of the EKC relationship vary radically across countries, with many countries having U-shaped EKCs. A common cointegrating vector in all countries is strongly rejected.

7. OTHER EVIDENCE

Dasgupta and colleagues present evidence that environmental improvements are possible in developing countries and that peak levels of environmental degradation will be lower than those in countries that developed earlier. They present data that show declines in various pollutants in developing countries over time. They show that although regulation of pollution increases with income, the greatest increases occur from low- to middle-income levels. In addition, diminishing returns to increased regulation would be expected, although better enforcement at higher income levels would also be expected. There is also informal or decentralized regulation in developing countries. Furthermore, liberalization of developing economies over the past two decades has encouraged more efficient use of inputs and less subsidization of environmentally damaging activities. Multinational companies respond to investor and consumer pressure in their home countries and raise standards in the countries in which they invest. Furthermore, better methods of regulating pollution, such as market instruments, are having an impact even in developing countries. Better information on pollution is available, encouraging government to regulate and empowering local communities. Those who argue that there is no regulatory capacity in developing countries would seem to be wrong.

Much of Dasgupta and colleagues' evidence is from China. Other researchers of environmental and economic developments in China came to similar conclusions. For example, China is adopting European Union standards for pollution emissions from cars with an approximately 8- to 10-year lag. Clearly, China's income per capita is far more than 10 years behind that of Western Europe. Furthermore, China has reduced sulfur emissions and even carbon emissions during recent years. Ambient air pollution has been reduced in several major cities, and with the exception of some encouragement of road transport, the government is making a sustained effort in the direction of environmentally friendly policies and sustainable development.

8. DECOMPOSING EMISSIONS

As an alternative to the EKC, an increasing number of studies carry out decompositions of emissions into the proximate sources of emissions changes described in section II. The usual approach is to use index numbers and detailed sectoral information on fuel use, production, emissions, and so on that, unfortunately, is unavailable for most countries. Econometric decomposition models may require less detailed data. Decomposition models represent the relations between energy use and the environment more explicitly than do EKC models.

The conclusion from the studies conducted so far is that the main means by which emissions of pollutants can be reduced is by time-related technique effects, particularly those directed specifically at emissions reduction, although productivity growth or declining energy intensity has a role to play, particularly in the case of carbon emissions where specific emissions reduction technologies do not yet exist. Estimates of emissions-specific reductions for sulfur range from approximately 20% globally over a 20-year period to 50 to 60% in West Germany and The Netherlands during the 1980s alone.

Although the contributions of structural change in the output mix of the economy and shifts in fuel composition may be important in some countries and at some times, their average effect seems less important quantitatively. Those studies that include developing countries find that technological changes are occurring in both developing and developed countries. Innovations may first be adopted preferentially in higher income countries but seem to be adopted in developing countries with relatively short lags. This is seen, for example, regarding lead in gasoline, where most developed countries had substantially reduced the average lead content of gasoline by the early 1990s but many poorer countries also had low lead contents. Lead content was much more variable at low income levels than at high income levels.

9. CONCLUSIONS

The evidence presented in this article shows that the statistical analysis on which the EKC is based is not robust. There is little evidence for a common inverted U-shaped pathway that countries follow as their incomes rise. There may be an inverted U-shaped relation between urban ambient concentrations of some pollutants and income, although this should be tested with more rigorous time series or panel data methods. It seems unlikely that the EKC is a complete model of emissions or concentrations.

The true form of the emissions–income relationship is likely to be monotonic, but the curve shifts down over time. Some evidence shows that a particular innovation is likely to be adopted preferentially in high-income countries first with a short lag before it is adopted in the majority of poorer countries. However, emissions may be declining simultaneously in low- and high-income countries over time, *ceteris paribus,* although the particular innovations typically adopted at any one time could be different in various countries.

It seems that structural factors on both the input and output sides do play a role in modifying the gross scale effect, although on the whole they are less influential than time-related effects. The income elasticity of emissions is likely to be less than 1.0 but not negative in wealthy countries, as proposed by the EKC hypothesis.

In slower growing economies, emissions-reducing technological change can overcome the scale effect of rising income per capita on emissions. As a result, substantial reductions in sulfur emissions per capita were observed in many developed countries during the past few decades. In faster growing middle-income economies, the effects of rising income overwhelmed the contribution of technological change in reducing emissions.

Glossary

competitive equilibrium The point, defined in prices and quantities, at which demand for goods and services equals the supply. All producers and consumers are so small that they cannot influence the prices in the market.

equity A normative concept related to the distribution of rights and goods. Equity seems to be a broader concept than fairness, while justice is sometimes taken to be an umbrella term that incorporates all dimensions of evaluation besides efficiency.

global justice The solution to a comprehensive redistributive scheme of society-wide justice, where global does not necessarily mean international.

libertarianism A theory for the organization of society emphasizing private property rights and individual freedom. The baseline is that individual freedom prevails except where others may be harmed.

market failure When the markets fail to allocate resources efficiently. Reasons for failure are imperfect competition, natural monopolies, externalities, and public goods. The existence of market failures requires market intervention in the form of supplementing, supplanting, or strengthening the market.

Pareto efficiency A situation characterized by no waste of resources. As long as resources can be allocated so that we experience an increase in production/utility of one firm/individual without increasing other firm's/individual's production/utility, we experience a Pareto improvement. An allocation is Pareto optimal if nobody can be made better off without reducing the well-being/production of others.

social welfare function A representation of the welfare of the society based on individual objectives. The most widely used analytical version is a function of utility of the individuals, in terms of both absolute and relative levels.

utilitarianism A theory for the organization of society. The utilitarian aim is to distribute goods so as to maximize the total utility of members of the society, where "goods" are interpreted broadly to include economic goods, rights, freedom, and political power.

utility possibility frontier A graphical representation of the maximum utility combinations two individuals or groups can attain, given the efficient allocations of finite resources in society.

welfare economics A normative theory for allocating scarce resources and distributing output and income.

The ideal goals of energy policy are to achieve efficiency in production and consumption, as well as an acceptable distribution, of energy goods and services. Efficiency is achieved without policy intervention if there are no imperfections in the market for energy and if all prices reflect the true value of resources. However, it is often necessary to correct prices (e.g., by taxes or subsidies) and to ensure competition (e.g., by anti-trust laws, trade liberalization, or deregulation). Still, even efficient markets can have undesirable distributional consequences for households and producers. A policy that leads to an efficiency gain may not be overall welfare improving if some are made worse off, or it may be viewed as inequitable if it widens the gap between rich and poor. Thus, the distribution of energy goods is also an important part of energy policy.

1. INTRODUCTION

1.1 Overview

Given the prominence of energy in many realms of society, as well as the several unique considerations surrounding its extraction, refinement, transportation, and end use, energy has long been the focus of policy making. This has ranged from minor tweaking of market allocation through taxes and subsidies to outright government control. Energy policy began with concern about market failure due to ordinary and natural monopoly but is now increasingly oriented to reducing externalities, primarily environmental pollution. It has oscillated between laissez-faire, government intervention, and deregulation. Allocation issues have dominated but distributional issues have long been important. Moreover, nearly all policies tended to improve the allocation of energy resources also have significant implications for distribution and its assessment in terms of equity or fairness.

This section first briefly summarizes the range of root causes of energy policy and how they relate to distribution and equity. It then offers some basic definitions of equity. Section 2 provides an overview of welfare economics, the theoretical underpinnings for energy policy, and provides some illustrations of key concepts. Section 3 provides some major examples of distribution and equity in energy policy. They are typical but not necessarily representative of the broad range of issues. Rather, they represent the authors' research interests. Finally, Section 4 provides a brief summary.

1.2 Pervasiveness of Energy Policy

1.2.1 Basic Issues

A combination of factors make energy policy pervasive throughout the world. All of these factors have important direct or indirect distributional implications. Energy is a basic necessity for individual, business, and national survival everywhere. In many places, energy is a major commodity of local production and external trade. All stages of the energy cycle are subject to market failures, which typically require policy intervention. Large rents accrue from energy, making it a ripe target, including for purposes of redistribution. Energy is not evenly distributed on a geographic basis, so there is a spatial mismatch between sources and uses. Many energy resources are finite and concern is mounting over the legacy we leave to our descendants. Energy, especially renewable energy, is a key to sustainable economic development, which appears to require much policy guidance. Energy is also the focus of major technological breakthroughs that often require large R&D funding. Finally, energy has become a major political tool and even a weapon.

1.2.2 Relationship to Distribution and Equity

Because energy is a necessity, there is concern that all consumers have access to it and at an affordable price. This has led to price controls or subsidies for lower income groups in many countries. The survival of business customers, however, is often left to the market, but there are some exceptions for small businesses or those in lagging regions. Other cases in which distributional considerations affect access to energy include the aftermath of an earthquake or terrorist attack, or in the face of an electricity shortage during a war or other crisis, where customers are prioritized for rationing. Interestingly, residential customers often receive higher priority than many businesses.

Several countries, and portions of many others, are highly dependent on energy for their livelihood directly or indirectly. Some, such as Appalachia, are relatively poor, while others such as Texas or the Middle East, are relatively wealthy. In essence, every major energy producing region has an exportable surplus that serves as a stimulus to its economy, though the competitiveness of the relevant energy market has significant effects on how much income is derived from this activity and how it is shared between the various factors of production. The situation has also been especially ripe for protectionist policies, especially at the national level, that often favor one segment of society over another. Environmental, technology, and trade policies have and will continue to cause major shifts in the relative economic vitality of these regions.

The uneven geographic distribution of energy has been a root cause of concentration of energy production, political tensions, and redistributional issues. This is most vivid in the international oil arena and several portions of the world where oil has been used as a bargaining chip or even a weapon. A massive redistribution of wealth has taken place in the more obvious case of the OPEC cartel, but also in the more subtle ways because comparative advantage is highly dependent on relative resource endowments.

One of the most prominent factors that require energy policy tension relates to market failure, the

inability of markets to allocate resources efficiently without policy intervention (including market strengthening). All four major categories of failure discussed below have strong implications for the distributional consequences of energy policy. With respect to externalities, defined as a by-products of activities not reflected in the market price, fossil energy use is probably the greatest single source of air pollution, and the production and transportation of fossil energy are major sources of water pollution. Moreover, these types of pollution have transboundary features, which means one geographic area that benefits from energy production or use imposes problems on other regions. Corrective measures, such as pollution taxes or tradeable permits, involve large sums of money. The imposition of a tax may be on a producer, but through economic interdependencies and tax shifting, its incidence is often spread much more broadly. The relative progressiveness and regressiveness of these policy instruments is a long-standing issue in terms of socioeconomic entities (income classes, racial/ethnic groups, age groups). At international levels, this has become a serious issue in terms of burden-sharing between industrialized and developing countries.

The major consideration in the area of public goods is what is often referred to as the subset of common property resources, where the good is nondivisible but does have nonexcludability/nonappropability (of payment) characteristics. One example of this subset may be oil and gas fields. Conventional markets lead to degenerate competition in terms of over-production and plummeting prices. Solutions such as unitization involve difficult decisions on the distribution of rents.

Ordinary monopoly, or market power in general, is one of the most visible market failures in the energy area. This includes U.S. oil companies, state-owned hydropower in many countries, and the world crude oil market. Not only does this cause a misallocation of resources but also a transfer of wealth in the direction of the monopolist. In fact, many public policies (e.g., excess profits taxes) stem from distributional rather than efficiency concerns of this type of market failure.

Natural monopolies arise because scale economies and other factors imply the efficiency of single providers. In addition to the conundrum of attempting to find efficient prices in this context, there is the concern that deviations from competitive levels will come at the expense of consumers. Over the past decade, there has been a reassessment of the extent to which natural monopolies do in fact exist. Deregulation or restructuring have in some cases been poorly designed and have had dramatic distributional consequences, most vividly illustrated by the crisis in California.

Not only does the market often fail to allocate resources efficiently but even more often it fails to distribute them, on the proceeds from them, fairly. Essentially, the market is blind to equity, and extra-market means are usually necessary to steer it in the right direction.

Large rents (profits) accrue from energy production making it a prime target for policy machinations to capture them. These rents are often viewed as indicating monopoly profits or as unfair; however, in many cases, they relate to scarcity rents, returns to high risk in mineral extraction, or to superior quality deposits. The existence of large rents has led to aggressive policies or outright regulation. Also, in the United States and other countries, vast amounts of energy resources are located on public lands, so that the distributional issues are in the forefront. Public officials must often make hard choices between constituencies. This typically has to be accomplished in the absence of market signals, though an increasing number of market institutions have been developed to address the issue (e.g., bonus-lease bidding).

Many energy resources are finite, and there is concern about utilizing them today and leaving fewer or higher cost deposits for future generations (intergenerational equity). This has also caused energy policy to become intertwined with sustainability issues, which have both normative and positive (e.g., public participation) distributional consequences. This has also shifted the emphasis to renewable energy as discussed later.

Energy is key to economic development, especially of the sustainable type. Market forces alone will not promote development, so this is another, and very broad sweeping, area of policy, replete with distributional consequences and equity considerations. Economic development is not simply pursued to raise the absolute standard of living but also to help close the economic gap between countries.

The form of energy has major distributional implications. Fossil fuels are geographically concentrated and subject to natural monopoly considerations, especially in their transportation. Renewable energy, such as solar, wind, dry-rock geothermal, and biomass, are relatively ubiquitous. Hence, they have the potential for decentralizing energy production and even eliminating a great deal of the transportation/transmission needs. These alternate energy resources thus have the ability to lessen the impact

of OPEC and large producers of energy in general and thus to redistribute wealth.

Energy is the subject of major technological advances. This arises because fuels and conversion lend themselves to technical refinement. Major breakthroughs can cause major geographic and socioeconomic redistributions. Much of the research is undertaken or subsidized by government. Issues abound concerning industry favoritism. A "level playing field" is absent here, as well as in most areas of energy policy.

Energy is a political tool. Wealth has always been a major basis for political power, and the concentration of energy deposits, and the nature of energy refining and transportation, have been a major source of strength and tension. The Arab oil embargo is a vivid example, and many contend that the Gulf War, as well as the invasion of Iraq, have been motivated by the politics of oil. The situation is complicated in many parts of the world as a battle between the haves and have-nots or as a remnant of colonialism, one of the ultimate distributional issues.

1.3 Definition of Equity

The concepts of efficiency and equity are central in policy analyses. While Pareto optimality, a situation characterized by no waste of resources, is an accepted efficiency principle, there is not a consensus on a best equity principle. As a result, most economic analyses, also those related to energy, have concentrated on efficiency problems, and equity often plays a secondary role in economic policy making, even if it will always play an important role as a principle of all social interactions.

Distinguishing between the related concepts of equity, fairness, and justice may in general be difficult, and we do not attempt to make extensive distinctions. However, fairness often has a specific meaning in economic theory and philosophical theories of justice. One example is to define fairness as nonenvy. Equity seems to be a broader concept than fairness, while justice is sometimes taken to be an umbrella term, incorporating all dimensions of evaluation besides efficiency.

2. *WELFARE ANALYTICS*

2.1 Welfare Maximization

One branch of mainstream economics studies equity by formalizing the concept of a social welfare function (SWF), in which it was possible to separate efficiency and equity considerations though tradeoffs between the two objectives still prevail. We can illustrate this by a simple diagram containing two major constructs. First is a utility possibility frontier, or UPF, which traces the maximum combination (m) of the utility (U) two individuals or groups (1,2) can attain, given all the efficient allocations of finite resources in society (see curve $U_m^1 U_m^2$ in Fig. 1). Interestingly, all the points on the UPF are Pareto optimal, (i.e., one person cannot be made better off without another person being made worse off). Thus, points such as C and D in Fig. 1 are not Pareto optimal. Note that there are an infinite number of Pareto optimal points on the UPF. We can be assured, under ideal conditions, that the market will lead to a point on the UPF, thus illustrating the first fundamental theorem of welfare economics. But from the standpoint of efficiency alone, the points on the UPF cannot be ranked.

However, if we introduce equity, then we have a way of preferring some to others. In fact, that is the essence of the definition of a social welfare function—a complete ranking of all states (resource allocations and product or income distributions) of the economy. Although many alternative equity concepts exist, the one most prevalently used in welfare economics is "vertical" equity, which holds that equity increases as utility (or income) disparities between individuals decrease. Generally, equity is

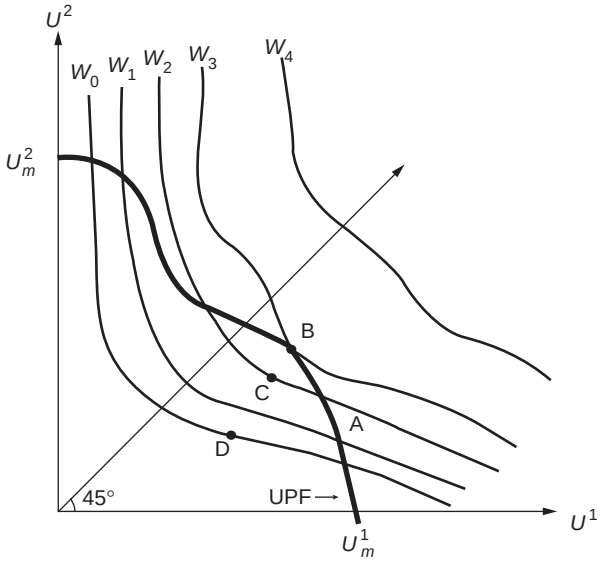

FIGURE 1 Welfare maximization and efficiency-equity trade-offs.

enhanced as joint utility allocations in Fig. 1 move closer to the 45° line.

A social welfare function that embodies both efficiency and equity can be superimposed on Fig. 1. The welfare contours (W_0, W_1, W_2, W_3, W_4) are analogous to indifference curves (i.e., they are horizontal slices of a three-dimensional surface). The shape of these contours reflects equity; the more bowed toward the center, the greater the emphasis on equity.

The welfare optimum is given by point B. Again, there is no guarantee that a market economy will lead to this outcome, and, in fact, given the infinity of possible Pareto optimal outcomes, it is likely that it will not. Moreover, while theoretically society can move from a competitive equilibrium that is not a maximum welfare outcome, such as A, to point B through the use of various types of transfers, there may be some limitations in practice, as discussed in the following section.

For some, one major justification for downplaying equity is the efficiency-equity tradeoff. This refers to the possibility that transfers to promote equity will create a work disincentive to the transferring party (usually the well-to-do), with the ensuing inefficiency limiting society to a lower level of welfare even when utilities (or incomes) are equal or made more equal. Still, this is an empirical question, though most studies indicate the disincentive effect is rather small.

We can use Fig. 1 to illustrate this potential problem. Previously we noted the ideal transfer would move society from point A to point B. However, if the disincentive effect exists, and is weak, the move would be from point A to point C, whereby there is an efficiency-equity tradeoff but an unequivocal welfare gain. But it is also possible that the disincentive is strong and will result in a move from point A to point D, whereby overall welfare is even lower than in the original state. The threat of moving to point D, and even the possibility of moving to point C (note the discussion of benefit cost analysis below), causes many economists to be nervous about pursuing equity goals. We can be more certain of achieving equity with the minimum of efficiency loss if we utilize lump sum transfers, or if we avoid price-distorting policies. The difficulty is that there are few lump sum transfers (i.e., transfers that are not based on effort).

2.2 Social Justice Theories

So far we have discussed distribution within the framework of a social welfare function, which is the mainstream approach in economic theory. These welfaristic theories (meaning theories that focus on welfare outcomes) are in the tradition of utilitarianism. We will now take a brief look at this theory, and also consider some nonwelfaristic approaches.

A theory of justice is, as theories of rationality and ethics, a normative theory. Such a theory has two aspects. First, it will regulate individual rights (and duties); second, it will propose or evaluate a distribution of goods (and burdens). Different theories of justice may weight these two aspects differently. They are, for instance given equal weight by utilitarians, while John Rawls gives political freedom and rights a lexicographical priority over economic distribution.

In the following, we will consider philosophical theories of justice (or global justice theories)—that is, theories that are centrally designed for the whole society and are intended to compensate people for various sorts of bad luck that may result in low levels of income. This means that we will not consider theories for decentralized distribution decisions (or local justice theories), such as who shall perform military service, who shall receive organs for transplantation, and so on, but theories that provides suggestions to society-wide problems such as income distributions or the social security system. These theories are also relevant for energy policy, as we will see in Section 3.

2.2.1 Utilitarianism

The utilitarian aim is to distribute goods so as to maximize the total utility of members of the society, where "goods" are interpreted broadly to include economic goods, rights, freedom, and political power. A utilitarian welfare function is usually defined as the sum of the utility of all the members (i.e., all individuals have an equal weight). One problem with this function as well as for other forms of SWFs is the interpersonal comparison of utility, which is not a straightforward issue. We will, however, not examine these problems in this article.

Even though utilitarianism does not explicitly address equity, its welfare maximization objective does have distributional implications. Different versions of the theory exist. One important distinction is the difference between act-utilitarianism and rule-utilitarianism. The former enjoins us to perform the act that will maximize the utility on every single occasion, while the latter tells us to act so that we will maximize total utility over time. These two forms of utilitarianism may conflict, as many actions

provide immediate pleasure but long-run costs. For example, a high level of fossil fuel consumption today may maximize current welfare, but due to the accumulation of greenhouse gases it will cause a reduction of maximum attainable welfare in the future.

2.2.2 Rawlsian Theory

The theory of John Rawls can basically be seen as a critique of utilitarianism. According to Rawls, utilitarianism has no respect for individuals. A person is not seen as valuable and worth protecting on his or her own right. A classical but grotesque example is if you kill a healthy person and use his or her organs to save the life of five other human beings. This may increase the utility of the society, but it does not respect individual rights. Rawls argues that a theory of justice should respect the individuals as ends in themselves.

The methodological starting point of Rawls theory is the original position. Most persons would argue for what is just or unjust depending on their own position in the society. Therefore, as a starting point to decide the basic structure of the society, which according to Rawls is the primary subject of justice, we have to think about a hypothetical and idealized world where all individuals sit behind a veil of ignorance; the original position. They do not know their abilities, sex, race, or position in the society. All they know is that they are going to live in the society about which they are going to decide the basic structure. In this hypothetical situation, Rawls argues that they will agree on certain principles:

First principle. Each person is to have an equal right to the most extensive total system of equal basic liberties compatible with a similar system of liberty for all.

Second principle. Social and economic inequalities are to be arranged so that they are both (1) to the greatest benefit of the least advantaged and (2) attached to office and positions open to all under conditions of fair equality of opportunities.

The first principle, the principle of greatest equal liberty, is about individual rights. As this principle has a lexicographic priority, none of the basic liberties should be traded against material advancement. However, it is the first part of the second principle, the difference principle, that is mostly referred to. One common misinterpretation in economics is that Rawls argues for maximizing the utility of the least advantaged. However, Rawls theory is not utilitarian, rather an alternative theory and Rawls argues for distributing "primary goods"—that is, goods everybody needs to realize his or her plans of life, independent of what the plan is. While the first principle distributes one subset of the total set of primary goods, the basic liberties, the difference principle distributes another subset including wealth, income, power, and authority. The last part of the second principle, the principle of fair equality of opportunity, requires that we go beyond formal equality of opportunity to insure that persons with similar skills, abilities, and motivation enjoy equal opportunities. Finally it should be noted that Rawls's theory is a theory of intragenerational distributive justice, and the principles cannot easily be extended to intergenerational concerns.

One element of Rawls's theory of justice, which may be particularly relevant when discussing energy policy, is what he defines to be morally relevant and morally arbitrary. The distribution of goods should not be based on morally arbitrary components. To illustrate, consider two elements that are often claimed to contribute to economic growth. One is the human-cooperative activity, and the other is the natural component. The second element is components present on the earth's surface, which are not due to human production. One example is natural resources or assets that are arbitrarily distributed on the earth's surface. In the literature, these are compared to the distribution of natural endowments, defined as such contingencies that are inescapable and present from birth, and may contribute to material advancement, or economic growth because of the implications for human cooperative activity. Examples are nationality, genetic endowments, race, gender, and social class. According to Rawls, natural endowments are "neither just or unjust; nor is it unjust that men are born into society at any particular position. These are simply natural facts. What is just or unjust is the way that institutions deal with these facts." The distribution of natural assets and endowments are, in general, assumed to be morally arbitrary and unacceptable as standards for distribution, since they are beyond the control of human beings. One interpretation is that the geographical distribution of natural resources like oil and gas are simply facts, in the same way as individual talent is a fact. This distribution is, therefore, not just or unjust. However, the income generated from these resources should be considered when discussing justice. Thus, this may be an argument for taxing this income as a part of a distributional policy.

2.2.3 Libertarian Theory

Probably the most widely used decision rule in economic theory is the Pareto criterion, which is most often applied to efficiency and political feasibility (e.g., in bargaining theory). It has also been applied to equity, for instance by a common-sense conception of justice. In libertarian theory, the baseline is that individual freedom prevails except where others may be harmed. Thus, this ethic is in the same line as Pareto superiority saying that there is an improvement in welfare if one or more persons are made better off due to change in resource use as long as the other persons are at least as well off as before. A strict interpretation of libertarian theory is that an act is only immoral if anyone is worse off because of it.

Robert Nozick's theory is the best-known statement of libertarian thought. The theory can be summarized in three principles: justice in appropriation, justice in transfer, and justice in rectification. A distribution of goods is just if it is the end result of an unbroken chain of just transfers, beginning from a just original appropriation. If these conditions are not satisfied, justice in rectification requires that we should establish the distribution that would have occurred if all unjust links in the chain had been replaced by just ones.

The first principle is essentially a finder's keepers principle, where the basic idea is that anyone has the right to appropriate, exploit, and enjoy the fruits of any unowned piece of nature. The principle of just transfers says that the outcome of any voluntary transaction between two or more individuals is just. It is assumed that there is no coercion. If individuals agree on a contract that will benefit all, there is no reason to stop the contract. The only reason to invalidate the contract is if anyone uses its power to make the nonagreement state worse for other parties than it would otherwise have been. The last principle is probably the main weakness of the theory, as identifying the point in time where the earliest violation occurred and thereafter the counterfactual chain of just transfers may be rather indeterminate.

2.3 Link to Energy Policy

Despite the prevalence of distributional and equity considerations in energy policy, much less attention has been paid to them in contrast to the attention to efficiency, policy instrument design, and various industrial organization topics. Several reasons exist for this situation but paramount is the fact that distribution nearly always, and equity by its very essence, are in the realm of normative economics. Energy policy, of course, is also inherently normative, but most analysts feel more comfortable promoting an objective such as economic efficiency, for which the definition has almost universal consensus. Moreover, most interpretations of efficiency call for making all parties better off (or at least not making anyone worse off). On the other hand, there is no consensus on the best definition of equity, as illustrated by the different theories described earlier. Furthermore, the promotion of this objective (in a static context, as opposed to a case like economic development) is often viewed as a zero-sum game, where improvements for one entity must emanate from another one.

Of course, in the real world, few policies do not at least have some adverse effect on some parties. However, this is finessed by benefit-cost analysis (BCA), which evaluates only the overall net gain (and ignores the fact that some incur net cost). In essence, BCA stipulates that benefits and costs be evaluated equally no matter to whom they accrue. Some attempts have been made over the years, however, to introduce distributional issues into BCA by suggesting winners compensate losers and by assigning weights to individuals. However, when choosing a SWF for doing a BCA analysis, ethical views and other specific assumptions are made at the same time. Thus, another approach is to provide sufficient welfare indicators (i.e., information that can be used as input in a BCA analysis). Instead of providing information that is the output from a certain BCA analysis, the analyst can provide factual information about different population groups (such as their social state, size, or characteristics, as well as their changes in income and access to public goods).

As will be shown later, in the primary theoretical underpinnings of economic policy, welfare economics, equity receives considerable attention. Moreover, direct redistribution is viewed as a sound and even ideal, policy option to promote equity, while not adversely affecting efficiency. The classic example is the debate over natural gas well-head price ceilings in the United States. In 1953, a U.S. court ruled that natural gas extraction had monopoly elements and imposed price caps at the wellhead. Opposition to this policy increased over the next two decades because of the bureaucratic backlog of legitimate cost adjustments and instances of major gas shortages. The counter-argument, however, began to hinge less on the monopoly condition and more on concern that, if wellhead activity were deregulated, the ensuing fly-up of gas prices would have an

especially adverse effect on the poor. Thus, the debate hinged on the relative merits of two approaches: (1) maintaining price caps to make low-cost natural gas available to the needy, while distorting market signals potentially causing shortages, and (2) deregulating gas prices and providing some form of tax relief to low income groups. Natural gas wellhead prices were in fact deregulated beginning in 1978. No major legislation was passed to provide subsidies or tax relief for low income groups, though attempts were made to lessen the potential fly-up by a slow phasing in of deregulation, and hence market price increases. Fortunately, large price increases did not take place, primarily due to the drop in world oil prices and economic recession of the early 1980s. This is an example showing that efficiency and equity can be in conflict, though external circumstances can modify the tension. Also, ideal policies do not always take place (an example of political failure analogous to market failure), and distributional issues may have a lower priority than overall efficiency.

3. ILLUSTRATIVE EXAMPLES

3.1 Carbon Taxes

A number of studies have examined the income distribution impacts of carbon taxes or carbon emission permits. The complexity and international nature of the issue is one reason, an increasing number of analyses are performed in a general equilibrium context.

Gbadebo Oladosu and Adam Rose begin an examination of this issue by summarizing the three special features most emphasized to distinguish the impacts of these policies in contrast to the incidence of taxes in general. First, although the initial focus is on a few but very prominent sectors that emit carbon (coal/oil/gas extraction, transportation, and refining), the fundamental role of these products, however, means that carbon reduction policies will eventually ripple throughout the economy, with possibly surprising outcomes. This is one of the major reasons computable general equilibrium models are used (i.e., numerical simulation models based on behavioral responses by producers and consumers to price signals in interconnected markets).

Second, fossil energy products and most energy-intensive processed goods (food, housing, automobiles) are necessities, making it relatively more difficult to substitute away from them. Spending on necessities is inversely related to income and, hence, all other things being equal, carbon taxes would lean toward being regressive in partial equilibrium terms.

Third, unlike most existing taxes, carbon taxes are not aimed primarily at raising revenue. Moreover, they do not create a distortion in the price system but are intended to correct one. The factors have important implications for the disposition of carbon tax revenues (or revenues from the auction of carbon emission permits), including the possibility of using carbon tax revenues for tax relief that promises to reduce the distortionary nature of the preexisting tax system. This revenue recycling can take a number of forms (reductions in personal income taxes, corporation income taxes, etc.), with different distributional impacts (both regressive and progressive). Again, however, the final impacts of these alternatives are not a priori obvious when one allows for general equilibrium considerations.

Overall, a large number of other factors, both unique to carbon taxation and applicable to tax policy in general, can have a major bearing on the relative unevenness of impacts. It is also important to note several factors that affect the size of the aggregate impact, since it will also have a bearing on the degree to which the baseline income distribution changes. Of course, the size of the aggregate impact can affect the distribution of impacts in highly nonlinear models or where such factors as income elasticities (i.e., the percentage change in demand following from a 1% increase in income of demand vary strongly across income groups). Major factors include the following:

1. The energy-intensity of the economy. The higher this factor, the larger the overall impact and the more profound income inequalities of impacts can become in relation to the baseline.

2. The magnitude of the carbon tax or emission permit price, for reasons similar to factor 1.

3. The unit upon which the tax is based (e.g., energy equivalent, carbon emissions, or carbon content). This bears on the relative bluntness or precision of the policy and hence its cost-effectiveness and overall impacts.

4. The narrowness or breadth of products or entities on which the tax is imposed. For example, a tax on energy as a whole may be regressive but a tax on motor fuels may be progressive.

5. The point of initial imposition of the tax (i.e., upstream suppliers of energy or downstream users of energy). This is related to whether a tax on production or consumption is specified. Progressivity

is likely to be greater if imposed upstream and if tax shifting is difficult.

6. The ability to shift the tax forward onto customers or backward onto factors of production. In terms of the latter, shifts on to labor are likely to be more regressive than shifts onto capital.

7. The extent of factor mobility, as in the regressivity of transitional effects on coal miners having to find jobs in other industries.

8. The extent to which general equilibrium effects are taken into account. While this typically exacerbates the level of impacts, it mutes their unevenness as they are spread out over the economy as a whole.

9. The extent of production/income distribution/consumption interactions. For example, a large decrease in coal production may have a disproportionate effect on income of high-wage unionized miners, but the decrease in their consumption may be for products that are characterized by a predominant number of low-wage earners.

10. The extent to which dynamic effects are taken into account (e.g., with respect to savings and investment). The income distribution has an effect on economic growth, which in turn affects future distribution. Here progressivity is often thought to have a detrimental effect on future growth, though the effect on future income distribution is ambiguous.

11. The use of annual income versus lifetime income as a reference base (e.g., as proxied by consumption). The latter is the more appropriate measure given the long-run nature of the issue.

12. The extent to which demographic considerations pertaining to household composition are taken into account; related to this is the demarcation of income groups, especially at the highest and lowest levels.

13. The type of revenue recycling (including lump-sum transfers) and in contrast to alternatives such as budget deficit reduction and individual and corporate tax relief. The latter is usually considered the most regressive.

14. Asset market considerations, such as the extent to which financial returns are affected. This factor bears primarily on higher income groups.

15. The degree to which the impacts result in unemployment. Those already in lower income groups are less able to withstand the shocks of both temporary and long-term unemployment.

16. Basic parameters and assumptions of the analytical model (especially price elasticities of demand and supply, elasticities of substitution with respect to inputs and imports, market structure, etc.). For example, the higher the elasticities of substitution between energy and other factors, the less the negative impacts. Also, the greater the variation in price and income elasticities of demand, the greater the potential progressivity or regressivity.

If we try to summarize studies of carbon taxes on households, we find that the distributional effects of a carbon tax can often be regressive unless the tax revenues are used either directly or indirectly in favor of the low-income groups. Consequently, there seems to be a conflict between efficiency and equity goals, although some analyses are less conclusive. Due to the many causal factors involved and the relative lack of analyses on this topic, it is difficult to draw conclusions about country differences. The same applies to the impact of model type or size of the carbon tax.

3.2 OPEC and Environmental Policy

A carbon tax also has distributional consequences for producers of energy. One important issue in the international context is how a carbon tax affects the producers of fossil fuels. In the ongoing international climate negotiations, the possible impacts on fossil fuel producers and producing countries have played an important role, and both coal producers and OPEC countries have shown a very reluctant position in the negotiations.

A study by Elin Berg, Snorre Kverndokk, and Knut Einar Rosendahl shows the impacts on fossil fuel producers and especially oil producers, as well as the distribution of burden between producers and consumers, of a global carbon tax. This is analyzed by an intertemporal equilibrium model for fossil fuels, where the dynamic aspects of resource extraction is taken into account. According to their results, a global carbon tax of $10 per barrel will hurt OPEC more than other producers. The reason is that the cartel finds it optimal to reduce its production in order to maintain a high price level when the tax is introduced. Hence, the crude oil price is almost unchanged initially, and, in the first 40 years, the tax is almost completely shifted to the consumers. As the producer price of oil grows slower compared to the reference case, non-OPEC accelerates its oil production. Thus, while the market structure is important in explaining OPEC's behavior in the model, the dynamic aspect explains the behavior of the fringe. The oil wealth of non-OPEC is reduced by merely 8%, whereas OPEC's wealth is reduced by more than 20%. Thus, if we do not consider the environmental

benefits, the main losers under the carbon tax regime will be the consumers and OPEC, while the tax revenue is collected by the governments in the consuming countries.

The importance of market power is demonstrated by the results of a competitive model—that is, a model where all consumers and producers behave competitively (no market power). Here low-cost producers (OPEC countries) supply significantly more initially than in the model with market power, which implies a much lower oil price, making oil production unprofitable for high-cost producers (non-OPEC) in the first period. In this situation, a carbon tax will have a relatively much higher impact on the non-OPEC oil wealth compared to that noted earlier (i.e., about 40%), as the low-cost producers will no longer act to maintain the price. However, this reduction is less dramatic for non-OPEC than the original change in market structure, which reduces the oil wealth by more than 70%. For the OPEC countries the relative loss due to the carbon tax is about the same as mentioned previously.

The results may explain why OPEC countries are reluctant to introduce global carbon taxes or other restrictions on carbon emissions. In contrast, other oil producers seem to have less to fear if such an agreement were reached, and this seems to be partly consistent with their positions toward carbon restrictions. Therefore, economic factors may be important in explaining attitudes of oil producers in global warming negotiations.

3.3 Distribution of Tradable Emission Permits

Several alternative criteria have been put forth for the interregional and international analysis of the equity implications of environmental policy. Nine equity principles, a general operational rule emanating from each, and a corresponding rule applicable to the allocation of tradable emission permits at the regional level are presented in Table I.

Of course, there are other levels of application of equity criteria, including sectors and households. In some ways, these units are superior to regions, because they address the issue of relative impacts in terms of welfare of the individual (the basic unit in a democracy). Two reasons are offered for orienting the analysis to the regional level, however. First, are limitations on the availability of data for production and household delineations according to welfare levels (e.g., income brackets or profit rates). Second, political realities indicate that regions are important. This is reinforced by the "regional" character of legislative bodies and several major economic sectors (e.g., oil and gas production, steel), which have translated into regional influence in previous environmental policy making, such as U.S. acid rain legislation. Several other important regional dimensions of the issue relating to natural and social science considerations.

To be operational, an equity criterion must be applied to a reference base, essentially a metric or index, which itself has no ethical content. Consider the following six permit allocation formulas (consisting of an equity criterion and an associated reference base):

1. Sovereignty (emissions based)
2. Egalitarian (population based)
3. Economic activity (GRP based)
4. Ability to pay (inverse-GRP based)
5. Sovereignty (energy-use based)
6. Sovereignty (energy-production based)

Note that there is not a one-to-one correspondence between criteria and reference bases. For example, the sovereignty criterion can be implemented according to more than one reference base, and gross regional product (GRP) can serve as a reference base for more than one criterion. Reference base distinctions are important for several reasons. First, as in the case of three bases applied to the sovereignty criterion, they can reflect alternative energy policy positions. For example, Formula 5 simulates a downstream administered program on fossil energy end users, while Formula 6 simulates an upstream program on fossil energy producers. Most important, the welfare implications of various references bases for the same equity criterion will differ as well.

The results of the application of the six equity formulas to the sharing of the Kyoto protocol target within United States by Adam Rose and Zhong Zhang are presented in Fig. 2. Some interesting results arise.

First, for some of the formulas (e.g., Sovereignty/Energy Use), there is very little variation of welfare gains across regions. Second, for some regions (e.g., Southwest, Mid-Atlantic, New England), there is little difference across equity formulas. For some regions, the equity formula does matter greatly (e.g., south central, north central). Note also the results for some equity criteria differ greatly from their application in the international domain. For example, the egalitarian (per capita) criterion leads

TABLE I

Alternative Equity Criteria for Greenhouse Gas Mitigation Policy

Criterion	Basic definition	General operational rule	Operational rule for CO_2 permits
Allocation based			
Sovereignty	All regions have an equal right to pollute and to be protected from pollution	Cut back emissions in a proportional manner across all regions	Distribute permits in proportion to emissions, energy-use, land area, etc.
Egalitarian	All people have an equal right to pollute or to be protected from pollution	Allow emissions in proportion to population	Distribute permits in proportion to population
Ability to pay	Mitigation costs should vary directly with regional economic well-being	Richer regions should shoulder a higher proportion of gross cost of abatement[a]	Distribute permits inversely to GRP
Econ Activity	All regions should be allowed to maintain their standard of living	Richer regions should not be penalized	Distribute permits in proportion to GRP
Outcome based			
Horizontal	All regions should be treated equally in terms of changes in welfare	Equalize net welfare change across regions (net loss as proportion of GRP equal for each region)[b]	Distribute permits to equalize net welfare change (net loss as proportion of GRP equal for each region)[b]
Vertical	Welfare gains should vary inversely with regional economic well-being; welfare losses should vary directly with GRP	Progressively share net welfare change across regions (net loss proportions directly correlated with per capita GRP)[b]	Progressively distribute permits (net loss proportions directly correlated with per capita GRP)[b]
Compensation	No region should be made worse off	Compensate net losing regions	Distribute permits so no region suffers a net loss of welfare
Process based			
Rawl's Maximum	The welfare of the worst-off region should be maximized	Maximize the net benefit to the poorest regions	Distribute largest proportion of net welfare gain to poorest regions
Consensus	The negotiation prices is fair	Seek a political solution promoting stability	Distribute permits in a manner that satisfies the (power weighted) majority of regions

[b] Net welfare change is equal to the sum of mitigation costs + permit sales revenues − permit purchase expenditures.

to the relatively greatest cost burden being incurred by one of the regions of the United States with the lowest per capita income (south central states). This is just the opposite of the result in the international domain, where countries such as China and India stand to gain the most from application of this criterion.

4. CONCLUSION

Energy is a necessity in both consumption and production. Thus, energy policies may have large consequences on income and profit. The ideal goals of this policy are to achieve efficiency, as well as an acceptable distribution of energy goods and services. However, even efficient markets can have undesirable distributional consequences for households and producers. A policy that leads to an efficiency gain may not be overall welfare improving if some are made worse off, or it may be viewed as inequitable if it widens the gap between rich and poor. This makes the distribution of energy goods an important part of energy policy.

This article briefly summarizes the range of root causes of energy policy and how they relate to distribution and equity, and it provides an overview of welfare economics and social justice theories, the theoretical underpinnings for energy policy. It also provides some illustrations. As our survey shows, there is no single best equity principle nor one that is universally agreed upon. Therefore, it is difficult to develop unambiguously good policy proposals with respect to the distributional effects of energy policy

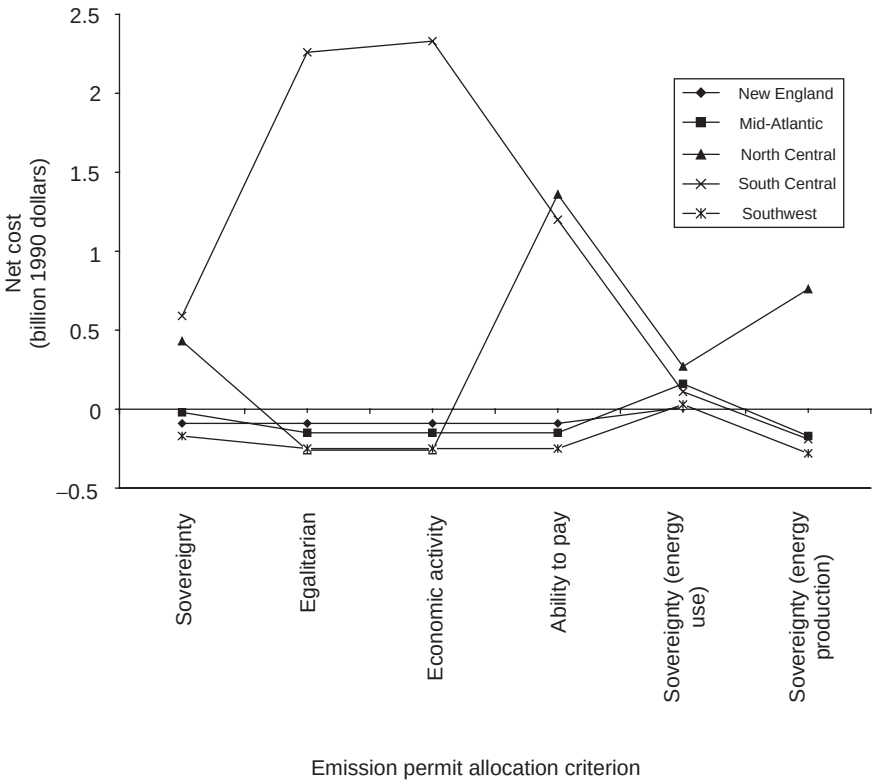

FIGURE 2 Net cost of meeting U.S. Kyoto protocol commitments in selected regions under alternative permit allocation criteria.

in particular. However, policymakers should be aware of the distributional effects before a policy is implemented in general.

Glossary

anhydrous ethanol Essentially pure ethanol containing very little, if any, water.

biomass Plant matter of recent (nongeologic) origin or materials derived therefrom.

cellulase A combination of enzymes that catalyze the reaction of water with cellulose to release shorter chains and ultimately soluble glucose sugar.

cellulose A polymer of up to about 10,000 glucose molecules joined by beta 1-4 linkages in long, straight cellulose chains that can align parallel to one another and join by hydrogen bonds in crystalline regions that typically contain much of the cellulose. About 40 to 50% of the structural portions of plants is cellulose.

cellulosic biomass Biomass composed primarily of inedible fibrous plant parts having cellulose as a prominent component. Examples include grass, wood, and agricultural and forestry residues. Also known as lignocellulosic biomass.

corn A grain composed of about 70% starch, 10 to 11% crude protein, 4.5 to 6.0% oil, 6% hemicellulose, 2 to 3% cellulose, 1% lignin, and 1% ash.

E85 A mixture of 85% ethanol with 15% gasoline.

E95 A mixture of 95% ethanol with 5% gasoline.

enzymes Proteins originating from living cells and capable of catalyzing chemical changes in organic substances.

ethanol A chemical compound with the formula C_2H_5OH that is widely used in beverages, solvents, cosmetics, and other commercial products and is also an excellent transportation fuel. Ethanol is readily metabolized and biodegradable and does not persist in the environment.

hemicellulose An amorphous and noncrystalline polymer usually containing arabinose, galactose, glucose, mannose, and xylose sugars and typically including lower amounts of other compounds such as hexuronic acids and methoxyl, acetyl, and free carboxyl groups. Hemicellulose represents about 25 to 30% of the overall dry weight of cellulosic biomass and works with lignin to cement the cellulose fibers into a composite material of great strength.

hydrolysis The reaction of water with a compound to form other compounds.

hydrous ethanol Often a mixture of 95.5% ethanol and 4.5% water as used in Brazil.

lignin A complex phenylpropanoic acid polymer that is chemically linked with hemicellulose to cement cellulose together. Lignin represents about 15 to 20% of the dry weight of cellulosic biomass and is not fermentable at an appreciable rate.

starch A polymer of glucose molecules joined predominately by alpha 1-4 linkages.

sugar A family of simple, often sweet, compounds consisting of carbon, hydrogen, and oxygen obtained in the juice of many plants and particularly from sugarcane and sugar beets. Also refers specifically to sucrose, a particular type of sugar. Other sugars typically contained in biomass include arabinose, galactose, glucose, mannose, and xylose.

Ethanol provides a valuable liquid fuel alternative to a transportation sector that is disproportionately dependent on one politically volatile and finite energy source: petroleum. In 2000, the United States consumed almost 100 quads of energy (a quad is 10^{15} BTUs or 1 EJ), with the largest single fraction, almost 40%, coming from petroleum. Furthermore, while the domestic supply and demand for all other energy sources are nearly balanced in the United States, close to two-thirds of petroleum is imported, with unstable regions of the world controlling the largest sources, and imports continue to increase as domestic well productivity drops. This high dependence on imported oil results in strategic vulnerability to price and availability disruptions such as

occurred in the "energy crises" of the 1970s. Imported petroleum also accounts for about 45% of the net trade deficit of the United States and was the single largest contributor at $59.2 billion in 1999. Transportation uses over two-thirds of petroleum consumed in the United States and is almost totally dependent on oil, with over 96% of transportation energy from this one source. Furthermore, vehicle miles and total numbers of vehicles continue to rise, increasing petroleum demand more. Thus, abundant alternative domestic energy sources for transportation are vital. Although other countries may not have the high per capita transportation energy use of the United States, many suffer from similar oil-related strategic and economic vulnerabilities.

Our transportation fuel situation presents other important challenges. First, petroleum is a finite resource that cannot be sustained indefinitely, and its price must increase and availability decrease over time. Petroleum also represents a valuable resource for chemicals and materials that benefit from the unique complexity of petroleum far better than burning it to carbon dioxide and water. Additionally, burning petroleum contributes about 43% of the carbon dioxide released into the atmosphere each year in the United States, and this large quantity makes carbon dioxide the most potent greenhouse gas that could cause global climate change. Furthermore, because of its high dependence on petroleum, transportation contributes about 33% of the carbon dioxide released in the United States annually, more than for residential, commercial, or industrial applications. The United States is the largest contributor to release of greenhouse gases accounting for about 25% of the world total, and new fuels that dramatically reduce such emissions are essential to change this situation. Better transportation fuels and utilization systems can also substantially improve urban air quality and reduce environmental effects of handling and consuming fuels.

Ethanol has favorable fuel, resource, and environmental attributes as a transportation fuel. Ethanol is a liquid fuel that readily integrates with our infrastructure, is widely accepted for blending with gasoline, and can be used in nearly pure form. Large quantities of this fuel are now made from starch in the United States and sugar in Brazil as well as lesser amounts in other countries. Ethanol can also be made from abundant, sustainable sources of low-cost cellulosic biomass such as agricultural and forestry residues, portions of municipal solid waste, and herbaceous and woody crops that can dramatically reduce petroleum consumption and greenhouse gas emissions. For the latter, costs could potentially be reduced to be competitive as a pure fuel. This article summarizes some of the key attributes of this beneficial fuel and outlines how it can be produced from these resources.

1. USE AS A FUEL

1.1 Background

Ethanol is also known as ethyl alcohol or fermentation alcohol. Although ethanol is often referred to as just "alcohol," particularly as a beverage, the term "alcohol" technically refers to a broader family of compounds with the chemical formula ROH in which R contains one or more alkyl groups containing carbon and hydrogen atoms and OH refers to the hydroxyl group containing oxygen and hydrogen atoms, respectively. Ethanol is a member of the alcohol family and has the chemical formula C_2H_5OH in which C, H, and O refer to carbon, hydrogen, and oxygen atoms, in that order.

Ethanol is a colorless, clear liquid that looks like water and is completely miscible with it. Ethanol has a somewhat sweet flavor when diluted with water; a more pungent, burning taste when concentrated; and an agreeable ether-like odor. It is widely used in medicines, lotions, tonics, colognes, rubbing compounds, and solvents and also for organic synthesis. Beverage ethanol dates back to ancient times, with Sumerians and Babylonians making beer before 6000 BC. It was also among the earliest compounds investigated with the study of ethanol from distillation of wine likely in 11th-century Italy.

1.2 Transportation Fuel in Internal Combustion Engines

Ethanol is more volatile than water, flammable, burns with a light blue flame, and has excellent fuel properties for spark ignition internal combustion engines. Its research octane number (RON) is 109, its motor octane number (MON) is 90, and its average octane is 99 while the latter for regular gasoline is typically about 88. The latent heat of vaporization of 663.4 kJ/liter (2,380 Btu/gal) is higher than that of gasoline at about 250 kJ/liter (900 Btu/gal). The energy content of ethanol is 21.2 mega joules/liter (76,000 Btu/gallon), as the lower heating value, about two-thirds that of gasoline at about 30.1 mega joules/liter (115,000 Btu/gallon). Thus, somewhat more ethanol is needed to achieve the same

range as gasoline. On the other hand, engine efficiency can be improved by running at higher compression ratios that take advantage of the better fuel properties of pure ethanol, and ethanol can achieve about 75% or more of the range of gasoline on a volume basis for an optimized ethanol engine. The boiling point of ethanol is 78°C (172°F) while that of gasoline is about 27°C (81°F), and the Reid vapor pressure (closed vessel pressure at 38°C (100°F)) for ethanol is only 16 kilopascals (2.3 psi) versus about 71 kilopascals (10.3 psi) for gasoline. Thus, evaporative emissions that cause smog formation are less for pure ethanol than for gasoline, but because ethanol is a polar molecule that resembles water more than gasoline, low levels of ethanol blended with gasoline increase vapor pressure. Although vapor pressure drops as more ethanol is added, U.S. vehicle manufacturers do not warranty conventional vehicles with these blends, and fuel providers have been reluctant to reduce the vapor pressure of gasoline to compensate. The lower vapor pressure of pure ethanol also means that starting is more difficult in cold weather. Ethanol has a very low toxicity, particularly in comparison to other fuels, and is readily biodegradable in water and soils, reducing penetration of plumes from leaks and consequences of spills compared to MTBE and petroleum-based fuels.

In Brazil, ethanol, mostly from cane sugar, is produced as either anhydrous ethanol that contains 99.6% ethanol and 0.4% water for use in 22% blends with gasoline or as hydrous ethanol containing 95.5% by volume ethanol and 4.5% water that is burned directly as a pure fuel. Brazil originally promoted ethanol use through creating a state-owned company, Petrobras, which guaranteed sales to companies and sold the fuel to customers at a discount relative to gasoline. Economic incentives were also offered to ethanol producers. As a result, annual production of hydrous ethanol fueled vehicles climbed from only 3114 in 1979 to more than 697,000 at the peak in 1986. Hydrous ethanol use peaked at about 10.88 billion liters (2.88 billion gallons) in 1989 with another 1.72 billion liters (0.46 billion gallons) added to gasoline as 22% ethanol blends during that year, as shown in Fig. 1 However, incentives were then reduced, and hydrous vehicle manufacture virtually ceased by 1999 due to sugar pricing and ethanol supply problems. Although production of some hydrous ethanol vehicles resumed recently and the Brazilian government approved increasing ethanol content in blends to 26% for gasoline and 3% for diesel, Fig. 1 shows that total ethanol production slipped to about 11.15 billion liters (2.95 billion gallons) in 2001 with only about 5.14 billion liters (1.36 billion gallons) used as hydrous fuel as ethanol vehicles have been replaced with those that use anhydrous/gasoline mixtures.

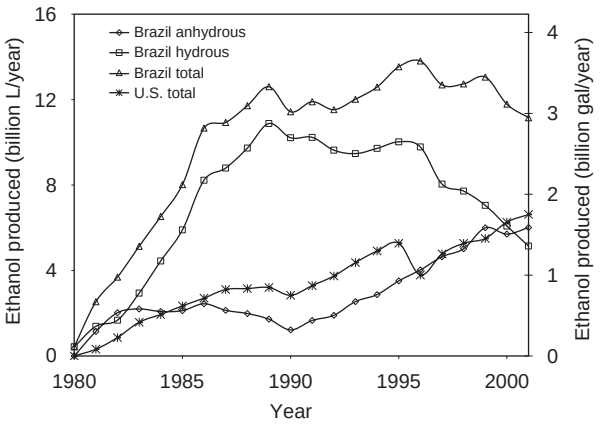

FIGURE 1 Annual production of fuel ethanol in Brazil and the United States since 1980. Ethanol is made from cane sugar in Brazil and from starch crops (mostly corn) in the United States. In Brazil, anhydrous ethanol is sold as 22% blends with gasoline, while hydrous ethanol, containing about 4.5% water, is used as a pure fuel. Almost all the fuel ethanol sold in the United States is used as a 10% blend in gasoline.

In the United States, fuel ethanol production grew from virtually nothing in 1980 to about 6.63 billion liters (1.75 billion gallons) by 2001, as shown in Fig. 1. Most of this ethanol is from corn starch and is used as 10% ethanol blends, reducing gasoline consumption and extending petroleum supplies. Ethanol also improves octane, decreasing the need for other octane boosters such as benzene, which are toxic and often carcinogenic, and oxygen in ethanol reduces emissions of unburned hydrocarbons and carbon monoxide, particularly for older vehicles that tend to burn rich.

Special vehicles are sold in the United States that can burn any fuel containing from 0 to 85% ethanol in gasoline, the latter being designated as E85, with 15% gasoline being used to promote cold starting. Only 172 of these vehicles were on the road in 1992, but the number rose to 48,022 in 2001, with 13,342 net new vehicles added that year. E85 engines consumed about 26.2 million liters (6.9 million gallons) of ethanol in 2001. These flexible fueled vehicles have in line sensors that measure ethanol levels and adjust the air-fuel ratio to maintain proper combustion. Although the compression ratio cannot be adjusted to fully capitalize on the favorable fuel properties of ethanol in high-level blends as with hydrous ethanol in Brazil, the technology ensures

fuel availability. Catalytic converters are needed to minimize tailpipe emissions of aldehydes, the primary pollutant resulting from incomplete ethanol combustion, and NO_x formation could increase for high-compression engines designed to maximize fuel utilization efficiency.

Ethanol has been used in compression ignition engines, but the lubrication properties and cetane of ethanol are not matched to conventional diesel technology. Thus, the engines must be modified or additives used to improve compatibility. On the other hand, adding ethanol to diesel fuel reduces particulate emissions, a key need, and formulations have been developed to stabilize dispersion of ethanol in diesel fuel.

1.3 Fuel Cells

Fuel cells are attractive because of low emissions and good efficiencies. Fuels cells react hydrogen with oxygen to make water at controlled conditions that minimize formation of pollutants such as NO_x and produce no unburned hydrocarbon emissions. In 2002 nearly every major automaker had large teams working on vehicle fuel cells, with most focused on operation with either gasoline or hydrogen. Because storing hydrogen onboard vehicles is challenging, using a liquid fuel such as ethanol as a hydrogen source is highly desirable but more complex to implement. Reformer technologies being developed for gasoline in fuel cells would generally be capable of using ethanol, but experience is limited on releasing hydrogen of acceptable quality from either one. Reforming methanol to hydrogen for fuel cells in buses and cars was developed and demonstrated in the United States, Germany, and Japan before environmental concerns about methanol limited this option. Reforming ethanol requires more steps, and this technology has been demonstrated in the laboratory but not onboard vehicles. Ethanol can also be partially oxidized to hydrogen, carbon monoxide, and carbon dioxide followed by reaction of carbon monoxide to hydrogen, and a partial oxidation reactor coupled to a shift reactor and a polymer electrolyte membrane (PEM) fuel cell followed by heat recovery achieved an efficiency of 43% with undetectable emissions of hydrocarbons, carbon monoxide, and nitrous oxides. Thus, ethanol fuel cells are very promising, but considerable research and development would enhance the readiness of this not widely studied technology.

2. ETHANOL PRODUCTION APPROACHES

Ethanol is manufactured by two primary paths: (1) fermentation of sugars derived from sugar, starch, or cellulosic materials or (2) reaction of ethylene with water. The former is favored for production of fuel. The latter has been used to make industrial grade ethanol for solvents, cosmetics, medicines, and so on, but purification of fermentation ethanol is displacing ethylene-derived ethanol for these applications. Some new processes are under development for fermentation or catalytic conversion of synthesis gas (carbon monoxide and hydrogen) from wood, natural gas, or coal, but synthesis gas from sustainable resources such as biomass is expensive. This article focuses on fermentation ethanol because it can potentially meet fuel cost and volume needs for large-scale fuel production, while ethylene is too expensive and supplies would likely be stretched.

3. PRODUCTION FROM SUGAR CROPS

3.1 Processing Sugar to Ethanol

Brazil produced about 18.5 million metric tonnes (20.4 tons) of processed sugar in the 2001/2002 harvest, with approximately 9.45 million metric tonnes (10.4 tons) used domestically and the rest exported. Brazilian sugar is mostly derived from sugarcane, a drought-tolerant tropical and subtropical crop containing about 12 to 17% sugars (90% sucrose, 10% glucose) and 68 to 72% moisture. Brazil grew about 272 million metric tonnes (300 million tons) of sugarcane in the 2001/2002 season, making it second to India in world cane production that year. In 1975, Brazil adopted a Pro-Alcool Program to convert sugar to ethanol to reduce dependence on petroleum imports that were damaging the economy, and Fig. 2 summarizes the sugar extraction and fermentation approach. In dedicated ethanol plants, cane juice is heated to about 105 to 110°C (221 to 230°F) to reduce microbial contamination and then fermented. In combined ethanol-sugar facilities, sucrose is removed by crystallization and the remaining molasses containing up to about 65% sugars is fermented. In either approach, sugar, $C_6H_{12}O_6$, is readily fermented to ethanol, C_2H_5OH, by common yeast such as *Saccharomyces cerevisiae* according to a reaction carried out for

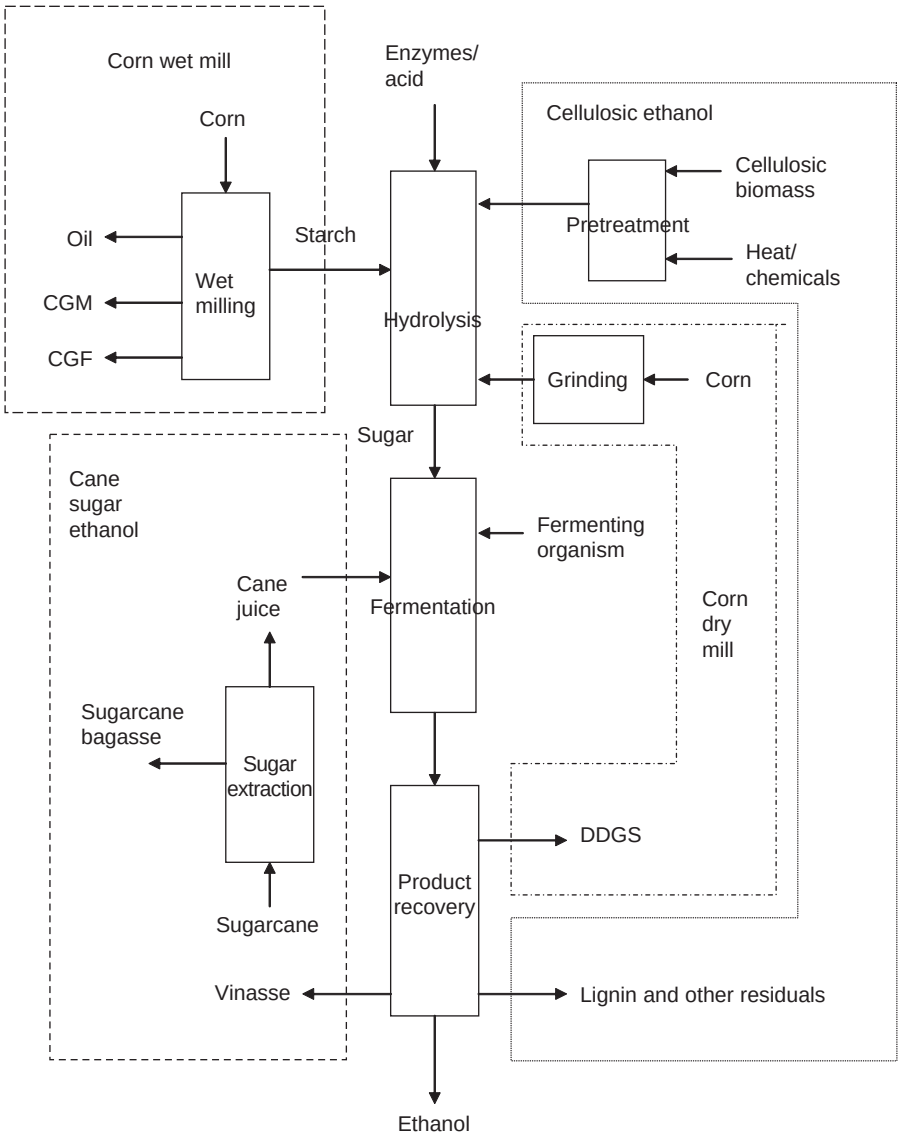

FIGURE 2 A simplified process flow diagram for production of ethanol from cane sugar, corn, and cellulosic biomass. All have similar fermentation and ethanol recovery operations but use different approaches to release sugars and generate different coproducts. Sugar can be directly extracted from sugarcane, and the residual bagasse is used as a boiler fuel to provide much of the energy for the extraction and ethanol production and recovery operations. In a corn dry mill, corn is ground, and enzymes and heat are added to hydrolyze starch to sugars for conversion to ethanol ,while the oil, protein, and fiber in corn are recovered after fermentation as an animal feed known as DDGS. Wet mills first fractionate corn to separate corn oil, corn gluten meal (CGM), and corn gluten feed (CGF) to capture value for food and animal feed, and the starch can then be hydrolyzed to sugars for fermentation to ethanol. For cellulosic biomass, heat and acids or enzymes hydrolyze the hemicellulose and cellulose portions to release sugars that can be fermented to ethanol, and the lignin and other remaining fractions can be burned to provide all the process heat and electricity for the conversion step with excess electricity left to export.

millennia:

$$C_6H_{12}O_6 \rightarrow 2C_2H_5OH + 2CO_2 \qquad (1)$$

in which CO_2 is carbon dioxide released during this process. About 70% of Brazilian ethanol facilities, often called distilleries, use batch operations in which sugar, nutrients, and other ingredients are added at the beginning of the fermentation or fed batch processes in which one or more of these ingredients are added as fermentation proceeds. However, continuous processes in which ingredients are constantly added and product removed from

fermentation vessels are also used. Yeast is typically concentrated and separated from the fermentation effluent, washed with sulfuric acid to reduce bacterial contamination, and recycled to fermentors, resulting in high cell densities that shorten fermentations to 6 to 10 h at temperatures of about 33 to 35°C with high ethanol yields (90 to 92% of theoretical) and concentrations (8 to 11% on a volume basis). According to Eq. (1), no more than 51.1 kg of ethanol can be obtained from fermentation of 100 kg of sugar, with yeast achieving about 90 to 92% of this. Thus, about 460 to 470 kg (920 to 940 pounds) or 580 to 590 liters (139 to 142 gallons) of ethanol result from a metric tonne (ton) of sugar. Following yeast removal, the fermentation broth containing ethanol, water, nutrients, and some yeast passes to distillation to make 95.5% "hydrous" ethanol, which can be taken to 99.6% "anhydrous" ethanol in a dehydration section, if desired. The remaining dissolved solids, called vinasse, are used as a fertilizer and in irrigation. About 5170 liters of ethanol could be obtained from a hectare of land in Brazil in 1996, and 13.9 billion liters (3.7 billion gallons) of ethanol in addition to 13.5 million metric tonnes (14.9 million tons) of sugar were made from 273 million metric tonnes (300 million tons) of sugarcane that year.

3.2 Costs

The costs of making ethanol in Brazil are estimated to be about \$0.006 to 0.007/liter (\$0.023 to 0.026/gallon) for labor, \$0.004 to 0.006/liter (\$0.015 to 0.023/gallon) for maintenance, \$0.002/liter (\$0.008/gallon) for chemicals, \$0.002 to 0.003/liter (\$0.008 to 0.011/gallon) for energy, \$0.004/liter (\$0.015/gallon) for other items, and \$0.127 to 0.134/liter (\$0.481 to 0.507/gallon) for sugar. Thus, the total cash cost of ethanol is on the order of \$0.167 to 0.185/liter (\$0.632 to 0.700/gallon). The overall capital investment is about \$0.52/annual liter (\$2.00/gallon) of capacity for a process that operates for 150 days/year making about 240,000 liters (900,000 gallons) of ethanol per day. Allowing another \$0.04 to 0.06/liter (\$0.15 to 0.23/gallon) for interest on capital, capital recovery, and other fixed costs, the total cost including return on capital as applied in Brazil is about \$0.21 to 0.25/liter (\$0.79 to 0.95/gallon) at the plant gate without transportation, distribution, taxes, and other costs. More on-stream time would greatly reduce the unit capital cost charged to ethanol. Hydrous costs about 7% less than anhydrous ethanol because less energy and capital are needed to meet final product specifications. Costs in Brazil dropped at about a 30% rate with each doubling of experience through 1990 and continue to decline at about a 10% rate due to learning curve effects resulting from commercial experience. Opportunities have been identified to reduce costs by about 23%, mostly by reducing the intensity of growing cane but by also improving conversion operations.

3.3 Energy Balance

About 197 to 222 mega joules of fossil energy are used for providing seeds, labor, power for agricultural operations, agricultural equipment, fertilizers, lime, herbicides, insecticides, and cane transportation to grow a metric tonne of sugarcane (169,000 to 191,000 Btu/ton). However, much of the energy for sugar extraction and fermentation is provided by burning the bagasse left after processing, but some fossil energy is used for electricity generation, chemicals and lubricants manufacture, erection of buildings, and manufacture of equipment, a total of about 40 to 70 mega joules/metric tonne (34,000 to 60,000 Btu/ton) of cane. Overall, about 237 to 292 mega joules of fossil energy are consumed (204,000 to 251,000 Btu/ton) compared to 1707 to 1941 mega joules of energy in the ethanol from a metric tonne (1.470×10^6 to 1.669×10^6 Btu/ton). Based on these values, the energy balance ratio of ethanol energy output to fossil fuel input is between about 5.9 to 8.2, not including the 175 to 328 mega joules/metric tonne of cane (150,000 to 282,000 Btu/ton) left from burning bagasse after sugar has been extracted, a very favorable energy balance.

3.4 Greenhouse Gas Emissions

In simple terms, accumulation of methane, carbon dioxide, nitrous oxide, and other gases that trap infrared radiation are predicted to cause global climate change, and carbon dioxide has the greatest impact because of the huge quantities released when fossil fuels are burned. Burning coal, petroleum, and natural gas, in order of decreasing impact, release previously trapped carbon into the atmosphere, resulting in a net accumulation of carbon dioxide. On the other hand, if fuels are made with renewable biomass such as wood, carbon dioxide released during processing and burning can be recaptured by photosynthesis when more biomass is grown to replace that harvested. While biomass is carbon dioxide neutral, fossil inputs to plant, grow, harvest,

transport, convert, and distribute biomass and its products contribute to greenhouse gas accumulation and must be considered.

Burning bagasse can provide 100% of the thermal energy and 92% of the electricity for processing of sugar to ethanol, and less than about 8% comes from fossil sources. Based on Brazilian experience that 1.2 liters of ethanol can replace 1.0 liters of gasoline, the net contribution to carbon dioxide accumulation by vehicles running on hydrous ethanol is less than about 10% of gasoline, and substituting surplus bagasse or other renewables for fossil fuel to generate electricity could improve the balance further. However, intensive sugarcane agricultural practices raise serious concerns about its sustainability, and low and no-till and other practices will be needed for cane sugar to become more viable.

4. PRODUCTION FROM STARCH CROPS

4.1 Starch Processing

Corn grain contains about 70% starch, 10 to 11% crude protein, 4.5 to 6.0% oil, 6% hemicellulose, 2 to 3% cellulose, 1% lignin, and 1% ash and is the dominant choice for current fuel ethanol production by dry or wet milling operations in the United States. In a typical dry mill, grain is milled to a powder, heated with water addition to about 85°C, mixed with alpha-amylase enzyme, held for up to an hour, heated further to 110 to 150°C to liquefy the starch and reduce bacteria levels, cooled back to about 85°C, and held with more alpha amylase for about 1 h. Then, the stream is cooled further, and glucoamylase enzyme added to complete conversion to sugars known as dextrose. This overall saccharification operation occurs by the hydrolysis reaction:

$$(C_6H_{10}O_5)_n + nH_2O \rightarrow nC_6H_{12}O_6 \qquad (2)$$

in which $C_6H_{12}O_6$ is a glucose sugar molecule formed when the alpha bonds linking n units of $C_6H_{10}O_5$ in long chains of starch are broken and combined with n molecules of water, H_2O. Yeast then ferment glucose to ethanol and carbon dioxide, just as in Eq. (1). The fermentation can be in batch operations held until the fermentation is complete in about 48 h or by continuous processes with ongoing sugar addition and takeoff of fermented broth known as beer. The beer containing about 12 to 14% or more ethanol is typically distilled to around 95% purity, close to the azeotropic composition at which further enrichment by ordinary distillation ceases, and this mixture is dehydrated with molecular sieves to anhydrous ethanol. The solids containing the remaining protein, oil, and fiber are dried to a 27% protein product known as distillers dried grains with solubles (DDGS) or just distillers dried grains (DDG), depending on whether process syrup is combined with the solids or not, and used in animal feeds. The carbon dioxide can be sold for carbonated beverages, dry ice, and other applications. Overall, about 460 to 490 liters (110 to 118 gallons) of ethanol weighing 365 to 390 kg (730 to 780 lbs), 357 to 335 kg (714 to 670 lbs) of DDGS, and 350 to 370 kg (700 to 740 lbs) of carbon dioxide result from each metric tonne (per ton in parentheses) of corn processed—close to equal masses of each coproduct. Figure 2 presents a simplified block flow diagram for dry milling.

Although the greatest number of facilities are dry mills run by smaller producers, more ethanol is made in larger wet milling operations generally owned by larger companies. In wet mills, corn is first steeped and milled to separate the starch, protein, fiber, and germ, again as summarized in Fig. 2. Corn oil is removed from the germ for food, and the remaining germ meal is combined with the fiber and water from steeping as a 21% protein animal feed known as corn gluten feed. A portion of the corn protein is sold as corn gluten meal, a 60% protein product added to chicken and other animal feeds. Starch can be used directly for industrial uses and food or broken down by enzymes as for dry milling to make dextrose that can be enzymatically converted to high fructose corn syrup for a beverage sweetener or fermented to ethanol. One metric tonne (1 ton in parentheses) of corn can yield approximately 34 kg (67 lbs) of oil, 52 kg (105 lbs) of corn gluten meal, 283 kg (567 lbs) of corn gluten feed, 470 liters (112 gallons) or 370 kg (740 lbs) of ethanol, and 354 kg (708 lbs) of carbon dioxide. Again, all corn components are utilized, with protein sold for animal feed, the major market for corn.

4.2 Costs

Although ethanol costs tend to be site specific and business sensitive, recent surveys provide a useful picture. The average cost of all feedstocks for dry and wet mills was about $0.23/liter ($0.87/gallon) of ethanol with dry mills varying from $0.25/liter ($0.94/gallon) for small plants to $0.21/liter ($0.79/gallon) for medium plants and $0.22/liter ($0.82/gallon) for large facilities and wet mills being about $0.024/liter ($0.09/gallon) greater than the overall

average, apparently because of the greater quantities of corn required. The multiple wet mill coproducts provided revenue of $0.11/liter ($0.43/gallon) of ethanol versus about $0.07/liter ($0.28/gallon) for dry mills. The difference between the cost of corn and coproduct revenues, termed the net cost of corn, is about $0.14/liter ($0.53/gallon) for dry mills and $0.13/liter ($0.48/gallon) for wet mills but varied between $0.095/liter ($0.36/gallon) and $0.24/liter ($0.91/gallon) for wet mills and $0.12/liter ($0.44/gallon) and $0.25/liter ($0.95/gallon) for dry mills over the ten years ending in 2000.

Other costs are also incurred. Averages for electricity and fuel were about $0.030/liter ($0.112/gallon) for wet mills and $0.035/liter ($0.131/gallon) for dry mills for an overall weighted average of $0.031/liter ($0.118/gallon). Operating labor, repairs, and maintenance were lower for dry mills at about $0.029/liter ($0.109/gallon) compared to wet mills at about $0.033/liter ($0.124/gallon). Yeast, enzymes, chemicals, and other ingredients contributed another $0.024/liter ($0.090/gallon) for dry mills and $0.030/liter ($0.114/gallon) for wet mills. Averages for management, administration, insurance, and taxes were similar at $0.009/liter ($0.037/gallon) for dry mills and $0.010/liter ($0.038/gallon) for wet mills. All other costs averaged about $0.019/liter ($0.072/gallon) for wet and $0.013/liter ($0.051/gallon) for dry mills. Thus, total cash costs for other than corn were about $0.12/liter ($0.46/gallon) for wet mills and $0.11/liter ($0.42/gallon) for wet mills, and combined with net feedstock costs, the average cost is about 0.25/liter ($0.94/gallon), with a less than 1% advantage to wet mills. This gate cost does not include transportation, distribution, taxes, and other costs to the consumer.

The difference between ethanol revenues and cash costs of production must be weighed against capital costs to determine return on investment. Capital costs are estimated to be between $0.283/annual liter ($1.07/annual gallon) to $0.631/annual liter of capacity ($2.39/gallon), varying with facility type, size, and technology. Wet mills tend to cost more than dry mills, and larger dry mills generally cost less than smaller ones per volume of ethanol made because of economies of scale. Capital and operating costs have dropped over time through learning curve effects and research.

Several considerations apply to starch ethanol costs, many of which apply to ethanol from sugar. Costs and coproduct revenues vary with location and economic climate, and many costs components do not always work together. For example, the value of ethanol usually drops with gasoline prices. In addition, higher corn or sugar prices or softer coproduct markets increase the net feedstock cost. In this vein, increasing corn ethanol production would eventually drive up corn prices and drive down coproduct selling prices, making further capacity increases uneconomic. On the other hand, technology improvements enhance profitability.

Tax incentives in the United States promote blending with gasoline and were essential to initiating ethanol production in the late 1970s and early 1980s in response to petroleum shortages and price spikes. Over time, this excise tax exclusion dropped to $0.0140/liter ($0.053/gallon) of 10% blended fuel, reducing ethanol costs by $0.140/liter ($0.53/gallon) of ethanol used. Alternatively, the tax on blended gasoline is reduced by $0.0110/liter ($0.0416/gallon) for 7.7% ethanol and $0.0081 ($0.0308/gallon) for gasoline containing 5.7% ethanol. This exemption is not paid to farmers but is an avoided tax for blenders of ethanol from any form of biomass with gasoline. Blenders could apply an income tax credit instead of the excise tax exemption. The exemption is scheduled to be further cut to $0.0137/liter ($0.052/gallon) of 10% blended fuel in 2003, $0.0135/liter ($0.051/gallon) in 2005, and eliminated on December 31, 2007. Many states, particularly in the Midwest, also provide incentives to encourage ethanol use. Although subject to controversy, tax and other assistance policies are vital for introducing new technology, particularly for commodity markets, and have supported emergence of new industries such as the large petrochemical sector that grew out of World War II.

4.3 Energy Balance

Incorrect and outdated data are periodically used to spur controversy about whether making corn ethanol consumes more or less energy than contained in the product. However, up-to-date facts show continual improvements, with reductions in energy demand as the technology matures resulting in favorable energy benefits. Accounting for the variability of corn productivity over time and with location, an input of 2789.3 mega joules/dry metric tonne (57,476 Btu/bushel or 2,415,100 Btu/dry ton) of corn was determined for all the energy required to grow and harvest corn and haul it to storage. The energy to transport corn from storage to ethanol production was estimated to be about 292.3 mega joules/dry metric tonne (6020 Btu/bushel or 253,000 Btu/dry ton) or 690.6 J/liter (2.263 Btu/gallon) of ethanol made. Recent surveys showed that about 13.594 mega

joules of heat and electricity are needed to make one liter (48,772 Btu/gallon) of ethanol via dry mills and about 15.118 mega joules/liter (54,239 Btu/gallon) for wet mills. However, new plants generally achieve on the order of 11 mega joules/liter (40,000 Btu/gallon) or less. The survey showed about 460 and 467 liter of ethanol/dry metric tonne (2.64 and 2.68 gallons/bushel or 111 and 113 gallons/dry ton) were derived from corn in dry and wet mills, respectively. Finally, about 442.6 kilojoules/liter (1,588 Btu/gallon) of ethanol was required to distribute ethanol to end users. Combining these estimates, dry and wet mills required about 20.75 and 22.16 mega joules/liter (74,447 and 79,503 Btu/gallon) of ethanol, respectively, with the average weighted by number of facilities being about 21.525 mega joules/liter (77,228 Btu/gallon).

Some energy should be assigned to coproducts from corn milling, with distribution by energy inputs, energy content, relative market values, relative weight, and the amount of energy needed to replace them analyzed. However, the latter based on the energy to produce equivalent feed and food as from coproducts is often favored, with growing soybeans an appropriate alternative. On that basis, the final estimate is a net energy displacement of about 6.307, 5.369, and 5.883 mega joules/liter (22,629, 19,262, and 21,105 Btu/gallon) for dry, wet, and weighted average facilities, respectively, when ethanol is made from corn compared to the higher heating value for ethanol of 23.402 mega joules/liter (83,961 Btu/gallon).

This analysis means that one volume of ethanol generates about 37%, 30%, and 34% more energy than needed to manufacture it by dry, wet, and the overall weighted average of production facilities, respectively. Furthermore, because about 6.34 units of liquid fuel energy result from 1.0 energy unit of petroleum, corn ethanol provides even greater advantages for displacing imported liquid fuels, a major concern for economic and political stability in the United States.

4.4 Greenhouse Gas Emissions

The positive energy balances suggest that corn ethanol has a lower impact on global climate change than gasoline. Again, if the greenhouse gas emissions that would result if soybeans were grown to meet markets served by corn ethanol coproducts are subtracted, burning ethanol from starch crops as a mixture of 85% ethanol with 15% gasoline (E85) reduces carbon dioxide emissions by about 40% and emissions of all greenhouse gases including methane and nitrous oxides by about 20 to 30% relative to pure gasoline. Because a significant portion of greenhouse gases comes from the gasoline in E85, greater reductions would be possible if technology were developed to use hydrous ethanol as in Brazil. If corn stover or other renewable energy sources were substituted for fossil fuels to power dry and wet mills as in Brazil, the greenhouse gas benefits of corn ethanol would be better yet.

5. PRODUCTION FROM CELLULOSIC BIOMASS

5.1 Cellulosic Biomass

Ethanol can also be made from sugars contained in the structural portion of plants. In particular, about 40 to 50% is cellulose—up to about 10,000 glucose molecules joined by beta 1-4 linkages as long linear molecules that can align parallel to one another and join by hydrogen bonding in crystalline regions that typically contain much of the cellulose. Another sugar polymer known as hemicellulose represents about 25 to 30% of the dry plant mass; unlike cellulose, hemicellulose is amorphous. Hemicellulose is typically made up of the five sugars arabinose, galactose, glucose, mannose, and xylose, along with lower amounts of other compounds including hexuronic acids and methoxyl, acetyl, and free carboxyl groups. Lignin represents about another 15 to 20% by dry weight and is a complex phenylpropanoic acid polymer. Lignin and hemicellulose are joined by covalent bonds and cement cellulose fibers into microfibril bundles. Plants also contain lesser amounts of minerals, free sugars, proteins, and other components that vary with species. Together, this composite of cellulose, hemicellulose, lignin, and other generally lesser ingredients is called lignocellulosic, or just cellulosic, biomass and has great strength to support the aerial portion of plants.

Cellulosic biomass is abundant with prominent examples including agricultural residues (e.g., corn stover, sugarcane bagasse), forestry residues (e.g., forest thinnings), industrial wastes (e.g., paper sludge), major portions of municipal solid waste (e.g., waste paper), herbaceous plants (e.g., switchgrass), and woody species (e.g., poplar). In addition to its abundance, cellulosic biomass can be grown with low energy inputs and is comparable in cost to

petroleum. For example, biomass costing about $44/dry metric tonne ($40/ton) is competitive with petroleum at about $6.00/barrel based on equal mass or about $12.70/barrel based on equivalent energy content. Some cellulosic wastes such as rice straw can be obtained for lower prices, and in some cases, such as paper sludge, users would be paid to dispose of them (i.e., tipping fee). Waste conversion to ethanol can also help solve serious disposal problems.

5.2 Processing of Cellulosic Biomass

As outlined in Fig. 2, the overall process for making cellulosic ethanol is conceptually similar to processing corn but with distinctions that have important energy balance and greenhouse gas emission implications. Sulfuric and other acids can convert both hemicellulose and cellulose into fermentable sugars. Alternatively, enzymes known as cellulase hydrolyze cellulose to glucose while a collection of enzymes loosely termed hemicellulase could breakdown hemicellulose. The remaining lignin cannot be converted to sugars but can provide boiler fuel for process heat and electricity or be reacted into coproducts.

Biological conversion of cellulose to glucose by cellulase and fermentation of glucose to ethanol realize high yields vital to success, and the advances of the evolving field of modern biotechnology promise significantly lower costs. In this case, mills or other devices reduce the feed material size, facilitating transfer of heat and chemicals later, and the material is pretreated to expose cellulose to cellulase to realize high glucose yields. Currently, pretreatment is often by dilute acid hemicellulose hydrolysis because good yields of sugars are realized from hemicellulose during pretreatment and from cellulose in the subsequent enzymatic hydrolysis and acid costs are relatively low. In this approach, cellulosics are reacted in 0.5 to 1.0% sulfuric acid at about 160 to 190°C for approximately 10 minutes, releasing most hemicellulose sugars by a hydrolysis reaction similar to Eq. (2) but including up to five different sugars as well as other compounds in the cellulosic matrix. The contents are flash cooled to stop the reaction as the temperature quickly drops to about 100°C and also to remove some acetic acid, furfural, and other fermentation inhibitors that are released from biomass or produced by degradation reactions during pretreatment. Next, the solid and liquid fractions are separated and ion exchange employed in some designs to remove a portion of acetic acid and much of the sulfuric acid from the liquid. Lime is added to neutralize the remaining sulfuric acid and then increase the pH to about 10 in an "overliming" operation that removes toxics to downstream biological steps.

A small portion of the solids alone or including treated liquid is fed to make cellulase by an organism such as the fungus *Trichoderma reesei*. The effluent is then combined with the bulk of the pretreated solid to hydrolyze cellulose to glucose, and an organism such as yeast is added to convert the glucose to ethanol soon after release in a simultaneous saccharification and fermentation or SSF approach. Because SSF rapidly converts glucose and the two glucose molecule cellobiose to ethanol, the concentration of both of these powerful inhibitors of cellulase activity are reduced. Thus, the rates, yields, and concentrations for ethanol production are all improved via the SSF approach compared to sequential hydrolysis and fermentation even though the temperature has to be reduced from optimum levels for hydrolysis alone to accommodate less temperature tolerant yeast. The SSF configuration also eliminates about half of the fermentation vessels, cutting costs, and ethanol accumulation reduces the likelihood of successful invasion by unwanted organisms that thrive if sugar accumulates. Alternatively, conditioned liquid hemicellulose hydrolyzate can be added to SSF in an approach labeled simultaneous saccharification and cofermentation (SSCF) if the organism used ferments hemicellulose sugars and glucose to ethanol. Of course, hemicellulose sugar fermentation can be performed in a separate vessel by such an organism, albeit at the expense of more equipment and somewhat higher costs.

Distillation concentrates approximately 5% fermentation beer streams to about 95% ethanol, and this azeotropic mixture is often passed to molecular sieves to recover a nearly 100% ethanol product suitable for blending with gasoline or use as a pure anhydrous fuel. For use as a pure fuel without gasoline addition, the 5% water might be left in a la Brazilian experience. The solids and solubles remaining following SSF/SSCF pass out in the distillation column bottoms, are concentrated, and then are burned to generate steam that can provide all of the process heat and electricity with some excess electricity left to export. Water from the system is treated by anaerobic digestion, and the resulting methane is burned for steam generation.

5.3 Technical and Economic Progress

The United States and other counties have funded research to improve cellulosic biomass conversion to

ethanol, and despite modest and sporadic funding, the total estimated cost at the plant gate including capital charges dropped from about $1.05 to 1.32/liter ($4.00 to 5.00/gallon) of ethanol in 1979 to approximately $0.29 to 0.32/liter ($1.10 to 1.20/gallon) now, a value competitive with corn ethanol. For a facility making about 197.6 million liters/year (52.2 million gallons/year) of ethanol, the capital costs were projected to be about $234 million, the feedstock cost about $19.3 million/year, the other variable operating costs about $5.7 million/year, and the fixed operating costs about $7.5 million/year. Such cost projections depend strongly on location, estimation methods, available data, key performance parameter assumptions, technology applied, and financing arrangements and vary considerably. Furthermore, although corn and sugar conversion costs are based on commercial experience, no cellulosic facilities are yet operational. Thus, while useful for guiding research, cellulosic ethanol costs are approximate indicators of actual costs. However, the fact that several firms are working to commercialize the first cellulosic ethanol facilities confirms the economic merits, and their biggest challenge is financing the substantial capital cost for first-of-a-kind technology in light of its perceived risk.

Progress on two major fronts has fed the cost reductions outlined. First, important improvements have been made in overcoming the recalcitrance of biomass. Dilute acid pretreatment has been optimized to increase sugar yields from both the hemicellulose and cellulose fractions, and better cellulase formulations have achieved higher yields with lower doses. SSF improved economics substantially, with enzymes or organisms that utilize cellobiose, a polymer of two glucose molecules, proving particularly important by reducing the concentration of this powerful cellulase inhibitor.

The second hurdle, overcoming the diversity of sugars, was a major breakthrough vital to economic viability. Native organisms cannot ferment all five sugars typically contained in cellulosic biomass to ethanol with high yields, a necessity to competitiveness. However, in the late 1980s, researchers genetically engineered bacteria to make ethanol from all the sugars at close to theoretical yields by inserting two genes from the bacteria *Zymomonas mobilis* into other host bacteria to produce the enzymes pyruvate decarboxylase and alcohol dehydrogenase that transform pyruvate, an intercellular compound in the host, to ethanol instead of the products ordinarily made. This accomplishment increases revenue while reducing costs for disposal of unused sugars.

5.4 Energy Balance

Burning solids and concentrated solubles after distillation, solids from aerobic treatment, and methane from anaerobic treatment can generate enough steam to meet all process heat and power demands. In addition, about 10.9 MW of surplus power is left for sale for a currently envisioned ethanol plant fed 2000 metric tonnes/day (2,205 tons/day) of cellulosic biomass, resulting in about 0.4 energy units of ethanol and close to 0.1 energy units of electricity per unit of energy in the biomass feed. The amount of ethanol will improve as yields are increased through learning curve effects and better technology, and power exports to the grid will increase as (1) cellulosic ethanol technology improves to use less heat and power and (2) more efficient cycles are used for making electricity from steam. The key is that no fossil fuel is needed to convert cellulosic biomass into ethanol, and significant amounts of excess electricity are left for sale into a market compatible with large-scale fuel production.

It has been estimated that about 6 to 15% of the ethanol fuel value is required to grow biomass, another 1 to 4% to transport it to the conversion facility, and 1 to 5% for fuel distribution. If all of these energy needs are met from fossil sources, about 4.0 to 6.7 times as much ethanol energy is released as fossil fuel used for the overall cellulosic ethanol process, but the ratio increases to about 4.3 to 7.2 if the thermal value of exported electricity is included. More comprehensive analyses project that current cellulosic ethanol technology provides a net energy output from about 16.7 to 21.2 mega joules/liter (60,000 to 76,000 Btu/gallon) of ethanol compared to its lower heating value of 21.2 mega joules/liter (76,000 Btu/gallon), depending on the feedstock employed. Overall, these low fossil inputs result from the low-energy demands to supply cellulosics, generation of all heat and power for conversion from lignin and other biomass residues, and to a lesser extent, export of excess power.

Given its favorable energy balance, cellulosic ethanol could be substituted for gasoline or diesel fuel to harvest and transport cellulosics to the process and distribute ethanol to market. In addition, methane produced by anaerobic digestion of process residues could be converted into ammonia to reduce fossil fuel use for growing biomass. The result would be that virtually no fossil fuels are needed to grow, convert, and transport ethanol when it is made from cellulosics while both fuel and power are produced, and the ratio of energy outputs to fossil energy inputs

would become very large. Advances in ethanol production and power generation would improve this picture.

A recent study showed that fossil fuel inputs for cellulosic ethanol were lower than for a large number of options including gasoline, other petroleum-based fuels, natural gas–based fuels, and electrolysis hydrogen. Yet the total energy required to make cellulosic ethanol was toward the high end. This apparent contradiction is readily explained because burning lignin and other residues totally meets the large process energy demand without fossil fuels. The fact that most of the more efficient technologies in the study are practiced commercially while cellulosic ethanol is not suggests that significant improvements will evolve for cellulosic ethanol through the commercial learning curve, and the likely outcome is that the energy balances will improve dramatically, increasing the energy displacement benefits far more.

5.5 Greenhouse Gas Emissions

As shown for ethanol from sugar and corn, carbon dioxide generation by burning fossil fuels has a large impact on greenhouse gas emissions, and the low fossil energy inputs for cellulosic ethanol production are expected to have important implications for global climate change. In fact, studies have shown that using 85% cellulosic ethanol with gasoline, E85, reduces GHG emissions by about 65% compared to straight gasoline, and that running E95 in vehicles would decrease GHG emissions by about 75 to 78%. A large part of these emissions comes from the gasoline, and even greater reductions in GHGs of about 85% or more are possible if pure ethanol were used. Advances in both ethanol production and power-generation technologies should improve yields, reduce energy inputs, and generate more electricity, reducing GHG emissions even more.

5.6 Some Other Technologies for Processing Cellulosic Biomass

A favorable pretreatment must produce highly digestible cellulose, recover hemicellulose sugars with high yields, have a low capital cost, require limited energy inputs, minimize degradation, use low-cost chemicals, minimize problems with chemical additives, and integrate well with the overall process. Many studies with physical pretreatments such as size reduction and radiation and biological pretreatments with various fungi have been unsuccessful, and only a few chemical pretreatments other than dilute sulfuric acid currently promise to be cost-effective. In the ammonia fiber explosion (AFEX) process, ammonia added to biomass reduces cellulose crystallinity, opens up the structure for enzymes, can be mostly recovered and recycled, provides fermentation nutrients, and produces a readily fermentable hydrolyzate without post treatment. A near neutral pH approach favors soluble oligomer release from hemicellulose to keep formation of sugar monomers that can degrade low. Ammonia circulation through biomass removes lignin, improving cellulose hydrolysis yields. Lime also removes lignin, but the reaction is slow. Dilute nitric acid reduces materials of construction costs compared to sulfuric but is itself more expensive. More research is needed to better understand the performance and costs of these and other options that promise to meet the demanding criteria for effective pretreatment.

Acids can be used to breakdown cellulose. Concentrated acids realize high yields vital to economic success, but the cost of required acid recovery operations must be significantly reduced. Substantial experience exists for dilute acid hydrolysis, but yields are not high unless practical countercurrent flow configurations can be developed.

5.7 Opportunities for Further Improvements

The pretreatment step and combined biological operations for cellulase production, cellulose hydrolysis, and sugar fermentation are the most expensive in the currently defined process. *Trichoderma reesei* and other fungi generally used for manufacturing cellulase arose out of World War II research to combat decay of cotton gear in the tropics. Commercial cellulase is estimated to cost over $0.26/liter ($1.00/gallon) of ethanol produced, and making it on site is estimated to cost about $0.092/liter ($0.35/gallon). Although now expensive, cellulase offers near theoretical glucose yields from cellulose, and the evolving tools of modern biotechnology promise reduced costs by improving its effectiveness in hydrolyzing cellulose and increasing the rate of making enzyme. Better pretreatment could also reduce cellulase use, and development of continuous processes could cut equipment idle time and eliminate expensive propagation systems.

Although subsidies are needed for ethanol at current costs to compete for blending with gasoline, the cost of cellulosic biomass is competitive with

petroleum, and ethanol promises to be competitive as a pure fuel without subsidies if yields are increased, energy used more efficiently, operating costs reduced, and capital costs brought in line with those for corn processing. Less energy for size reduction, lower cost materials of construction, lower chemical use, and reduced process energy while maintaining or enhancing yields are all important pretreatment targets. Combining the operations for cellulase production, cellulose hydrolysis, and fermentation in a continuous operation now referred to as Consolidated BioProcessing (CBP) promises to dramatically reduce operating and capital costs for biological steps. Together such improvements would drop total cash and capital recovery costs to about $0.13/liter ($0.50/gallon) based on performance judged to be achievable for mature technology or $0.09/liter ($0.34/gallon) if near theoretical performance results. Thus, research targeted at advanced pretreatment and biological process integration could lead to a cost-competitive sustainable fuel with major benefits. Alternative uses for lignin, minerals, organic acids, and other components in cellulosic feedstocks and chemicals made from the low-cost sugars could increase profitability.

Enhanced cellulosic crop productivity will reduce land requirements for a given fuel production, promote economies of scale, and reduce feedstock costs. Greater impact for a given land use can be achieved with more efficient vehicles (e.g., fuel cells, hybrid vehicles). Because feed for livestock is grown on most agricultural land, recovering protein from fast growing crops such as switchgrass also used to produce ethanol could support making both fuel and food.

Several steps in cellulosic conversion are well positioned for commercial applications. Recombinant organisms are effective now for conversion of all five sugars in cellulosic biomass to ethanol. Although erroneous information may suggest otherwise, ethanol purification is not expensive or energy intensive. Rather, attention should be focused on significantly advancing pretreatment and cellulose conversion to make cellulosic ethanol costs competitive.

6. DIRECTIONS AND OPPORTUNITIES FOR WORLD ETHANOL PRODUCTION

Brazil is the leading producer of fuel ethanol in the world and is increasing the ethanol in blends from 22 to 26% and promoting 3% ethanol in diesel fuel. However, replacement of ethanol vehicles with vehicles that burn low level blends will cut ethanol consumption unless large-scale purchase of hydrous ethanol fueled vehicles resumes.

Ethanol use is growing in the United States. The Clean Air Act Amendments of 1990 require 2% oxygen in gasoline to reduce vehicle tailpipe emissions of unburned hydrocarbons and carbon monoxide, and about 16.0 billion liters (4.2 billion gallons) of methyl tertiary butyl ether (MTBE) and 6.63 billion liters (1.75 billion gallons) of ethanol were used as oxygenates in 2001 to meet these requirements. Because MTBE works its way into groundwater from underground storage tanks, is a persistent contaminant, has a turpentine-like odor and solvent-like taste, and is a suspected carcinogen, U.S. legislation mandates phase out of MTBE. Ethanol does not have these problematic features and is the leading alternative. A renewable fuels standard (RFS) that bans MTBE, eliminates the oxygen requirement in gasoline, enhances clean air rules, and establishes a minimum renewable fuels standard that would grow to 5 billion gallons by 2012 appears likely. Passage of this or related legislation could triple ethanol use after 10 years and result in the United States overtaking Brazil as the world's largest producer of fuel ethanol. Enhanced ethanol production would reduce petroleum imports, the trade deficit, and greenhouse gas emissions, and would create domestic employment.

Other countries have begun or are about to begin ethanol production. Canada produced about 238 million liters (62.9 million gallons) of ethanol in 2001, with plans to more than double that output soon. Canada provides a federal excise tax exemption of $0.10/liter ($0.38/gallon) for the ethanol portion of blended fuels. Although most Canadian ethanol is from wheat and corn starch, Canada produces about 17 million liters (4.5 million gallons) of ethanol from a wood processing waste, spent sulphite liquor, but most of it is sold for industrial uses.

France has been the largest ethanol producing country in Europe, making about 115 million liters (30 million gallons) per year in 2000, mostly from beet sugar for conversion to ethyl tertiary butyl ether (ETBE) for use as an oxygenate in gasoline. However, Spain now has two grain plants with a total capacity of about 325 million liters (86 million gallons) per year, and a third plant planned to reach 526 million liters (139 million gallons) in capacity. Sweden made about 25 million liters (6.7 million gallons) of ethanol in 2000. Recently, the European Commission encouraged increased use of ethanol and biodiesel for

transportation with the goal of substituting 20% of diesel and gasoline by alternative fuels that reduce greenhouse gas emissions by 2020.

China planned to introduce 380 million liters (100 million gallons) of ethanol production capacity in 2001 and achieve a total annual ethanol production capacity of about 2.0 billion liters (534 million gallons) by late 2002. Mostly grain is used to relieve structural surpluses while also reducing oil imports, and blending ethanol will help address air pollution problems in major cities. India has a major program in progress to use some of their large sugar stocks to make ethanol for 5 and 10% blends with gasoline and plans for more than 30 facilities making up to about 380 million liters (100 million gallons) of fuel ethanol annually by the end of 2002. In addition, Thailand is pursuing production of ethanol from cane sugar and tapioca, corn, and rice starch with a near term goal of achieving an annual capacity of about 500 to 730 million liters (130 to 190 million gallons).

This expansion of ethanol production creates an immense opportunity for ethanol from cellulosic biomass. Cellulosic ethanol processes can be the low-cash-cost producer of ethanol, and the transition to cellulosics will become even more attractive as large-scale ethanol production from grains puts upward pressure on grain prices and likely reduces the selling price of coproducts. However, the perceived risk and higher capital costs of first-of-a-kind facilities present serious challenges to implementing this important technology. Advanced technologies that realize the low-cost potential of cellulosic feedstocks could lower capital investments and improve returns but delay implementation. Coupling development of advanced technologies with a commercial learning curve effect would accelerate the emergence of cellulosic ethanol as a competitive pure fuel without subsidies.

7. CONCLUSIONS

Considerable experience has been gained with low-level ethanol blends (10 and 22% ethanol in gasoline) and nearly pure (95.5% ethanol with the rest water and 85% with gasoline) in spark-ignition engines in Brazil and the United States that demonstrates its excellent fuel properties, and ethanol use is spreading. Ethanol can also be added to diesel fuel with additives and could undoubtedly provide hydrogen for fuel cells. Environmental attributes such as biodegradability and low toxicity avoid many problems with gasoline and MTBE.

When made from domestic biomass, ethanol provides an important alternative for a transportation sector almost totally dependent on economically, politically, and strategically vulnerable petroleum imports that continually climb. Furthermore, use of such resources can dramatically reduce emissions of greenhouse gases that trap radiation and cause global climate change.

Brazil led ethanol use as a pure fuel and for blending with gasoline, and a substantial fleet of dedicated ethanol vehicles evolved. However, world sugar demands and the phase down of incentives impacted pricing and availability, and dedicated vehicle production virtually stopped, hurting ethanol consumption. Because residues are burned to provide process heat and electricity, limited fossil fuel is needed to convert cane sugar into ethanol, and net emissions of carbon dioxide are much less than for gasoline. The cost of Brazilian cane sugar ethanol has dropped significantly through learning curve effects, but sugar prices and cultivation practices likely limit competitiveness with gasoline for large-scale uses.

In the United States, ethanol is produced from starch from corn and other crops, and the remaining components are used for feed and food to realize value from all of the grain. Energy consumption has dropped dramatically over time via technology advances and commercial learning curve effects, and corn ethanol now generates about one-third more energy than used to make it. Also, corn ethanol replaces about six times its energy content in petroleum, substantially reducing oil imports. Overall, the result is a reduction of about 40% in carbon dioxide emissions and 20 to 30% in total greenhouse gas emissions for E85 fuel relative to burning just gasoline with even greater reductions possible for pure corn ethanol use and powering the process by renewable resources. Further cost reductions would allow greater impact without tax incentives but become challenging if corn costs rise and coproduct prices drop as corn ethanol production expands.

Cellulosic biomass is abundant and competitive in price with petroleum. Costs for processing this recalcitrant, heterogeneous feedstock to ethanol have been reduced considerably, and companies are striving to introduce cellulosic technology commercially. Because burning lignin and other residues can provide the energy for conversion with electricity left for export and fossil energy requirements to provide biomass feed and distribute ethanol are low, at least four to more than seven times as much energy is contained in products than fossil energy inputs, and cellulosic ethanol would have less than 10 to

15% of the greenhouse gas emissions of gasoline for current technology. Once commercialized, learning-curve effects are expected to dramatically improve costs and environmental benefits, making it vital to successfully introduce cellulosic ethanol technologies soon. Costs and environmental attributes would further benefit through development of advanced technologies that reduce total production costs to compete with gasoline without subsidies and novel technologies that recover protein and other valuable cellulosic components. Ultimately, high productivity cellulosic crops would reduce land use and costs, while efficient transportation technologies would bring fuel demand in line with sustainable supplies. However, substantially more research is needed on advanced technologies to achieve these goals, and attention must be focused on overcoming perceived risk and capital investment challenges that now inhibit commercializing first-of-a-kind cellulosic ethanol processes before their major benefits can result.

Glossary

acquis communautaire The entire body of European laws. This includes all the treaties, regulations, and directives passed by the European institutions as well as judgments laid down by the European Court of Justice.

European Community (EC) The generic term for three different European communities: the European Coal and Steel Community (Treaty of Paris, 1951), the European Atomic Energy Community (Treaty of Rome, 1957), and the European Economic Community (Treaty of Rome, 1957). The EC formed the umbrella organization for these three communities following the signing of the fusion treaty in 1967.

European Economic Area (EEA) An agreement in 1992 between the European Community and three of the four members of the European Free Trade Association (i.e., Norway, Iceland, and Liechtenstein) to form a free trade area in all markets but agriculture; previously called the European Economic Space.

European Free Trade Association (EFTA) An organization founded in 1961; EFTA aims at supporting free trade among its members and increasing the liberalization of trade on a global basis, but particularly within Western Europe. Member states are Iceland, Liechtenstein, Norway, and Switzerland.

European Union (EU) The collective term for the European Community, the Common Foreign and Security Policy, and cooperation in the areas of justice and home affairs formed by the European Union Treaty (Maastricht Treaty, 1992).

European Union burden sharing The sharing out of emissions allowances among the 15 member states under the EU umbrella. The agreement on burden sharing was reached in June 1998 and is legally binding as part of the EU's instrument of ratification of the Kyoto Protocol.

single market (internal market) An economic area without internal restrictions, in which the four fundamental freedoms (free movement of goods, persons, services, and capital) can be realized. The Community's internal market project ("Europe 1992") was initiated during the 1980s and is the main reason for the huge movement toward integration at the end of the 1980s and beginning of the 1990s.

The European Union (EU) is one of the largest economic entities in the world. Although there is a significant and fast integration of many relevant policies of the EU member states, the development of a common EU energy policy in its different dimensions (single market, environment, security of energy supply, research, external relations, etc.) is a complicated process. Furthermore, the enlargement of the European Union creates new challenges for energy policy and the energy policy arena in Europe.

1. EUROPEAN UNION

With 15 states, a population of approximately 375 million, and economic output of roughly 8500 billion euros (€8500 billion), the European Union comprises one of the largest economic areas in the world. In 2004, 10 more states, primarily in Central and Eastern Europe, will join the European Union. The population of the EU will then increase to approximately 450 million, although the economic output will rise to only about €9000 billion as a result of the enlargement. The economic output is expected to rise to approximately €13,000 billion by

2020, although the population is predicted to decrease slightly for demographic reasons.

The primary energy consumption of the current 15 member states of the European Union (EU-15) is about 1450 million metric tons of oil equivalents; this has increased by ~1% annually in the past decade (see Table I). Oil is the largest source of primary energy in the EU-15, accounting for over 40% of energy consumption, followed by natural gas, which accounts for over 20%, and coal, accounting for ~15%. The dependency of the EU on energy imports has increased steadily in the past few decades. Over 70% of oil consumption in the EU is covered by imports, and natural gas and coal imports account for roughly half of the total demand.

Sources of energy in the EU that can be used at competitive costs are very unevenly distributed. The main countries that have large natural gas reserves are the United Kingdom, The Netherlands, and Denmark; it is expected that production in all three countries will decrease. Out of all the member states of the EU-15, only the United Kingdom, Germany, and Spain have large coal reserves, and coal production can only be sustained with massive subsidies. Substantial lignite volumes are produced in Germany and Greece (Table I). Nuclear power plays a very different role in each of the EU member

states. Only eight member states of the EU-15 operate nuclear power stations, and nuclear power accounts for ~33% of the total electricity volume overall within the EU-15, a proportion that remained more or less constant throughout the 1990s. The output of nuclear power stations has risen from ~117 to 125 gigawatts (GW) since 1990.

The framework for energy policy in the European Union is therefore based on a common economic area of considerable size, on the one hand, and on highly varied (1) energy industry structures in relation to primary energy volumes, (2) dependency on energy imports, and (3) orientation to specific energy sources, on the other hand. Ultimately, the basic conditions for European Union energy policy will change substantially as a result of the addition of new members in 2004.

2. AREAS OF REGULATION CONCERNING ENERGY POLICY

Since the beginnings of the European communities, the energy sector has formed a constituent element. Two of the three European treaties (European Coal and Steel Community and European Atomic Energy Community) particularly relate to the energy sector or to specific segments of the energy industry, even if the main reasons for concluding the treaties were primarily connected to security policy rather than to energy policy. The creation of the Single European Market, which was initiated in 1986 and includes the energy sector, lent a new quality to the energy policy and energy industry dimensions of the European Community (EC). However, the European Union has no direct jurisdiction over a European energy policy, and energy policy is the sole responsibility of the member states. Despite several attempts, all efforts so far to incorporate an energy chapter, which could be used to establish EU jurisdiction over energy policy, into the European Community Treaty have failed. Nevertheless, many of the areas of regulation that concern the energy sector directly or indirectly are influenced considerably by the European Union, even though, in practice, policy integration beyond the fundamental jurisdiction of the EU has been furthered in the different areas to a varying extent. The development of the European Single Market is very advanced. The liberalization of the electricity and gas markets is providing increasing dynamism for the energy sector. The development of trans-European networks belongs to the areas of energy policy that are explicitly within the jurisdiction of the EU. In the area of competition policy, the strict aid regulations concerning the reduction of state subsidies have, in particular, had a considerable effect on energy policy.

Integration has made relatively substantial progress in traditional environmental policy regulation areas. Above all, regulations for reducing conventional pollutant emissions are relevant to the energy sector in this respect. A common policy on climate protection is in the initial stages, but is becoming increasingly dynamic. In the area of nuclear energy, there are specific Community regulations that concern the area of research and development, the provision of beneficial financing, and the ownership and control of fissionable materials, whereas regulations concerning nuclear safety are strictly within the jurisdiction of the member states. A whole range of Community approaches to policy concern the area of research, development, and demonstration, albeit with very different equipment, deadlines and continuity.

The dialogue with energy-producing states is gaining in importance in the European Union's external relations. The strong relevance to energy policy of many EU regulations in related policy areas (single-market policy, competition policy, environment policy, etc.), despite the EU's lack of energy policy jurisdiction, leads to the situation that the principle of unanimity is claimed for policies and measures that have a significant effect on the energy sector (e.g., some fields of environmental policy). In reality, and above all in the 2004 new-member process, the veto option made possible with this principle is only of secondary importance.

3. ENERGY POLICY STRUCTURES

The European Commission has a key role in European energy policy. The Commission has the sole right of initiative for the legislation process and has a multitude of implementation, arbitration, and monitoring functions and the like. The Commission's Directorate-Generals for Energy and Transport, Competition, the Internal Market, and Environment are particularly relevant to energy policy. The governments of the member states participate in the decision-making processes through the Council of Ministers of the EU. The course of important compromises in Community policies is set here. The Council of Ministers for Energy, the Council of Ministers for the Environment, and the Council of Ministers for Finance are the main decision-making bodies important for energy policy.

The role of the European Parliament, which is directly elected by EU citizens, has become much more significant over the past few years. For most, but not all, legislation processes in the EU, the European Parliament must be involved on a graded basis. This involvement may take the form of codecision, assent, or hearing. For activities concerning energy policy, the codecision process is most important: three readings take place in both the Parliament and the Council of Ministers and a Conciliation Committee procedure may be initiated if necessary. The most important committees for energy policy in the European Parliament are the Committee on Industry, External Trade, Research, and Energy, as well as the Committee on the Environment, Public Health, and Consumer Policy.

European Union law arises from the founding treaties of the Community (primary law) and from secondary law, i.e., the legal instruments produced by the institutions of the Community. European Union regulations are wholly binding and are directly valid in each member state. European Union directives are binding for each member state with respect to the result to be achieved, and the directives must be translated into domestic law. However, the member states do have some freedom to choose the form and methods. The Court of Justice of the European Communities has gained in importance for energy policy. It checks the legal instruments of the EU and the member states to ensure that they are consistent with the treaties, and it decides on the requests of national courts concerning the interpretation or application of European Union law.

4. ENERGY POLICY, COMPETITION, AND THE SINGLE MARKET

The development of the European single market for energy forms a crucial basic condition for European energy policy. On the basis of the directives for liberalization of the electricity and gas sector that came into effect in 1997, the member states had to open their electricity and gas markets to competition by 1999 and 2000, respectively, and had to meet specific minimum requirements for regulation (decartelization, network access provisions). However, the minimum requirements for opening the markets (33% through 2003) and for network access transparency (possibility of negotiated network access), as well as the unbundling requirements for the companies, remained low.

Although the creation of a European single market was a priority during the liberalization, the electricity and gas markets essentially remained national markets, despite the fact that they were opened for competition. Energy prices became particularly dynamic, even on the national markets, and dropped considerably, especially at wholesale level. Even 4 years after the markets opened, changes in supplier are the exception rather than the rule in most member states, both for large customer groups and other consumer groups. The directives were revised in 2003 after the various member states found liberalization to be sluggish in reality. Accordingly, all member states must amend their national legislation by 2007 such that the electricity and gas markets are fully open to competition. The minimum requirements for companies (more rigorous rules for unbundling of generation, transmission, distribution, and sales), for regulation of the electricity and gas markets, and for consumer information are being intensified. The conditions for cross-border energy supply within the European Union are regulated directly by a corresponding European Union regulation. In addition, the EU has identified a range of infrastructure projects for electricity and natural gas, with which network bottlenecks are to be eliminated and cross-border trade intensified.

In contrast to the grid-bound final customer markets, the energy supply companies have become Europe oriented relatively quickly. A large number of company transactions in which the major European companies (EDF Energy, E.ON Energie, RWE Solutions, Vattenfall, etc.) played a particularly active role have been performed within and between the member states. These companies have stopped pursuing a large number of activities in the nonsupply industry and are instead pursuing massive growth strategies in the core business of energy through mergers and acquisitions. Non-European supply companies are rarely involved. Due to differences in timing of implementation of the market opening process, and also to a number of national conditions, the process within the European Union has involved in part a strong increase in market concentration. Trends toward oligopolies, however, are emerging on some electricity and gas supply submarkets in Europe. Expansion of the dominant market position of some large European suppliers was also evident during the privatization process in Central and Eastern Europe and the Baltic states.

State aid for the energy sector is strictly forbidden in the European Union, unless specific assent has been given. This has particular significance for state-

subsidized coal production in the EU, which, at €6.2 billion annually, still reaches a substantial level; German coal production is awarded the largest proportion (over 65%) of these subsidies. In the past, coal subsidies have steadily been reduced, primarily due to pressure from the European Commission, and they will continue to decline in the future. The reduction of regulations specific to energy sources in the European single market is also evident from the fact that one of the EU founding treaties—the treaty establishing the European Community for Coal and Steel (ECCS)—was not extended when it expired after 50 years on 23 July 2002. After it expired, coal and steel gained the status of normal industrial products. Via a special regulation of the Council, degressive aid for securing resources, for reducing production activity, and for extraordinary financial burdens (inherited burdens) has been declared permissible, at least until 2007, without it having to be approved in individual cases. If state aid is to be used for the production of renewable energy, it is regulated by Community guidelines governing state aid for environmental protection.

Discussions within the European Commission on the admissibility of so-called national energy bases (in other words, specific proportions of primary energy consumption for which advanced subsidy options could be made available to the member states) have been very controversial.

5. ENERGY, ENVIRONMENT, AND CLIMATE PROTECTION POLICY

Based on the Community's jurisdiction over environmental protection, the European Union is implementing a whole range of policies that have considerable effects on the energy sector. The range of policies extends from EU measures with immediate effect, to directives involving limited degrees of freedom for the member states when they are implemented, to the specification of goals that can be realized by the member states in any way they wish.

Climate protection is one of the strategic priorities of the EU in relation to sustainable development. A Community strategy on climate protection is inevitable because the EU has ratified the Kyoto Protocol and has therefore undertaken a double commitment. On the one hand, the EU, as an independent party to the agreement, has promised to reduce greenhouse gas emissions by 8%, from 1990 levels, in the initial period of 2008–2012; on the other hand, the member states have undertaken varied commitments as part of EU burden sharing, ranging from promises to make reductions (Luxembourg, 28%; Germany and Denmark, 21%; United Kingdom, 12.5%) to achieving growth restrictions (Spain, +15%; Greece, +25%; Portugal, +27%). For this purpose, the EU has developed a European Climate Change Program (ECCP), which comprises a number of measures that are also relevant to the energy sector. They include a directive on the promotion of electricity produced from renewable sources (2001), a directive on the promotion of cogeneration (2003), a directive on energy performance of buildings (2003), and a directive on energy services (planned for 2004). In contrast to the directives on liberalization, these directives generally contain only basic restrictions and definitions, and in some cases indicate target goals for expanding specific technologies. For example, in the field of renewable energy, the target is to increase the contribution of renewable energy to total primary energy consumption from 6 to 12% by 2010 and to increase its contribution to electricity consumption from 11 to 22%. Because implementation of the directives allows member states considerable freedom, it cannot be assumed that the targets will actually be achieved. However, more binding specifications result from a range of other measures. These include, for example, Commission directives for labeling electric appliances with energy efficiency data (1999), for adopting the Energy Star system for office equipment from the United States (2001), and for creating minimum requirements for the energy efficiency of electrical devices (refrigeration equipment, 1996; washing machines, tumble driers, ovens, water heaters, television sets, video equipment, electric motors, pumps, air compressors, etc., per agreements negotiated with industry at the end of the 1990s).

The initiatives pursued in the European Climate Protection Programme and in an independent Community strategy for promoting energy efficiency serve to realize the goal of improving energy productivity in the EU-15 annually by an additional 1% compared with the usual levels. However, the most prominent basic conditions for European Union energy policy result from an EU-wide emissions trading scheme for greenhouse gases, the introduction of which is planned for 2005. CO_2 emissions should be restricted for all industrial plants with a thermal input capacity greater than 20 MW and made flexible using a Europe-wide system of tradable certificates. In addition to a range of Europe-wide

specifications (participating sectors, coverage of carbon dioxide only, incorporation of the flexible mechanisms of the Kyoto Protocol, Joint Implementation and Clean Development Mechanism, free allocation of most of the emission allowances at first, etc.), the member states have considerable freedom to shape the system, particularly when distributing the emission rights to the different plants on the basis of the national allocation plans.

Considerable progress has been made in the reduction of conventional pollutant emissions in the energy sector. Sulfur dioxide emissions from power plants in the EU-15 dropped by almost 60% in the 1990s, and the corresponding nitrogen oxide emissions decreased by roughly 25%. Particularly with the directive on the limitation of atmospheric emissions of certain pollutants from large combustion plants (2001), similar demands have been established at EU level for ecological standards for power plants in terms of conventional pollutants, and hence a consistent ecological framework has been created for competition in the field of thermal power plants. New power plants must meet strict standards, and existing plants must observe defined emission ceilings and targets. The directive on national emission ceilings for certain atmospheric pollutants (2001), which sets ambitious reduction targets for the entire spectrum of conventional atmospheric pollutant emissions within the respective member states, forms a framework beyond the energy industry in the strictest sense, but still has an important formative influence on the energy sector. One of the main targets of this directive is to halve, within a reasonable period, the number of areas in which the critical load of acidifying substances is exceeded.

6. NUCLEAR ENERGY AND ENERGY POLICY

Nuclear energy plays an important role in the energy supply of the European Union. Eight of the fifteen EU member states operate a total of 145 nuclear reactors with a net output of roughly 120,000 MW, which corresponds to about one-fifth of the entire power plant capacity in the EU-15. The most recent nuclear power plant in the EU-15 was commissioned in France in 1999.

In the EU member states that operate nuclear power plants, the proportion to power supply contributed by nuclear energy varies. In The Netherlands, ~4% of all electricity is generated by nuclear power plants, and in Finland, Germany, Spain, and the United Kingdom, the contribution is between 26 and 33%; in Sweden, Belgium, and France, it is 47, 58, and 75%, respectively. Three member states (Belgium, Germany, and Sweden) pursue an active policy of withdrawing from nuclear energy. Two member states (Finland and France) pursue a policy of setting up new nuclear power stations, although an actual project is underway in Finland alone. In the remaining three countries (The Netherlands, Spain, and the United Kingdom), it is expected from today's perspective that the use of nuclear energy will be phased out. Out of the 10 new EU member states, five operate nuclear power plants, which are predominantly of Russian design.

The treaty on establishing the European Atomic Energy Community (Euratom Treaty), which was signed in 1957 and is valid for an indefinite period, created the basis for a range of specific regulations on the use of nuclear energy; unlike other areas of regulation in the EU, these regulation should actually be part of secondary legislation. First, these special regulations relate to specific problems in the use of nuclear energy. This includes monitoring nuclear fuel in the EU and a range of other regulations on radiation protection. It must be emphasized in this respect that the nuclear fuels used in the EU are officially the property of the Community and the nuclear power operators have only rights of use. Second, there is a whole range of regulations concerning the promotion of nuclear energy. They include the promotion of research specifically concerning the use of nuclear energy, as well as special financing possibilities for nuclear energy projects. Funds for research into nuclear fission and nuclear fusion amounted to between €1.2 billion and €1.3 billion for each 4- or 5-year Euratom research program (see Section 7) in the past few years. In the framework of Euratom loans, the EU provides investments for nuclear projects, the (very favorable) refinancing conditions of which are based on those for public borrowers. In the period 1977–2002, a total of €3.2 billion was available through Euratom loans, which were also provided for nuclear projects in Central and Eastern European states, as well as in the states of the former Soviet Union, in order to commission new nuclear power plants, among other things. In 2002, the European Commission presented a proposal to increase the Euratom loan ceiling by a further €2 billion, which led to heated debates on the legitimation of Euratom loans, e.g., before the background of market distortions in favor of nuclear energy. Third, other regulations focus on the

Community control of fuel procurement. Based on the original assumption that diversification is a necessity due to a shortage of fuel, nuclear fuel procurement is predominantly handled by a separate institution, the Euratom Supply Agency, and strict checks are carried out to ensure adherence to specific import quotas (for example, from Russia). This has led to intervention in private contracts of individual power plant operators. Finally, the legislation procedures in the Euratom Treaty differ greatly from those in other EU regulations. In particular, this affects the participation of the European Parliament, whose opportunities for involvement and influence in the context of Euratom fall considerably short of the procedures provided for in the EU treaty.

With regard to nuclear energy, the concentration of binding regulations at the EU level is comparatively low, except in the fields of proliferation and health-related radiation protection. However, in the important and—in terms of the common market and competition provisions—cost-related regulation areas of disposal and liability, the regulations of the member states dominate. Therefore, the service specifications, implementation periods, and reserve variants that are relevant to fuel and plant disposal vary greatly among the EU member states, leading to significant differences in the disposal cost burdens of nuclear power generation, in addition to varying implementation efficiency. Companies operating nuclear power plants in EU member states must also make liability provisions to a widely varying extent, which is also connected to differing cost burdens. With regard to safety standards, the lack of coordinated regulations, particularly in the context of EU enlargement, has proved to be a major failing. Against this background, attempts have been made since 1999 to develop a common approach to reactor safety and corresponding regulation procedures in the Western European Nuclear Regulators Association (WENRA); however, the objective of establishing coordinated and binding safety standards for the use of nuclear power has not yet been achieved.

7. ENERGY RESEARCH POLICY

The European Union promotes energy research through specific programs. A distinction is made between nuclear and nonnuclear research in this respect. Nonnuclear energy research is implemented through the EU's general framework program for research. The sixth and most recent EU Framework Programme for Research and Technological Development (2002–2006) has a total budget of €17.5 billion, €2.12 billion of which is earmarked for sustainable development, global changes, and ecosystems. This also includes the field of sustainable energy systems, for which €810 million has been appropriated. Compared with the corresponding research field in the fifth Euratom framework program for research (1998–2002), this constitutes a reduction in funds (€1.042 billion was employed for nonnuclear energy research previously). The fourth Euratom framework program for research (1995–1998) had a budget of €1.03 billion in the field of research, development, and demonstration concerning nonnuclear energy technologies.

Renewable energy systems (including integration into energy supply systems), energy saving technologies, hydrogen and fuel cells, CO_2 separation and dumping, and socioeconomic research in the energy sector are promoted above all in this regard. Fossil energy generation technologies play a much smaller role in the current research program than in previous promotion programs. Research specifically for the coal sector was promoted until 2002 through the research and development programs of the European Community for Coal and Steel (ECCS). It is stipulated in the agreements on the expiry of the ECCS in July 2002 that income from the remaining assets of the ECCS will be placed in a research fund for coal and steel; 27.2% of this is earmarked exclusively for the coal sector.

The promotion of nuclear energy research is implemented in a special program in the scope of the Euratom Treaty. A total of €1.23 billion is provided for in the sixth Euratom research program for the period 2002 to 2006. The majority of the budget (€750 million) is earmarked for fusion research, the International Thermonuclear Experimental Reactor (ITER) project being the focus of the research. Research in the field of radioactive waste, radiation protection, plant safety, and new reactor designs is supported by the remaining funds. The budget for the promotion of research by Euratom has remained largely constant in comparison with previous promotion programs. In the fifth Euratom framework program for research (1998–2002), a total of €1.26 billion was employed, whereas the fourth Euratom framework program for research (1995–1998) had €1.336 billion.

Beyond research, the EU establishes framework programs lasting several years for supporting the field of energy research. The total budget for the energy promotion program from 1998 to 2002 was €175 million, the majority of which was earmarked

for energy saving (SAVE program; €66 million) and renewable energy (ALTENER program €77 million). The "Intelligent Energy for Europe" program (2003–2006) has a total budget of €215 million, which is to be used primarily in the areas of energy efficiency (continuation of SAVE), renewable energy (continuation of ALTENER), corresponding activities in the international field (COOPENER), and energy matters in the transport sector (STEER).

8. SECURITY OF ENERGY SUPPLY

The major oil price fluctuations in 1999/2000 led to discussions on the security of energy supply in the European Union being conducted with renewed intensity. The European Commission has drawn up a well-heeded discussion framework for this, as presented in the Green Paper, "Towards a European Strategy for the Security of Energy Supply," The particular challenges of energy supply security for the first two to three decades of the 21st century are a result of the EU's increasing dependency on imports (from the current 50% to an estimated 70% in 2030), the necessary reinvestment in the European energy industry on a large-scale, and increased environmental and climate protection requirements.

The main features of a long-term European Union strategy on energy policy are as follows:

- An increase in energy efficiency on the demand side of the market is to form an important core of future EU energy policy, because an increased energy supply from the EU member states cannot be developed under acceptable conditions.
- The precedence of climate-friendly energy sources, such as new and renewable energy sources for generating electricity and heat as well as for the transport sector; a further discussion on the use of nuclear energy in Europe is also required for this purpose in the view of the European Commission.
- The coordinated increase of strategic stocks of crude oil and natural gas.
- The development of new sources for energy imports and new import channels for crude oil and natural gas.

Even though the debate initiated by the European Commission on security of energy supply in the EU is clearly driven by a whole range of ulterior motives (fight for more jurisdiction for EU institutions over energy policy, attempts to reevaluate nuclear energy, etc.), and even though, despite an extensive discussion process, the Green Paper has continued to be merely discussion input from the European Commission (and other EU institutions, such as the European Parliament, have not become involved), the debate on energy supply security for EU energy policy will form an important framework in the future.

9. ENERGY POLICY AND EU ENLARGEMENT

Essential changes to the basic political conditions for energy policy in Europe will emerge from enlargement of the European Union in 2004. In addition to the accession of 10 states in mid-2004 (Malta, Cyprus, the Czech Republic, Hungary, Poland, Slovakia, Slovenia, Estonia, Latvia, and Lithuania), negotiations are continuing with other states (Bulgaria and Romania). The acceptance of Turkey into the EU will remain a highly controversial issue in the next few years. Other potential applicant states are those in the Western Balkans. The number of EU member states will therefore rise from 15 (EU-15) to 25 (EU-25) in the short to medium term. In the medium to long term, the number of member states may increase to over 30 (EU-30 +). In addition, the European Free Trade Association (EFTA) regulations and bilateral regulations with the non-EU states of Norway and Switzerland also form a specific European framework for energy policy. The decision-making structures in a European Union with 25, 30, or more member states will (have to) change considerably. Majority decisions and a clearer allocation of tasks will play a larger role if the capacity of the Community and member states to act is to be retained and expanded. At the same time, competition for available funds will increase.

The European Union's enlargement to the east is the enlargement with the greatest economic divide compared with previous enlargement phases. In the four enlargement phases up to 1995, the economic strength of the new member states was comparable to, or even greater than, that of the European Union. The states to be incorporated into the EU in 2004 have an average gross domestic product (GDP) level per resident of only ~20% of that of the EU today. The adjustment of the economic strength of the accession states to the level of the EU requires strong growth processes in these countries on the one hand, and a large rise in the cost efficiency requirements of EU policies on the other hand. With respect to their energy markets, the

future EU member states face a threefold challenge that none of the current EU members had to confront. They must (1) liberalize energy prices and the energy markets in a relatively short space of time and at the same time must (2) renovate and modernize their plants, and (3) they have much less economic strength and purchasing power compared to the EU as it is today.

The restructuring of the energy sector is progressing to a varying degree in the different states and is generally also closely associated with the privatization of the energy industries. The motives for privatization are varied, but are often mainly due to the generation of income as well as the necessity and expectation of a considerable influx of capital from international investors. In the privatization procedures that have taken place so far, the companies that were already strongest in the EU were particularly successful, so privatizations in the EU accession states have already contributed to a further concentration of companies and to a substantial increase in the market power of individual energy suppliers in the European energy industry. This results in competition-related and liberalization-related challenges for forming the basic conditions of the energy markets.

In many of the accession states, energy efficiency is much lower compared to the current level in the EU-15. Although the primary energy consumption per resident in the EU-15 is mostly (much) higher than it is in the accession states, energy productivity (expressed as primary energy consumption per unit GDP on the basis of purchasing power parities) is poorer in most of the accession states, compared to the EU-15 average, by a factor of roughly two. The degree of macroeconomic stabilization in the accession states will, in particular, play a large role in the creation of stable basic conditions for investment, particularly in the area of energy efficiency. Economic stability and a high degree of legal security are central requirements for corresponding investment. In view of the restricted purchasing power and rising energy prices, primarily for households and small consumers as a result of liberalization, increasing energy efficiency also has a strong social element.

The situation concerning emissions corresponds to the initial condition of energy productivity. There is a much higher specific output of the main pollutants (carbon dioxide and sulfur dioxide) in most states than there is in the EU-15. This means substantial exertions and expenditure are necessary for the states to observe the EU environmental standards quickly; in part, the air pollution control measures have already progressed relatively far, however.

In principle, at the date of accession, the entire body of European legislation (acquis communautaire) will be applicable to the accession countries, obliging them to fulfill the specific requirements of each piece of legislation. Against this background, EU enlargement creates for all applicant countries a process, in the course of which significant progress has to be achieved before official accession. The interaction of this basic requirement with economic restructuring has led to significant improvements in economic efficiency and in the quality of the environment. For example, total sulfur dioxide emissions from power plants in the Czech Republic have been reduced by 88% in the period from 1990 to 2000. Relevant reductions can also be observed for greenhouse gas emissions. Due to the provisions of the Kyoto Protocol, however, greenhouse gas reductions of the accession countries cannot be taken into account in compliance on the part of the European Union until 2012. The primary energy structure of an expanded EU will not change much on the whole as a result of enlargement. Nevertheless, in some of the future member states, substantial moves toward mineral oil and natural gas are to be expected. There are additional challenges for some countries that have a very specific energy industry structure.

Poland, the largest producer of coal in Europe today, will become a member of the EU. Although coal production has almost halved since the end of the 1980s, Polish coal production in 2001, at $\sim$100 million t, was 31% higher than the entire coal production in the EU. Due to the unfavorable geological conditions, Polish coal extraction has been classified as being just as uncompetitive as Western European production, so the massive reduction in subsidies deemed necessary by the EU will result in a considerable drop in production. The discussion on coal subsidies will therefore become more explosive in terms of European politics. Among the new and potential EU member states, some countries are extensive lignite producers (e.g., Poland, Czech Republic, Hungary, and Bulgaria). Because only Germany, Greece, and Spain (although the latter is cutting back) lay claim to significant lignite production in the EU, the role of lignite will change in the short, medium, and long term in an enlarged EU.

Substantial growth in oil and natural gas consumption is expected in most accession states in the

next few years. On the one hand, this places considerable demands on the inclusion of these states in the stockpiling regime of the International Energy Agency (IEA). On the other hand, the natural gas markets in most of the states applying for EU membership are still strongly oriented to procuring natural gas from Russia. The diversification of natural gas supplies for states in Central and Eastern Europe will therefore form an important factor in energy policy in the medium term.

With the enlargement of the EU, the Community is faced with specific safety problems concerning substantial nuclear power plant capacity (mostly Soviet-designed plants), even though nuclear power is a less significant energy source in most of the accession states than it is in the EU today. Because no generally binding safety standards apply at the EU level, only a comparison with the practices and regulations applicable in all member states was used as a measure for demands for high safety standards in the field of nuclear power in the EU accession process. An enlarged EU will then be confronted with a whole range of reactors that, in the general view, do not satisfy the requirements and practices commonly accepted in the EU and have (serious) design faults. Therefore, in the course of EU accession, the closure of reactors has been agreed with some states, although the implementation of this agreement has not yet been fully guaranteed. Other reactors need to be retrofitted urgently, but there is a dispute about whether and to what extent "acceptable safety levels" can be achieved through retrofitting measures, particularly in light of the fact that construction weaknesses and quality shortcomings have arisen when plants have been commissioned. Many questions concerning the ultimate disposal of highly radioactive waste and the financing of nuclear plant closures have not been answered at all by representatives of most of the new EU member states.

District heating accounts for a large proportion of the total energy supply (up to 25%) in most of the Central and Eastern European accession states, and in the Baltic accession states. This figure is much higher than the EU-15 average ($\sim$2%), and is also higher than the figure in states with a high proportion of district heating (Denmark, 15%; Finland, $\sim$11%; Germany, 4%). The renovation and modernization of district heating systems and the introduction of highly efficient combined heat and power (CHP) production is not only an area for action concerning the energy industry in the Eastern European EU applicant states, but also has far-reaching social effects.

10. ENERGY POLICY AND EXTERNAL RELATIONS

Energy policy is a feature in the external relations of the European Union to an increasing extent. This is mainly because of two processes. First, the EU set the target of creating a European single market that includes other countries, in addition to the EU member states. Second, there is also a need for stronger cooperation with some energy-exporting regions in light of the EU enlargement, and also due to developments on the global energy markets in view of energy supply security. An essential determinant for the EU's relations with its immediate neighbor states is the aim of developing network infrastructures in such a way that at least 10% of the respective domestic electricity consumption will be covered by cross-border supply.

The European Union is also trying to influence the competition structures in neighbor states. For example, the bargaining cartel of Norwegian gas producers for natural gas supplies in the EU was broken up due to pressure from the European Union. Establishment of comparable market access and specification of equal standards (especially in the field of nuclear energy) are at the forefront of single-market activities in relation to third-party states.

The EU has institutionalized three fields of external relations and has also defined further areas of particular interest in relationship to Russia, the Mediterranean countries, and southeast Europe. In October 2000, the EU agreed on a regular European Union–Russia Energy Dialogue proposal to develop a strategic energy partnership. Because Russia is the largest single partner of the EU for energy supplies, long-term natural gas supply agreements, the establishment of legal and investment security for energy projects, trade in nuclear materials, and environment and climate protection issues (with the Kyoto Protocol to the Framework Convention on Climate Change in mind) are at the forefront. Previously, in 1997, the European–Mediterranean Energy Forum was established in order to increase cooperation with a total of 12 Mediterranean countries (Egypt, Israel, Jordan, Lebanon, Malta, Morocco, the Palestinian National Authority, Syria, Tunisia, Turkey, and Cyprus, with observer status for Libya and Mauritania). The free trade area planned for 2010, energy supply security issues, and environmental projects in the energy industry are at the forefront here. Finally, since March 2002, the European Commission has been submitting proposals for setting up a regional electricity and natural gas single market

in southeast Europe, and it has signed corresponding agreements (Albania, Bosnia and Herzegovina, the Federal Republic of Yugoslavia, Bulgaria, the former Yugoslav Republic of Macedonia, Greece, Turkey, Croatia, Romania, Kosovo, with observer status for the Republic of Moldavia, Slovenia, Austria, Hungary, and Italy). Cooperation and planning work has been undertaken by the different state and industrial institutions in the so-called Athens Forum.

In addition to these comparatively strongly institutionalized external relations, the European Union has defined three areas of particular interest for EU energy policy. These include, first, the so-called Northern Dimension, which aims to increase cooperation between Baltic states and Russia (especially in the field of nuclear security and waste disposal). Second, the European Union has defined particular interests in relation to the oil and gas reserves in the Caspian Basin. Facilitating the transportation of Caspian resources to Europe is a key issue here. For this purpose, the development of transport infrastructure across Turkey and Iran is under consideration; great importance is also attached to cooperation with Azerbaijan and Kazakhstan, however. Third, Ukraine plays a particular role in EU energy policy; it is the most important country in the transit of Russian natural gas to Western Europe. However, development of a cooperative relationship is at a very early stage here.

Particularly with Russia and the other states of the former Soviet Union in mind, the Energy Charter may become very significant, increasing investment security and access to network infrastructures. The extent to which this instrument may affect multilateral cooperation between the energy industry and energy policy will mainly be decided by Russia's attitude toward this agreement, and this is somewhat unpredictable.

Glossary

energetics The study of the sources of energy, direct and indirect, available for mechanical work.
entropy In a closed system concentrations tend to disperse, structure tends to disappear, and order becomes disorder.
exergy The amount of energy converted into useful work.
exosomatic evolution The evolution by humans of outside-the-body tools and technology to supplement the limitations of our physically evolved bodies.
neoclassical economics The dominant school of economics whose core is the notion of general equilibrium and Pareto efficiency.
Pareto efficiency Exists when no further trading can make one party better off without making another worse off.
punctuated equilibrium The pattern of evolution tends to be one of long periods of stasis punctuated by periods of rapid change.
self-organization The tendency of an organic system, such as an ecosystem or the human economy, to actively shape its evolutionary environment.

Economic evolution has not been smooth or continuous. The history of the human occupation of Earth is characterized by long periods of stasis interrupted by periods of rapid movement to another system of socioeconomic organization. Major punctuations in human history include the use of fire, agriculture as the dominant mode of production, and the industrial revolution. All these changes involved the intensification of energy use and all of them signaled dramatic changes in social and economic organization. The past 100 years or so have seen the most rapid and dramatic increase in the human population and in the planetary impact of our species in the 100,000-year history of *Homo sapiens*. The 5-2 fold increase in population and the approximately 40-fold increase in the value of economic output since 1850 were made possible by the era of petroleum. Harnessing fossil fuels has led to unimaginable material wealth for a large percentage of the world's population. However, the orgy of economic growth has left billions in poverty and has also brought humans to the limits of Earth's life-support systems. The tools of mainstream welfare economics have proved to be of limited value in understanding the role of energy in the evolution of the economy. Standard neoclassical economics is a theory of the allocation of scarce resources among alternative ends. It has a lot to tell us about the nature of market exchange, but it does not contain a useful theory of economic evolution or a notion of humans as a biological species inhabiting a finite planet. Fortunately, other tools are available to economists in addition to the general equilibrium model of constrained optimization. An evolutionary approach to energy use can give us an appreciation of the uniqueness of energy as a primary input to economic activity and of the importance of the fossil fuel age in reshaping the planet we inhabit.

1. ENERGY AND THE EVOLUTION OF HUMAN SOCIETY

Two major energy-induced milestones in human cultural and technological evolution were the use of fire and the use of fossil fuels. The earliest evidence of the use of fire is associated with a human ancestor known as *Homo erectus*, who first appeared

 © 2004 Elsevier Inc. All rights reserved.

approximately 1.9 million years ago (there is controversy here, and some classify the earliest fire user as another species called *Homo ergaster*). Fire made possible the expansion of human occupation of the planet from Africa to the cooler areas of Europe and Asia. *Homo erectus* is arguably the most successful evolutionary human experiment in terms of having a sustainable technology (called the *Acheulean*) that lasted, essentially unchanged, for approximately 1 million years. Later humans used fire to dramatically change local ecosystems and landscapes. The Aborigines of Australia and Native Americans used fire to create habitats for large mammals that could be hunted. Much of the landscape encountered by the first Europeans in Australia and North America was the product of human alteration by fire.

Although coal has been used for heating and cooking for millennia, the age of fossil fuels was ushered in by the invention and refinement of the steam engine by Thomas Savery (1698), Thomas Newcome (1712), and James Watt (1769). In the 19th century, coal began to be heavily used in the booming industrialization of western Europe and the United States, especially in iron smelting. This development led to a dramatic increase in coal mining, forcing mining companies to dig deeper into the ground. Eventually, extraction activities became severely constrained by groundwater flooding. To remedy this problem, the mining industry relied on steam pumps. The use of these pumps was the first industrial application of the steam engine. The subsequent development and domination of steam and heat engines in the late 19th and early 20th centuries can be attributed, in retrospect, to an evolutionary accident that led to a technological lock-in and the current dependence of most nations on fossil fuels. What future historians will call the oil era will last only approximately 250 years, and we are now closer to the end of this era than to the beginning. The use of fossil fuel to power the industrial revolution not only had a dramatic effect on the level of economic output but also changed human society and the relationship between humans and the rest of the planet.

In the 19th century, Lewis Henry Morgan and Edward Tylor were among the first social scientists to apply an evolutionary approach to the study of traditional societies. However, it was the work of Leslie White and Fred Cottrell in the 1940s and 1950s that highlighted the central role of energy in the evolution of social systems. White argued that the evolution of human culture is conditioned by the ability of humans to harness and control energy: "Culture evolves as the amount of energy per capita per year is increased, and/or as the efficiency of the instrumental means of putting the energy to work is increased." He proposed a systemic analysis of cultural evolution. Human society, in his view, is organized around three systems: technological, sociological, and ideological. Via exosomatic evolution (the emergence of technology and material artifacts), humans managed to successfully harness and control different forms of energy. An example of exosomatic evolution is one of the most important "energy revolutions"—the development of the spear thrower, or atlatl, approximately 30,000 years ago. The additional power that this invention imparted to the human body revolutionized the hunting of big game animals in the Upper Pleistocene. According to White, the evolution of technology inevitably led to the creation of social institutions that, in turn, engendered a specific worldview or ideology (these three systems coevolved). White argued that cultural evolution was marked by two revolutions: the agricultural (harnessing and controlling cultivation and domestication) and the industrial (harnessing and controlling fossil fuels). Each revolution was subsequently characterized by an increase in technology that eventually reached a plateau due to inner systemic limits. A given technological system reaches its limit in terms of innovation, given the type of energy used, and the social system is no longer adequate to deal with the rapid growth of social units. Further cultural advance requires harnessing and controlling different energy forms, thus leading to a new revolution.

Much like White, Cottrell focused his analysis on the level of energy use as one of the key determinants in the emergence of complex cultural forms. Cottrell's historical account of energy use and social evolution and his methodology are similar to those of Julian Steward and subsequent ecological anthropologists. Steward criticized the unilinear aspect of White's evolutionary theory for failing to capture the complexity and diversity of human cultures. For Steward and Cottrell, there was no systemic reason for every culture to follow a given universal developmental path. Cottrell saw institutions and ideology as limiting factors toward the creation of a single world culture. Steward believed that regularities existed in cultural change but that local variations prevented the occurrence of universal stages of development. Nevertheless, beyond their theoretical and methodological differences, White, Cottrell, and Steward understood the importance of the laws of thermodynamics and the biophysical

constraints these laws impose on the availability and use of energy. More generally, their work emphasized the need for interdisciplinary approaches to the study of the role of energy in sociocultural evolution.

As documented by Cleveland, Daly, and Martinez-Alier, the development of energetics—the study of the role of energy in economic production—was an important contribution of the social sciences in the 19th and early 20th centuries. However, it was the growing concern over increasing environmental degradation and energy shortages in the 1970s that made the work of Patrick Geddes, Frederick Soddy, and others all the more relevant. The environmental movement led scholars, across disciplines, to focus on the role of energy in social and economic systems. In the 1970s, Adams, Ayres, and Georgescu-Roegen, among others, wrote extensively about the significance of the laws of thermodynamics to social and economic evolution. These authors taught us that socioeconomic processes are subject to the first and second laws of thermodynamics. The first law states that the total matter and energy for any system and its surroundings does not change over time. Matter and energy are conserved. The second law states that entropy always increases in an isolated system. Low-entropy (concentrated and useful) energy is irreversibly transformed in a closed system into high-entropy energy (dispersed and unusable). For Adams, exosomatic evolution provides human beings with the capacity to capture and degrade energy more rapidly and more effectively. Consequently, human activities speed up the march of entropy.

For Georgescu-Roegen, the unfolding of the entropy law is what the economic process is fundamentally about. Although there is little doubt that social and economic evolution is subject to the laws of thermodynamics, many issues are still unresolved. Georgescu-Roegen pushed the theoretical boundaries of the relevance of thermodynamics to economics by proposing a fourth law, which states that complete recycling is impossible (i.e., perpetual motion of the third kind is not possible). Ayres contested this proposition, arguing that although the creation of a "wastebasket" is inevitable due to the second law, this wastebasket, over a long period of time, can be a source of usable energy and matter. As Kozo Mayumi pointed out, the fourth law, as a consequence, needs to be qualified as follows: On an economic timescale, given the state of current technology and the limits to energy inputs, complete recycling is impossible.

With the growing literature and debates over the relevance of thermodynamics to social sciences during the past three decades, a consensus has developed about the issues of concern to environmental, energy, and ecological economists. First, economic production and consumption processes are constrained by biophysical limits and therefore are subject to the laws of thermodynamics. Second, increased human activity (economic growth) speeds up the entropic process (increases in heat and material wastes) and puts more pressure on the natural environment. Third, if unchecked, this will eventually limit the potential for economic and social evolution.

2. PRICES, ENERGY, AND SCARCITY

The relationship between energy and economic value has intrigued economists since the inception of economics as an academic discipline. Members of the first recognized school of economics, the 18th-century French physiocrats, saw solar energy as being the ultimate source of wealth in agricultural production. Later, Sardi Cournot experimented with the steam engine to show how much useful work could be obtained from a given amount of energy. William Jevons recognized the importance of coal to the British economy and warned of the consequences of its increasing scarcity. In the late 19th and early 20th centuries, a number of physical scientists, including Geddes and Soddy, wrote extensively about economic issues and warned of the consequences of ignoring the importance of energy to economic value. Geddes is particularly interesting because he is perhaps the first to criticize—in a letter to Leon Walras in 1883—the general equilibrium approach of mathematical economics for ignoring the physical nature of production and the biological nature of the human species. Geddes did not advocate an energy theory of value, but he did point out that there is more to economic value than mere "feelings." Coal, for example, was not just another commodity but rather an essential input for producing food and other necessities for human existence. Geddes and Soddy pioneered the field of energetics–that is, calculating the amount of energy required to produce various economic goods.

In the 1960s and 1970s, the work of Kenneth Boulding and Nicholas Georgescu-Roegen was tremendously influential in turning the attention of economists to biophysical constraints on economic activity. Geogrescu-Roegen's monumental work, "The Entropy Law and the Economic Process," inspired a generation of economists to consider the environmental consequences of economic growth. Georgescu-Roegen was emphatic in rejecting market

prices as a means of allocating irreplaceable natural resources or irreducible pollution. Since future generations cannot bid in energy markets, the allocation of these resources between generations should be a matter of public policy, not isolated individuals bidding at a particular point in time in ill-informed markets.

Kenneth Boulding's classic article, "The Economics of the Coming Spaceship Earth," captured the spirit of the new environmental movement by emphasizing that pollution and resource exhaustion were part of any economic process. Except for a few isolated voices, however, most economists were silent on the energy issue until the oil crisis in 1973. Even after energy prices quadrupled in a few months, mainstream economists such as Robert Solow downplayed the role of energy, stressing the ability of the economy to substitute other inputs for energy in the face of relative price changes. The energy economy debate frequently led to ludicrous statements on both sides. The economist Julian Simon stated that there is enough energy to fuel continual economic growth for the next 7 billion years. Although not in the same league as Simon in terms of fantasy, many environmentalists made overly pessimistic predictions, such as those of the Club of Rome warning of "a rather sudden and uncontrollable decline in both population and industrial capacity" because of resource shortages.

The relationship between energy prices and resource scarcity has been the subject of intense debate among economists. In the 1930s, Harold Hotelling described the ideal exhaustion path of an absolutely scarce resource. Hotelling assumed, among other things, that economic actors are aware of the total amount of the scarce resource, of present and future extraction costs, and, implicitly, of future extraction technology. Given these assumptions, rising prices will reflect the increasing scarcity of this resource. Numerous writers (e.g., Barnett and Morse) have incorrectly used Hotelling's result to suggest that since real energy prices have not significantly increased during the past 100 years, energy is not a scarce resource. Norgaard pointed out that this argument is logically flawed since it goes from Hotelling's conclusion (economic indicators will reflect scarcity) to his premise (if resources are scarce) while ignoring his caveat that resource allocators must be fully informed of future scarcity.

After more than 30 years of debate, punctuated by real-world energy crises, it is clear that changes in energy availability can have drastic consequences for the economy. It is also clear that market economies have a remarkable ability to adjust to energy shocks and, at least in the short term, to substitute technology for increasingly scarce resources. However, the role of essential inputs in production is one of the major unresolved issues in economics. We know that fossil fuel energy is an essential factor of production and we know that the supply of fossil fuels is finite. We also know that higher prices will call forth substitutes and more efficient technologies. So far at least, neoclassical theory has not provided much guidance to understanding the relationship between energy and economic growth. Crude estimates of the marginal rates of substitution between "energy" and "nonenergy" are methodologically flawed and do not tell us much about the ability of the economy to adjust to resource exhaustion. Evolutionary economics can give us guidance about the role of energy in the economy and suggest some policies to perhaps ensure a smoother transition to non-fossil fuel energy sources.

3. ENERGY AND ECONOMIC GROWTH

Among world leaders, economic growth is seen as the unique source of present and future well-being. Since energy is crucial to economic growth, one would think that its role should be an integral part of all growth theories. However, energy fails to appear as a variable in most mainstream models of economic growth. The traditional Solow model explains economic growth through the changes in two factors of production: capital (K) and labor (L). According to the model, output (Q) is generated through a production mix of K and L, whose physical properties are described by a Cobb–Douglas production function:

$$Q = AK^{\alpha}L^{\beta}, \tag{1}$$

where α and β are the partial output elasticities (and output shares) of K and L, respectively. In this model, one factor of production can potentially be completely replaced by another. Empirical estimations of the Solow model failed to explain most of the variation in economic growth. The part of the growth unaccounted for by capital and labor (approximately 87% of the total) was attributed by Solow to technical progress: The "Solow residual" (A in Eq. 1) represents a "catch-all" category dubbed technological change. Under the pressure of criticism from within and from outside the field, economists have developed more sophisticated growth models.

Recent models are based on endogenous growth and consider a broader array of relevant variables, including the Solow residual (hence the endogenous character of the theory), a research and development component, human capital, and natural resources. Even though the models possess a greater explanatory power, they still assume potential perfect substitution between all inputs. Moreover, in empirical estimations, a large part of the variation in economic growth remains unexplained.

To resolve some of the problems encountered in more conventional models, and to anchor them in biophysical reality, Charles Hall and colleagues developed economic growth models including energy as a factor of production. Hall's approach is to include energy in the production function as a full-fledged factor of production in a traditional Solow model. However, he explicitly rejects the assumption of perfect substitution because the unlimited substitution of energy by another form of capital would clearly violate the laws of thermodynamics. In a biophysical sense, energy cannot disappear during the production process (as the first law states) and economic production cannot take place without systematic inputs of low-entropy energy and subsequent dissipation of high-entropy energy (as the second law states). Hall's model successfully reproduced economic growth over a 30-year period for three industrialized countries—Japan, the United States, and West Germany. For Japan and West Germany, the model leaves unexplained less than 10% of the variation in output, even though the two countries underwent significant structural changes as a consequence of the two oil crises in the 1970s. For the United States, 98.3% of the variability in production is explained by the variables for the 1960–1977 period. The results are less conclusive for the 1978–1993 period. However, in this model, technological change is accounted for by a simple variable (creativity) that fails to capture the complex structural changes that resulted from the rapid development of energy-conservation technologies beginning in the 1970s. Hall's results clearly illustrate the prominent role played by energy in economic production.

A model by Ayres and Warr focuses on the concept of exergy, a measure of the conversion of energy into useful work. Exergy measures how much physical work can potentially be done by a system. Unlike energy, exergy is not conserved: It is used up by the system. Ayres and Warr introduce a measure of "useful work" (U) in the Solow model and they find that, since 1900, improvements in energy conversion into physical work explain most of the variation in technical progress; the unexplained residual is only 12%.

These findings emphasize the importance of the role of energy in economic growth. To a large extent, they constitute empirical evidence of the theoretical work of White, Cottrell, and other earlier writers on the role of energy in economic and cultural evolution. They also reflect an intuitive sense that increased energy use and efficient energetic conversion lead to increased growth and development. Figure 1 shows a clear correlation between gross domestic product (GDP) and energy consumption in the United States. The problem of causality remains, however, since the figure does not indicate whether increased GDP leads to increased energy use or vice versa. Cutler Cleveland and colleagues demonstrated, taking into account energy quality, that energy use is indeed the independent variable and economic growth the dependent one. Growing energy use and improving energy efficiency fueled the growth in GDP and provoked dramatic changes in cultural evolution.

Figure 2 illustrates the significant differences between developing and advanced nations in terms of energy use per capita. Industrialized countries have undergone major technological developments and a major improvement in their standard of living during the past 150 years. They are also the countries with very high levels of energy use. Of course, a contributing factor in the energy/GNP relationship is the ability of high-income countries to keep the energy flowing to them. Figures 1 and 2 suggest an essential relationship between energy use and economic activity—a relationship difficult to determine using traditional economic models.

4. ENERGY AND EVOLUTIONARY ECONOMICS

Evolutionary economics is not a well-defined field of economic theory. Economists who call themselves "evolutionary" hold a wide variety of views about the pace of evolutionary change, the nature of economic equilibrium, and the role of prices in economic theory and policy. Nevertheless, a number of useful concepts from evolutionary economics can be applied to the study of the role of energy in the human economy. Most of the debate within economics about resources and the economy has taken place within the framework of neoclassical growth theory, which merely extends the optimal factor allocation framework to the allocation of factor growth rates. In contrast, an evolutionary framework can examine discontinuous change, exogenous as well as endogenous factors, and biophysical limits. Three useful concepts from evolutionary economics are the notion of punctuated equilibrium, the existence of multiple equilibria, and the phenomenon of self-organization.

Punctuated equilibrium as a description of the fossil record was first proposed by Niles Eldredge and Stephen Jay Gould in 1972. They argued that evolution proceeds not only by gradual changes at the margin but also by quantum leaps from one form to another. Therefore, the evolutionary history of a particular species is characterized by periods in which it remains virtually unchanged, punctuated by abrupt events leading to a rapid transformation into another species. As discussed previously, the human epoch can be seen as a series of fairly stable regimes interrupted by periods of rapid change. The major transitions in human physical evolution 2.4 million years ago (*Homo habilis*), 1.9 million years ago (*H. erectus*), and 100,000 years ago (*H. sapiens*) were abrupt in terms of the fossil record. Likewise, human cultural evolution is also characterized by abrupt changes from one technology to another. The transition to agriculture was essentially complete within in a few thousand years and the transition to the industrial age was even more rapid. Georgescu-Roegen identified three "Promethean" technologies as fundamental qualitative changes in human history: fire, agriculture, and the steam engine. These were fundamental bioeconomic mutations that redefined the human presence on the planet.

What caused these punctuations? Increasing evidence suggests that evolutionary changes, including human evolution, have been driven by abrupt climate events. Good evidence exists linking the origin of the genus *Homo* to the onset of glaciation. The appearance of *H. erectus* coincided with a dramatic change to a cooler and drier climate in Africa. The transition to agriculture that occurred throughout the world after the end of the last ice age ushered in a warmer and uniquely stable climate. The industrial age coincided with an unusually warm period in Europe. Another punctuation will likely occur in the near future as the temperature of the planet adjusts to the massive pumping of carbon into the atmosphere by the burning of fossil fuels.

Evolution involves two critical features: variation and selection. It is increasingly accepted that Darwinian selection can occur at several levels, from the gene to the organism and the group. In contrast to the evolution of most other species, human traits may be culturally selected through various systems of rewards and punishments. This accounts for the incredible variety of human cultures. The existence of cultural "filters" for human traits means that institutions and institutional change are critical to economic evolution. The availability and use of energy sources depend on consumer attitudes, history and historical lock-in, as well as political intrigue. The experience of the energy price shocks of the 1970s holds two particularly valuable lessons. First, these shocks demonstrated the vulnerability of the global economy to changes in energy availability. Second, they showed the ability of markets to substitute energy efficiency and other sources of energy for petroleum.

The ability of the economy to adjust to energy shortages should not be overestimated. The short-term energy disruptions of the 1970s and early 1980s caused much economic damage and, being politically driven, they did not signal impending fossil fuel exhaustion. Another lesson is that the ability of policy intervention to change patterns of energy consumption should not be underestimated. Policies

promoting energy efficiency played a major role in softening the impact of the energy shocks, especially in Japan and Europe. The energy crises demonstrated, as careful commentators have been noting for more than a century, that energy is not just another commodity. It is essential to the production process. Cheap energy has been the ultimate source of the unprecedented economic growth of the past 150 years and the transition to a non-fossil fuel economy will be another punctuation in human history. The most important by-product of energy use, increased carbon in the atmosphere, will most likely cause another punctuation as the climate continues to respond to the perturbation caused by the fossil fuel age.

Multiple equilibria also characterizes the evolution of the human economy. Ecologists tell us that there is nothing inevitable about the evolution of a particular ecosystem. Small changes can cause an ecosystem to change to another equilibrium that might look quite different than the original one. Ecologists no longer accept the notion of a "climax forest," an inevitable and unique final form that would automatically evolve in a given area. Natural systems show that many equilibrium states are possible with any given set of initial conditions. Likewise, the market economy—contrary to the model of welfare economics that implicitly assumes a single, unique, global equilibrium—can have a large variety of stable equilibria. Human social systems have even more possibilities than natural ecosystems since cultural systems of rewards and punishment can create any conceivable social equilibrium. Also, there is no reason to say that one system is better than another.

The implications of multiple equilibria for energy use are both positive and negative. On the one hand, change can be abrupt and unpredictable. On the other hand, human institutions, including the market, can adjust rapidly to suddenly changing parameters. The global economy can most likely adjust to new energy shocks and probably even to the end of the fossil fuel age, but what the next economic system will look like is anyone's guess. Likewise, many surprising outcomes are possible as a result of the current episode of global climate change. The planet could continue to warm gradually or suddenly change to another state (much colder or much warmer).

In terms of policy choices, the existence of multiple equilibria implies that we need not be afraid of moving away from the one true optimum. The notion of a unique and stable Pareto optimum toward which the economy naturally moves is an illusion. Likewise, Pareto efficiency in allocation is a goal chosen by politicians and abetted by neoclassical economists, but there is nothing scientific or sacred about it. As Daniel Bromley argues, efficiency as the most important policy goal is an ideology, not a science-based conclusion. Rather than searching for the one true optimum, a more fruitful research project would be determining what categorizes different kinds of equilibria. What keeps a system in equilibrium in the face of fairly severe changes in the environment? Can we anticipate when a system is about to change to another state?

Self-organization refers to the process of the emergence of order in organic systems. It is a development process that is cumulative, discontinuous, irreversible, and creative. It incorporates processes at one level and creates new structures at higher levels. According to Stuart Kaufman, much of the order we see in the biological world may not be the result of natural selection at all but rather the spontaneous order of self-organized systems. Likewise, the (usual) order we see in economic systems may not be the result of the invisible hand of market selection but rather a spontaneous order of self-organized systems having little to do with prices or efficiency. The relationship between self-organization and thermodynamics is obvious. Self-organizing systems prosper by drawing down energy and information from surrounding systems. The global market economy expands by drawing down stocks of low-entropy fossil fuels, stocks of renewable resources such as forest and ocean systems, and, arguably, human cultural diversity.

The fossil record shows that the evolution of species is driven by interplay between internal and external forces. On the one hand, species compete according to the laws of Darwinian natural selection in self-organizing and adaptive systems. On the other hand, evolutionary outcomes are sometimes dominated by rapid and unpredictable external changes. Evolutionary systems cannot be understood without an appreciation of the interplay between external and internal, micro and macro, order and disorder. Like biological systems, the economy is an evolving complex system buffeted by constant changes in boundary conditions.

The current self-organization of the world economy is driven by the world's dowry of fossil fuels. Increases in economic activity mean increases in energy use, which also increase the dissipation of high-entropy energy, putting irreversibly more pressure on the natural environment and speeding up the emergence of scarcity in both renewable (e.g., via

pollution) and nonrenewable resources (via depletion and deterioration). Therefore, the increased dependence on fossil fuels may eventually limit the potential for diversity. As fewer resources are available for human beings to harness, control, and transform, fewer potential developmental paths are available. With fewer developmental paths to choose from, evolution becomes limited. To a large extent, evolution depends on diversity and variation, and if diversity is low, sorting mechanisms such as natural selection have less raw material with which to work.

5. CONCLUSION

The dependence of the market economy on fossil fuel energy, together with the fact that fossil fuels are being rapidly exhausted, paints a disturbing picture of the human prospect. Added to this is the fact that the major punctuations in human physical and cultural evolution have apparently been driven by climate change—occurring today because of carbon emissions from fossil fuels. On the other hand, our evolutionary history shows that we are an adaptable species, capable of making drastic changes in lifestyles and technology to meet new challenges. From an evolutionary perspective, market economies are not as stationary or as fragile as the standard economics model shows them to be. The global economy withstood a number of monumental shocks and it eventually adjusted to the new conditions. Also, there is no reason to believe that a "free" market equilibrium is superior. A number of stable states are possible, and a number of policy tools are available to make the adjustment to the end of the fossil fuel age smoother. We should not hesitate to use them out of fear of disturbing a "natural" free market system. The end of fossil fuels does not mean the end of civilization.

The technology already exists to enable us to move to a non-fossil fuel economy. With a little help from sound energy policy initiatives, the prospects for changing to another Promethean technology are good. Technological adjustment need not mean using ever more sophisticated technologies to hang on to the bitter end to an unsustainable system.

Glossary

commodity In economics, a physical object produced by a man-made process. In this article, commodity also includes dematerialized services.

objective function In optimization procedures, a mathematical expression depending on process parameters, whose extremum (minimum or maximum) corresponds to the "most convenient" combination of production factors for the assigned output.

Exergoeconomics (ee) is the branch of applied thermodynamics that deals with second law-based process synthesis and optimization methods. Per se, EE does not include optimization techniques: It provides the objective function, but the actual optimization of process performance (i.e., the achievement of the specified output with the most convenient combination of production factors) is carried out with one of the available mathematical techniques. Therefore, this articles does not deal with the numerical procedures that lead to the optimized system but rather describes and discusses the engineering background of the methods that lead to the formulation of the objective function.

1. INTRODUCTION

Exergoeconomics (EE) is a relatively new technique. It originated in the 1960s, first in Europe, where Wolfgang Fratscher (Germany), Jan Szargut (Poland), and Valeriy Brodyanskii (USSR) published papers on the "economic value of the concept of exergy," and then in the United States, where Myron Tribus, Yehia El-Sayed, and Robert Evans published a series of papers on a mathematical cost-optimization procedure based on exergy (which they called availability). The term thermoeconomics (TE) was first used in Tribus's MIT course notes in 1960 and in Evans' doctoral thesis in 1961. The concept was developed both in breadth and in depth in academic circles, but it did not impact process engineers, industrial managers, and energy planners until approximately 20 years later, mostly due to the efforts of El-Sayed, Richard Gaggioli, Tadeusz Kotas, and Michael Moran in the early 1980s and Antonio Valero and George Tsatsaronis in the late 1980s. In a series of papers from 1986 to 1989, Valero derived a general and completely formalized costing theory to calculate the exergetic cost of a product from the exergetic input into the process and the structure of the production process. In the 1990s, TE was extended (mostly by Christos Frangopoulos and Michael von Spakowsky) by adapting it to off-design conditions and time-dependent problems and by including environmental effects. The literature on TE is abundant, and a comprehensive review has not been attempted. Regarding EE, there is a qualitatively very interesting debate, expressed by the works of Valero, Göran Wall, Szargut, and Enrico Sciubba, that seems to lead to an exergetic theory of value on which to base societal planning (especially with respect to the much-debated issues of sustainable-development and limited-growth models).

In this article, the concept of exergy and cost optimization is briefly discussed, followed by separate treatments of TE and EE. A caveat is necessary: Some authors, most notably Tsatsaronis and von Spakowsky, use TE and EE as synonyms and consider irrelevant whether the optimization is carried using money or exergy as a quantifier. Here,

TE is considered as a special case of EE, and treatment of these is developed with this guideline.

2. THE CONCEPT OF EXERGY

Energy is considered an a priori concept in thermodynamics: We are taught that "energy is an extensive property of a system such that its change in value between two states is equal to the adiabatic work between these states." However, energy is known to manifest itself in several forms, each endowed with a different quality. The concept of quality can be fully explained only by referring to the second law, but in general the quality of an energy flux is a measure of its capacity to cause change. We can identify "ordered" or "high-quality" energy forms (potential, kinetic, mechanical, and electrical) that can be ideally converted into each other with 100% efficiency so that even after a number of transformations, as shown in Fig. 1A, the output flux of useful energy, En_{out}, is quantitatively equal to the flux of useful input, En_{in}. However, other forms (internal energy, chemical energy, thermal radiation, and turbulent kinetic energy) cannot be converted into each other, much less into high-quality energy, without an intrinsic efficiency loss, so the useful output En_{out} is now always lower than the useful input En_{in} (Fig. 1B). Since energy is conserved (this is a basic postulate in all physical sciences), the difference $En_{in}-En_{out}$ must be accounted for: Indeed, we invariably find that this difference has been dissipated into a low-temperature flux absorbed or provided by the environment. The "environment" is meant here in its usual layman sense—that is, as a system so large that its properties (pressure, temperature, chemical composition, kinetic or potential energy, etc.) are not affected by the interaction with the man-made system. These considerations, though formally incomplete from a scientific standpoint, convey the correct information in an easily understandable form.

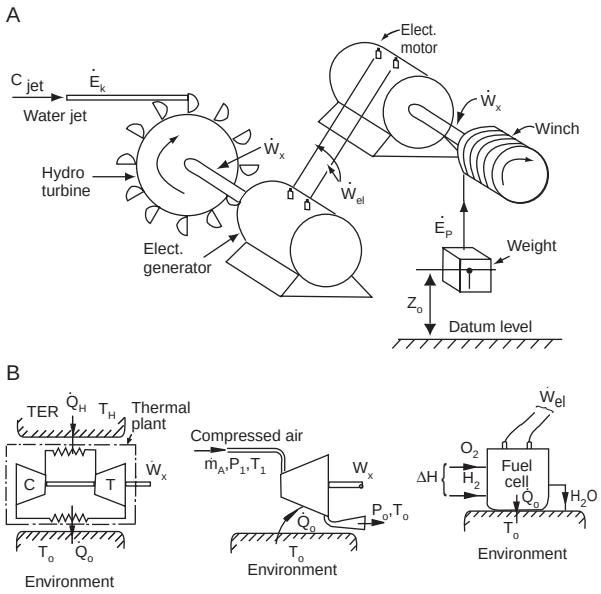

FIGURE 1 (A) A chain of ideal energy conversions of high-quality energy forms into each other. (B) Examples of conversion of low-quality into high-quality energy forms.

The concept of exergy has been developed to provide a congruent and coherent quantification to the quality of an energy form. Imagine that at a certain time t_o we place a system S identified by a certain set of thermodynamic properties (V, z_B, p, T, c, m, μ, etc.) in contact with the environment E and arrange things in such a way that S may exchange mass and energy only with E (Fig. 2). Our intuition tells us and experiments confirm that after some time t_{relax}, which depends on the extension of S and on the difference between its initial properties and those of E, S will come to equilibrium with E; that is, even possible dynamic interactions will occur at a macroscopically stationary state and will result in no net change in the mass and energy contents of either system. Exergy is defined as the maximum work developed in this ideal process. Since the interaction is between E and S, and we assume that all processes can be described by a succession of quasiequilibrium states (so that the time interval t_{relax} drops out from the problem formulation), exergy will be a function only of the initial and the final state of S (the final state being equal to that of the environment) so that it is an attribute of the pair (S,E) and not of S alone. S and E exchange energy fluxes under different forms: kinetic (all parts of S in relative motion with respect to E come to rest), potential (the barycentric position of S reaches a fixed elevation in the gravity field of E),

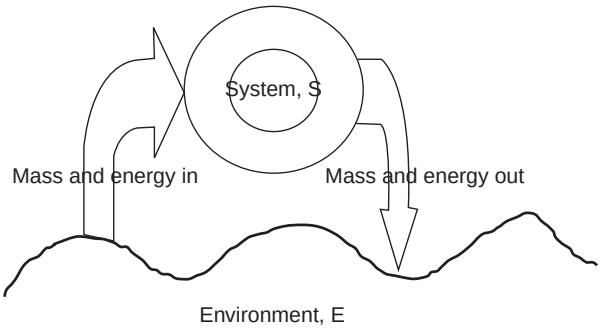

FIGURE 2 A system *S* and its environment *E*.

thermal (heat flows from S to E or vice versa depending on the initial temperature difference $T_S - T_E$), work interaction (E performs or receives work from its boundary interactions with S), and mass exchange (mass fluxes from S to E and vice versa carry different energies). Let us consider here only stationary interactions between S and E (this is the so-called control volume approach) in which flows of energy and matter from S to E are continuous and (on average) steady in time. By applying energy and entropy balances to the complex system composed of S and E, we obtain

$$\sum_j \left(1 - \frac{T_E}{T_j}\right) Q_j - W + \sum_{\text{in}} m_i e_i - \sum_{\text{out}} m_{\text{out}} e_{\text{out}} = E_\lambda, \quad (1)$$

where the first term represents the thermal exergy flow, the third and fourth the exergy in- and outflows due to material exchanges, and E_λ is the exergetic destruction. In Eq. (1), we make use of the definition of specific exergy:

$$e = h - h_E - T_E(S - S_E) + \Sigma_k(c_k \mu_k - c_E \mu_{k,E}) + 0.5V^2 + gz. \quad (2)$$

From Eqs. (1) and (2), we can draw several conclusions:

1. The initial kinetic and potential exergies of S are entirely "recovered" into useful work; in fact, they might be included in the enthalpic term by considering a baroclinic total enthalpy, $h_{\text{tot}} = h + 0.5V^2 + gz$.

2. Work exchanges between S and E are entirely recovered in the exergy balance. This derives from the fact that work is exergy and, as a consequence, the kinetic and potential energy contents are entirely equivalent to exergy. If we define a quality or exergetic factor as the ratio between the energy and the exergy content of an energy flux, and since electrical energy is equivalent to work, all these high-quality forms are seen to have an exergetic factor equal to 1.

3. Thermal energy has an exergetic factor equal to its associated Carnot efficiency: This reflects the fact that, under the given assumptions, the maximum work that can be extracted from a quantity of heat Q available at a certain temperature T is equal to $W_Q = (1 - T_E/T)\ Q$.

4. If S is initially at a lower temperature than E, thermal energy will flow from E to S, with a corresponding exergy flow equal to $E_Q = (1 - T/T_E)\ Q$. This amount is always positive.

5. For a simple substance whose states are defined by temperature and pressure (e.g., most gases for most practical engineering purposes), exergy is always positive, except for particular combinations of p_S/p_E and T_S/T_E.

6. The chemical potential of the elements in S cannot be entirely converted to work: Since S must come to equilibrium with E, the most we can recover for the generic kth component is the difference between the values of its Gibbs function in S and in E, each weighted by the respective concentration. In other words, we can ideally transform only a portion of the initial ΔG_S into useful work because the products of reaction must be at their respective environmental concentrations and chemical potentials at T_E and p_E.

7. Exergy is not conserved: In every real process there is an exergy destruction caused by irreversibility effects. In the simplest case (work $\Rightarrow$ work transformation), this exergy destruction is equal to the irreversible entropy generation due to frictional effects. This can be seen by considering that S exchanges only adiabatic work with E, and the loss is equivalent to frictional heat. If there is only one medium participating in the exchange, from Eqs. (1) and (2) we obtain

$$\begin{aligned} E_\lambda &= -W + m(e_S - e_E) \\ &= -W + m[h_S - h_E - T_E(s_S - s_E)] \\ &= -T_E(s_S - s_E)[W]. \end{aligned}$$

Since $s_S - s_E$ must be negative (S may spontaneously evolve only toward higher entropies), the destroyed exergy flux E_λ is positive and equal to the "lost work" defined by Gouy and Stodola.

8. From Eqs. (1) and (2), we obtain the general exergy equation for flow systems:

$$e_S = e_{\text{ph}} + e_{\text{ch}} + e_{\text{k}} + e_{\text{p}} + e_j[\text{J/kg}], \quad (3)$$

where the suffixes indicate the usual denomination of the various terms: physical, chemical, kinetic, and potential exergy, respectively. If other forms of energy fluxes are involved (magnetic, nuclear, etc.), one needs only to identify the suffix j and apply the corresponding definition.

9. Exergy is an extensive property so that $E_{(S1+S2)} = E_{S1} + E_{S2}$.

10. If two systems S_a and S_b interact, the maximum work obtainable from their exclusive interaction is $E_a - E_b$. Furthermore, if a stream a undergoes a series of transformations $i, j, k, \ldots, z$ in which it receives the exergies $E_i \ldots E_z$, its final exergy content is the sum of $E_a + E_i + E_j + E_k + \ldots E_z$. Exergy is thus an additive property. For engineering

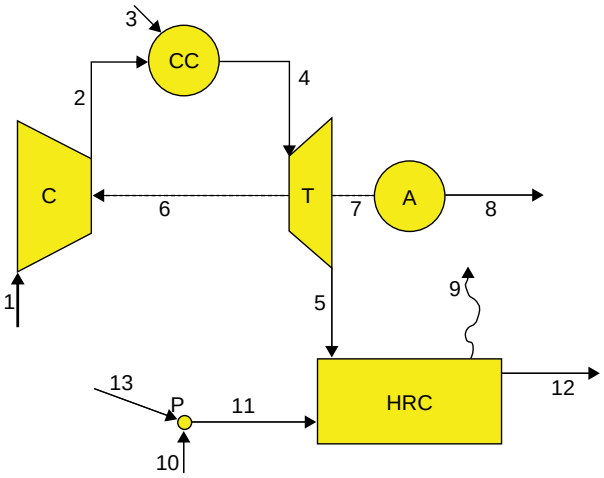

FIGURE 3 Schematic representation of a cogeneration plant.

(and EE) calculations, it is convenient to define a standard environment to which all exergy values can be referred, but this is by no means necessary, as Gaggioli and coworkers have shown.

Practical applications of the exergy concept are important: It can be shown that a second law efficiency defined on the basis of exergy fluxes provides more information than the first law efficiency based on energy fluxes. For example, consider the cogeneration plant shown in Fig. 3. From the design data given in Table I, the efficiencies shown in Table II can be calculated and the following considerations apply:

1. First law efficiency attains a value of 0.655: This means that 65% of the fuel chemical energy is converted into useful energy output. This is misleading, however, because it does not account for the temperature-dependent quality of the heat flux Q_{cog}. A exergetic analysis, in which all inputs and outputs are expressed in exergetic terms, provides an η_{II} of 0.347, correctly indicating that a substantial portion of the chemical exergy of the fuel has been "degraded" into heat (i.e., into a low-quality energy form).

2. Component exergetic efficiencies (η_{II}) also provide interesting information, especially if compared with their energetic counterparts (η_I). For example, whereas the quasi-adiabatic compressor and turbine display similar values for η_I and η_{II}, both the heat-recovery boiler and the condenser have $\eta_{II} < \eta_I$. This indicates that it is useless to invest excessive resources to improve boiler performance because this component is very efficient in transmitting the heat flux it is required to transmit

($\eta_{I,B} = 0.81$). The boiler low exergetic efficiency is intrinsic and not due to design errors: It degrades a high-temperature, high-exergy heat flux into a low-temperature, low-exergy one. Similar considerations apply to the combustor: It is the degradation of the relatively high-quality chemical energy into heat, and not its energy-transfer capacity, that lowers its exergetic efficiency: Energywise, the performance of a combustor is more than satisfactory (≈ 0.94). This is the rationale for the use of fuel cells, which exploit the ΔG of the fuel by means of chemical reactions, without combustion.

3. THE ECONOMICS OF A COMMODITY-PRODUCING PROCESS

Consider a process that produces a certain commodity (a good or a service) (Fig. 4), and assume that both its internal structure and its operating parameters are known so that all of its outputs **O** can be calculated if all of the inputs **I** are known (the transfer function Π of process P is known, where $\mathbf{O} = \Pi \times \mathbf{I}$). To produce a cumulative amount O_1 of the commodity over a period of time T, a certain amount of inputs $I_1, I_2, \ldots, I_N$ are used together with a certain amount of process exergy E_{in}. In general,

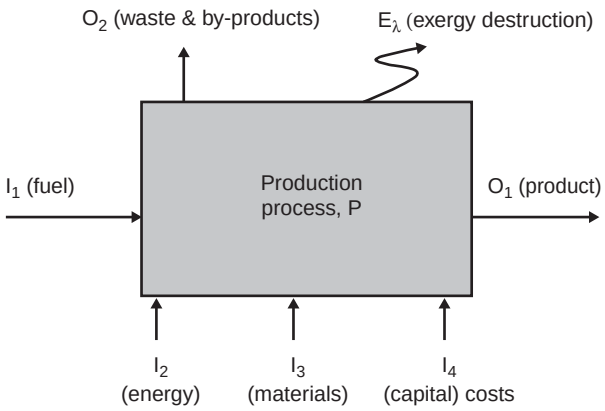

FIGURE 4 A commodity-generating process.

some waste O_3 and some by-product O_2 are also produced. Two additional production factors, namely labor and capital, must also be accounted for. From the process mass and energy balances we can compute the amounts of $m_{I1}, m_{I2}, \ldots, m_{IN}$ and the corresponding exergies $e_{I1}, e_{I2}, \ldots, e_{IN}$ necessary to produce one unit of the desired commodity O_1 (1 kg, one piece, or 1 kJ, depending on the type of product). We can also compute the unit expense for labor (man-hours for unit output) and for capital (€ of rate of return on investment in the equipment per unit output). Over the time period t_p (usually 1 year), we can thus compute O_1 production cost as the ratio of the sum of all expenses (materials, exergy, labor, and capital) to the cumulative amount of production of O_1, both computed in t_p:

$$c_{O_1} = \frac{Cumulative\ expenses}{Cumulative\ production} = \int_{t_p} \left(\frac{C_I + C_E + C_L + C_C}{O_1} \right) dt \quad [€/kg,\ €/unit,\ or\ €/kWh] \tag{4}$$

where O_1 is measured in proper units (kg/s, units/s, or kW). Such a production cost is dependent on both the structure of the production line and its efficiency. If we improve the efficiency, we can obtain a larger amount of O_1 with the same amount of inputs or, conversely, the same O_1 with a reduced input. If we decrease the number of components in the plant, we can lower the capital expenditures for the same amount of output. In practice, the functional relation between efficiency and capital cost is such that higher efficiency components have a higher initial cost, and thus lead to higher capital expenditures. However, the relationship is not linear, and this indicates the possibility of performing process optimization (i.e., searching for process structures and/or operating parameters that lead to a lower production cost C_{O_1}). A whole branch of engineering, called engineering economics, deals with these issues: We can explore some of its implications by examining a simple example consisting of an elementary energy conversion device, a heat exchanger.

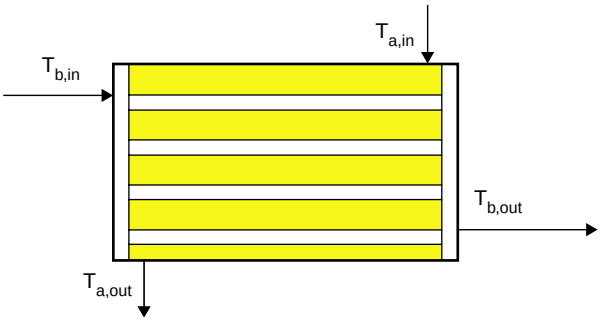

FIGURE 5 Schematic representation of a heat exchanger.

The function of a heat exchanger is to transfer a quantity of energy Q to a medium at lower temperature. In Fig. 5, fluid a (the heat donor) transfers a portion of its sensible heat, $m_a c_{pa} (T_{a,in} - T_{a,out})$ to fluid b (heat acceptor), which increases its temperature from $T_{b,in}$ to $T_{b,out}$. The process can be described by the following equations:

$$\text{Energy balance}: m_a c_{pa}(T_{a,in} - T_{a,out})\eta_{exchanger} = m_b c_{pb}(T_{b,out} - T_{b,int}) \tag{5}$$

$$P_{pump,tot} = \frac{m_a \Delta p_a}{\rho_a \eta_{pump,a}} + \frac{m_b \Delta p_b}{\rho_b \eta_{pump,b}} \tag{6}$$

$$\text{Heat transfer at the interface}: Q_{a\to b} = m_b c_{pb}(T_{b,out} - T_{b,int}) = UA_{HE} LMTD \tag{7}$$

In Eq. (7),

$$LMTD = \frac{(T_{a,in} - T_{a,out}) - (T_{b,in} - T_{b,out})}{\ln\left(\frac{(T_{a,in} - T_{b,out})}{(T_{a,out} - T_{b,in})} \right)}$$

is the log-mean temperature difference calculated under the following assumption: For fixed mass flow rates, the amount of heat transferred from a to b increases with LMTD. Since $T_{a,in}$ and $T_{b,out}$ are specified, this means that a smaller terminal temperature difference, $TTD = T_{a,in} - T_{b,out}$, is desirable. However, to lower the TTD more, heat exchange (HE) area must be used, and this leads to an increase in the pressure losses Δp_a and Δp_b in the heat exchanger passages and to a higher pump work. Here, Reynolds effects on the overall heat-exchange coefficient U and on the friction factor f are neglected, both of which are assumed to remain

fixed throughout. The design problem can be rephrased as follows:

1. The effectiveness of the HE increases with an increase in the active HE surface so that more output $[m_b \times c_{p,b} \times (T_{b,out} - T_{b,in})]$ is generated by the same input $[m_a \times c_{p,a} \times (T_{a,in} - T_{a,out})]$.
2. The parasitic losses that the pumps and fans must compensate for also increase with the active HE surface so that a proportionally larger amount of electrical energy must be purchased.

Let us formulate a costing problem on the following bases: The cost of the unit of heat acquired by stream b is given by the rate of cash outflow c_{HE} corresponding to the installed cost C_{HE} of the exchanger (for simplicity, only the active area A_{HE} is considered here) plus the cost of stream a c_a plus the cost of the electricity c_{el} needed to power the pumps. The following expressions may be used:

$$c_{HE} = CRFC_{HE} \tag{8}$$

$$\mathrm{CRF} = \frac{i(1+i)^N}{(1+i)^N - 1}, \tag{9}$$

where $i = 0.05$ is the yearly interest rate and $N = 15$ years is the assumed technical life of the HE:

$$C_{HE} = K_{HE}\left(\frac{Q_{a\to b}}{U \times \mathrm{LMTD}}\right)^x = K_{HE}A^x,$$
$$\text{with } K_{HE} = 2000\,€/m^2 \text{ and } x = 0.6. \tag{10}$$

where $K_{HE} = 2000\,€/\mathrm{m}^2$ and $x = 0.6$.

$$c_a = K_a \times m_a \times c_{p,a}(T_{a,in} - T_E) \tag{11}$$

$$c_{el} = 7.7\,¢€/kWh \tag{12}$$

$$\Delta p_b = f \times m_b^2, \text{ with } f = 0.01 \quad 1/(\mathrm{m} \times \mathrm{kg}) \tag{13}$$

where $f = 0.01[1/(m \times \mathrm{kg})]$. For a fixed c_a and assuming a zero cost $c_{b,in}$ for stream b at the entrance of the heat exchanger, the specific cost of the heating of stream b is given by

$$c_{b,out} = \frac{c_{HE} + c_{el}}{m_b} = \mathrm{CRF}\,\frac{K_{HE}A_{HE}^x}{m_b} + \frac{c_{el}P_{pump,tot}}{m_b}. \tag{14}$$

Since m_b increases almost linearly with A (Eq. 7), whereas P is proportional to the square of m_b (Eq. 13), the area-related cost term in Eq. (14) will decrease with an increasing heat exchange area and the pressure-loss term will increase linearly (because f is constant). Figure 6 depicts the situation: The total cost $c_{b,out}$ exhibits a minimum that can be found by optimizing, under the given assumptions and constraints, Eq. (14) with respect to A_{HE}. By manipulating the costing equations, the following

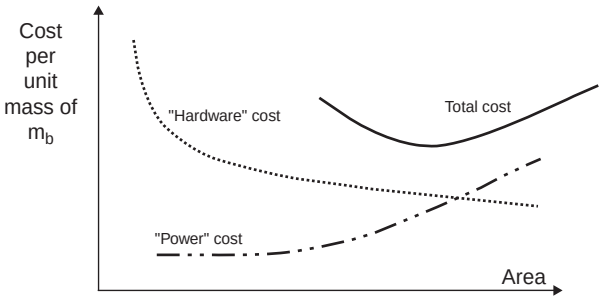

FIGURE 6 Determination of the optimal cost of the heated stream.

(approximate) expression is obtained:

$$c_{b,out} \approx C_{area} \times A_{HE}^{-0.4} \times C_{power,1} \times A_{HE}^{-1} + C_{power,2} \times A_{HE}^{2} \tag{15}$$

which derived w.r.t. A_{HE} and equated to 0 provides an expression for the optimal heat exchange area A_{opt}:

$$-0.4 \times C_{area} \times A_{opt}^{1.4} - C_{power,1} \times A_{opt}^{-2} + 2 \times C_{power,2} \times A_{opt} = 0 \tag{16}$$

where

$$C_{area} = \frac{\mathrm{CRF} \times K_{HE} \times c_{p,b} \times (T_{b,out} - T_{b,in})}{U \times \mathrm{LMTD}}$$

$$C_{power,1} = \frac{c_{el} \times m_a \Delta p_a \times c_{p,b} \times (T_{b,out} - T_{b,in})}{\rho_a \times \eta_{pump,a} \times U \times \mathrm{LMTD}} \textit{and}$$

$$C_{power,2} = \frac{c_{el} \times f}{\rho_b \eta_{pump,b}}\left[\frac{U \times \mathrm{LMTD}}{c_{p,b}(T_{b,out} - T_{b,in})}\right]^2.$$

The approximation here is due to the fact that the constants depend on LMTD and $(T_{b,out} - T_{b,in})$, which in turn vary with A.

The method of engineering economics is employed in process and design engineering to assess the solution to a design problem not only from a thermodynamic standpoint but also from an economic one. As demonstrated in the previous example, this method is based on the following assumptions:

1. Mass and energy balances exist for the process under consideration.
2. A suitable cost equation can be derived for all products of interest.
3. The coefficients in this cost equation may be expressed in terms of process parameters.
4. The specific cost of all incoming streams is known.

Of course, in real engineering practice problems are not so crisply posed as purported here. The

following are the most common difficulties encountered in industrial cost analysis:

1. Only approximate or incomplete mass and energy balances exist. In this case, good technical common sense must be used to approximately close all balances.
2. Cost equations are not known for all production factors (material, energy, labor, and capital), or they are known only for plants of a different scale. The missing data must be judiciously extrapolated from the existing ones or prudently estimated on the basis of known data in related fields.
3. The cost of incoming streams is not known since they originate from the environment or are cogenerated in the same process. For the flows of raw materials of unknown origin, usually transportation costs may be used as a good approximation. For water or air at ambient temperature, the cost is usually assumed to be equal to zero. In this case, however, a better choice is to charge the incoming stream with the (real or virtual) effluent treatment costs necessary to restore its original environmental quality.
4. Labor costs are site dependent so that the same process may have different economic optima in different locations. The location becomes a design parameter.
5. Capital costs (interest rate, social costs, taxation level, etc.) are site dependent. Furthermore, they are also time dependent. Economic optimization must be performed independently for each site. Regarding the time dependency, levelization methods exist that allow the engineer to average out both market fluctuations and changing financial conditions by referring the calculations to a fixed economic state of reference (current money and constant money formulations).
6. There are more than one useful outputs, and their production lines share some of the components, materials, labor, and energy inputs. Allocation decisions must be made about what share of capital, material, labor, and energy costs must be allocated to which product. The optimal point is substantially affected by the allocation criteria.

Engineering economics encompasses more complex topics than those described here: the treatment of cash flows, the allocation of equipment depreciation, the inclusion of inflation and taxes in the economic calculations, etc. Interested readers may consult the book by Bejan, Tsatsaronis, and Moran.

The limits of engineering economics, in the formulation presented here, depend on the fact that it entirely neglects second law considerations. The efficiencies that appear in its formulation are first law efficiencies and as such are incapable of assessing the thermodynamic quality of participating streams. This is particularly inconvenient when the inputs and/or outputs of the process under consideration have different qualities, as in the frequent case of combined or cogenerating power plants. In these cases, engineering economics provides the wrong answer: Both the optimum it suggests and the relative cost ratio between different products are incorrect. It is from a critical analysis of these weaknesses that TE was first formulated.

4. SECOND VS FIRST LAW OPTIMIZATION

Suppose we wish to find the optimal pressure ratio β for the turbogas of the cogeneration plant shown in Fig. 3. This is indeed a credible design task. An increase in β leads to higher efficiency, but also to a lower air mass flow rate, and for a fixed turbine inlet temperature T_4, it leads to a decrease in T_5 so that for a fixed water return temperature T_{10}, the amount of generated steam decreases as well. A decrease in β, on the other hand, reduces the efficiency of the gas turbine cycle and, for a fixed required power output, increases the mass flow rate at compressor inlet, produces a higher T_5, and produces a higher steam mass flow rate. Figure 7 displays the sensitivity of the plant outputs (P, Q_{12}, and E_{Q12}) to the variation of β. First and second law efficiencies are shown as well. It is clear that η_I and η_{II} peak for different values of β. Which objective function is correct—the one based on η_I or the one based on η_{II}? From a purely thermodynamic standpoint, η_{II} provides the correct solution, and the reason is apparent if we look at the energy and exergy flow diagrams of the process, which are called the Grassmann (for exergy) and

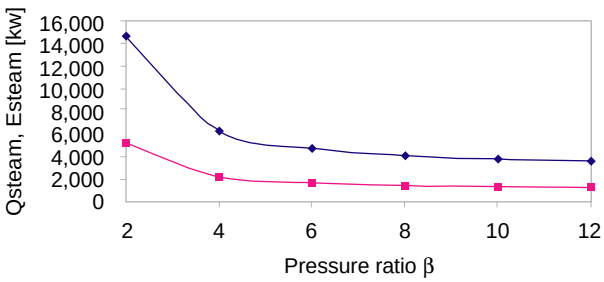

FIGURE 7 Cogeneration plant: sensitivity of the global performance indicators to β.

Sankey (for energy) diagrams (Fig. 8). These diagrams constitute a very effective pictorial representation of the energy and exergy flow within the process: They consist of boxes interconnected by arrows, with each arrow representing a stream and its width being proportional to the relative energy or exergy flux associated with it (usually normalized with respect to the main fuel input). Each box represents a component. For the plant under consideration, the energy diagram indicates that the losses, measured as percentage of the total input, are approximately the same for all components: 20% for the pump, 15% for the compressor and the boiler, 10% for the turbine, and 5 and 2% for the alternator and combustor, respectively. On the basis of this information, if we wanted to improve the design, we would concentrate on the pump first, then on the compressor and boiler, and so on. The diagram provides a ranking of the relative importance of each component in the energy dissipation during the process. The exergy diagram tells a different story, however: The highest losses (approximately 40%) are in the combustor and the boiler. This reflects more accurately the physics of the phenomena: In these two components, we enforce strongly irreversible transformations of high-quality into low-quality energy, irrevocably destroying exergy. A more accurate analysis (not performed here) would show that these low exergetic efficiencies are almost independent of the process parameters: They cannot be cured by improving, for instance, the thermal insulation of the combustor or by increasing the global heat transfer coefficient in the boiler. The irreversibility is introduced by the type of transformation these two components enact, and to remove the corresponding exergy destruction we would have to select a different device (e.g., a fuel cell instead of the combustor and a back-pressure steam turbine instead of the boiler). Thus, the proper objective function to use in the thermodynamic optimization is the one based on second law concepts.

Caution should be exercised here because energy conversion systems display a relatively high degree of interdependency: Components interact in complicated ways with each other, and an improvement in the efficiency of one component may lead to increased exergy destruction in other units, resulting in no net change or even a decrease in η_{II}. Furthermore, the installation cost of a component depends in a nonlinear way on its efficiency, and it may also affect the magnitude of other production factors, such as labor or material input. Therefore, an exergy analysis by itself does not tell the entire story. Methods are needed that combine exergy

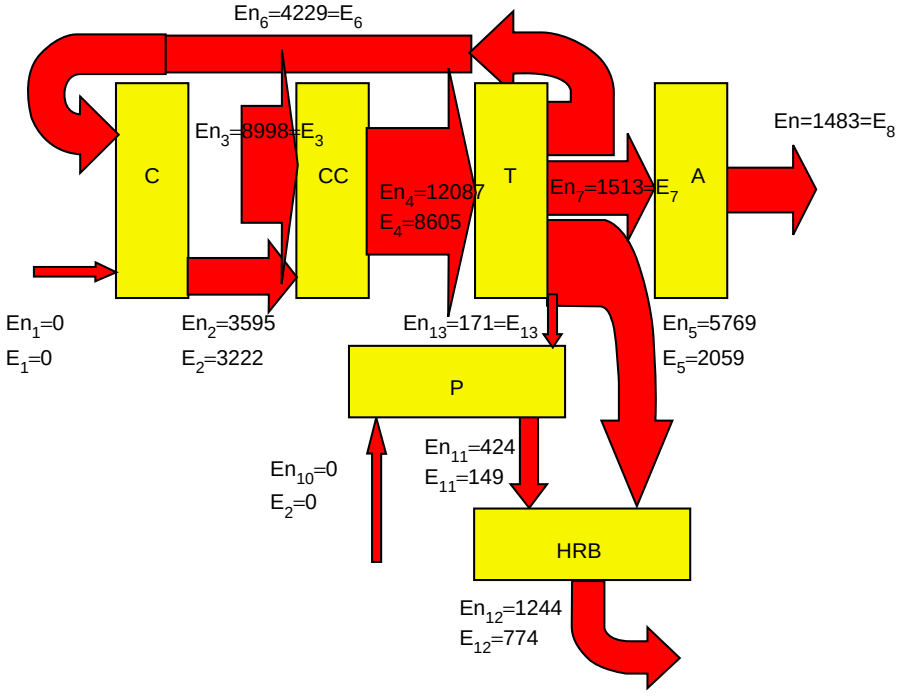

FIGURE 8 Energy (Sankey) and exergy (Grassmann) flow diagrams for the cogeneration plant shown in Fig. 3. En, energy flux; E, exergy flux (both in kW).

analysis and costing, as engineering economics does with energy analysis and costing. The simplest of these method is TE.

An entirely different type of optimization problem encountered in practice is the so-called design synthesis problem, in which the goal is to find the process structure (interconnectivity) that yields a maximum of the objective function. This is a much more difficult task, and some of the possible solution methods are discussed by Frangopoulos. In general, second law analysis provides more insight than its first law counterpart. Especially for synthesis problems, it is important to correctly assess the contribution to the overall process performance of each component, and the exergy flow diagrams offer an immediate glimpse into the real causes of the irreversibilities occurring in the process.

5. STRUCTURAL REPRESENTATION OF ENERGY CONVERSION SYSTEMS

One of the major difficulties in the assessment of the optimal performance of an energy conversion system regards the complex interconnection of its components. As a result, the response of the system to variation in the performance of one of its subunits is not easily predictable: It may well happen that an increase in the efficiency of one component leads to an overall performance deterioration. Several methods have been proposed to represent these cross-effects: The symbolic exergoeconomic method, first formalized by Valero and coworkers in 1988 and 1989, is discussed in detail here, complemented by a formalism adapted from the book by Kotas.

Consider again the cogeneration process of Fig. 3, which we refer to as **P** in this section, and define a matrix CM (connectivity matrix) constructed according to the following algorithm:

1. The jth column ($j = 1, \ldots, N$) of CM represents the jth process streams.
2. The ith row of CM ($i = 1, \ldots, M$) represents the ith component.
3. The generic element CM_{ij} is 0 if flux j does not interact with component i, 1 if flux j enters component i, and -1 if flux j exits component i.

For $M = 6$ and $N = 13$, Fig. 9 represents the ***CM***(6,13) for the plant shown in Fig. 3. This matricial representation of a process can also be derived from an application of graph theory (the Leontief input–output model) and is the basis for a compact and elegant computational procedure. By examining the streams in the cogeneration plant, we see that some of them transport mass and exergy (1–5 and 9–12) and some only exergy (6–8 and 13). We can correspondingly define a mass vector **vm**(13), every element of which represents the mass flow associated with the corresponding stream, and two energy and exergy vectors **vh**(13) and **ve**(13), which contain the energy and exergy values of each stream, respectively. As a further convention, vm contains a 0 in all positions corresponding to a "massless exergy carrier" (a flux of mechanical or electrical energy). It turns out that the mass and energy balances as well as the exergy accounting of the process are described by the scalar product of the matrix CM with the three vectors **vm**, **vh**, and **ve**, respectively.

ve is a vector that contains the exergy destructions in each component. On the basis of this formalism, Valero developed a procedure to symbolically compute the general transfer function of the process—that is, the matricial function Π that premultiplied by any property vector of the input streams (the fuels in Valero's terminology) provides the resulting property vector for the output streams:

$$\begin{aligned} \Pi \times \mathbf{mv}_\mathrm{I} &= \mathbf{mv}_\mathrm{O} \\ \Pi \times \mathbf{hv}_\mathrm{I} &= \mathbf{hv}_\mathrm{O} \\ \Pi \times \mathbf{ev}_\mathrm{I} &= \mathbf{ev}_\mathrm{O} \end{aligned} \tag{17}$$

There is a direct relationship between CM and Π, the second being a sort of augmented form of the former, but with the 0 and 1 substituted by influence coefficients. Note that Π is necessarily square, whereas CM is not. This transfer function is of course a function of the internal characteristics of each component, particularly the efficiencies. Once a closed-form expression for Π is known, we can study the sensitivity of the process performance to that of each one of its components. It is convenient here to adopt the formalism of the influence coefficients, first

proposed independently by Beyer and Brodyanskii in the 1970s and later systematized by Kotas. For each component, we thus define a coefficient of structural bonds σ_{ij} and a coefficient of influence π_{ij}:

$$\sigma_{k,\,i} = \frac{\left(\partial E_{\lambda,\,P}/\partial x_i\right)}{\left(\partial E_{\lambda,\,k}/\partial x_i\right)} \tag{18}$$

$$\pi_{j,\,i} = \left(\frac{\partial E_{in}}{\partial E_j}\right)_{x_i=\text{variable}}. \tag{19}$$

In Eq. (18), $E_{\lambda,P}$ and $E_{\lambda,k}$ are the exergy destructions of the entire process and of the kth component, respectively, linked to the efficiency by

$$\eta = 1 - \frac{E_\lambda}{E_{\text{input}}}. \tag{20}$$

If the ith thermodynamic variable x_i is varied, it produces in general a series of modifications in the efficiencies of some of the components: The sensitivity of each component is measured by $\partial E_{\lambda,k}/\partial x_i$. At a higher aggregation level, the coefficient of structural bonds $\sigma_{k,\,i}$ measures the sensitivity of the process to a variation of the efficiency of the kth component. However, the variation of the efficiency of components that operate on quantitatively small exergy flows is not as important for the process as that of a major components that elaborate the main fluxes of exergy: This aspect is quantified by the influence coefficient π_{ij}. If a variation of the ith thermodynamic variable x_i causes a variation in the magnitude of a certain exergy flux E_j, π_{ji} measures the influence on the overall input of the process.

Once we know σ and π, we can formally analyze (i.e., without to a numerical process simulation) the influence of a variation in a design or operating parameter of the plant. The problem, of course, is that to obtain these coefficients we must perform either an extensive experimental campaign or numerical process simulations.

6. THERMOECONOMICS

Thermoeconomics, in Tsatsaronis' definition, is exergy-aided cost minimization. It is a relatively new branch of engineering sciences that combines engineering economics and exergy analysis to answer the question of the "optimal" process structure and design. The major assumption in TE is that exergy is the only rational basis for constructing a costing function. The difference between TE and EE lies in the treatment of the monetary production factors: TE considers a monetary product cost optimized in terms of exergy considerations, whereas EE transforms monetary expenses into equivalent exergy fluxes and performs an optimization operating solely on exergy fluxes.

In TE, a cost is associated with each stream according to its exergy content. For the generic component shown in Fig. 10, a cost balance shows that the sum of the cost rates associated with the output flows is equal to that of the cost rates associated with the input flows plus the cost rates due to the nonenergetic production factors (capital, labor, and environmental costs). The latter are computed exactly as they would be in engineering economics, taking into account interest rates, inflation, taxes, plant depreciation, etc., and they are denoted here by Z (€/s). The cost balance equation for the component of Fig. 10 (a boiler) is

$$\sum_{\text{in},j}\left(c_{\text{in}} m_{in} e_{\text{in}}\right)_j + c_q E_q + c_w E_w + Z = \sum_{\text{out},i}\left(c_{\text{out}} m_{\text{out}} e_{\text{out}}\right)_i, \tag{21}$$

where the mass flow rates m_j, the corresponding exergy values e_j, and the heat (E_q) and work (E_w) exergy flows are known from previous process calculations. If there are N inputs and M outputs, there will be $N+M$ exergetic cost coefficients c_k. For the analysis to be feasible, the N coefficients relative to the input flows must be known, either from the design specifications or from the analysis of upstream components. We are left with M unknowns, and we need $M-1$ auxiliary equations to supplement Eq. (22). These auxiliary equations are derived on the basis of thermodynamic cost-allocation considerations. In essence, these auxiliary relations express the designer idea of the purpose of that particular component. Note that they are needed to make the transfer function matrix Π square. In our case, the reasoning is as follows:

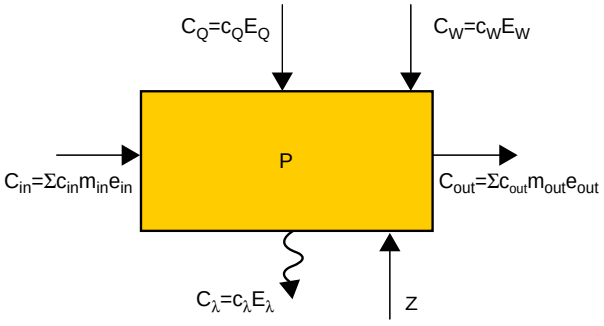

FIGURE 10 Thermoeconomic representation of a process *P*. All flows in €/s.

1. Since the flue gas must pass through a gas-treatment unit before being discharged into the environment, the cost rate associated with the installation and operation of this unit must be charged to this stream:

$$c_3 = -Z_{\text{Desox}}/m_3e_3. \tag{22}$$

2. Similarly, the ash must be charged with the costs of the ash-handling and -disposing equipment:

$$c_4 = -Z_{\text{inert}}/m_4e_4. \tag{23}$$

3. Regarding the boiling and the superheating sections of the tubes, we can consider that the boiler must provide both streams with the respective exergy increase at the same time; therefore, for both streams the cost increase is proportional to the exergy increase with the same constant of proportionality:

$$\frac{m_6c_6 - m_5c_5}{m_6e_6 - m_5e_5} = \frac{m_8c_8 - m_7c_7}{m_8e_8 - m_7e_7}. \tag{24}$$

Bejan, Tsatsaronis, and Moran provide examples of commonly used auxiliary equations for various components.

Once we have M equations in M unknowns, we can solve the TE problem and compute the cost of each stream, particularly that of the final products. If we want to execute an optimization, however, we need additional functional relationships to link the exergetic efficiency of each component to its installation cost (which is reflected in the capital flow factor Z). In the past decade, data have been published by several authors: we recommend the 1998 compilation by El-Sayed.

TE is the most advanced and powerful technique for the cost optimization of complex production systems. It requires an understanding of the exergy method of system analysis and a working knowledge of engineering economics: Both topics are included in most engineering curricula. In every monthly issue of every energy-related technical journal, one may find original applications of TE or a revisitation of an old application. Its impact on the engineering community has been profound because it has promoted the shift, advocated by exergy analysis methods, toward the consideration of irreversibilities and of their real causes in industrial processes. However, it has two weak points. First, being in essence a revised version of engineering economics, it suffers from the adoption of two separate quantifiers: one (exergy) to assess the technical worth of a process, and the other (money) to assess the profitability of the product. There is something inherently awkward in the "pricing" of a physical stream that makes one consider whether it would not be more convenient to base decision tools on purely physical parameters. Second, as a consequence of the first weakness, a correct assessment of environmental issues is problematic in TE. Despite some attempts, for instance, by Frangopoulos and von Spakowsky and independently by Szargut, the problem of attributing a cost to environmental damage remains an open and controversial issue. The current solution is to use the results of large-scale medical studies to attribute a "social cost" to the unit of pollutant discharged into the environment and then charge this cost to the product(s) of the plant. Since pollution effects are inherently nonlinear, and the translation of "a tolerable amount of health risk" in monetary terms is somewhat perplexing, this issue has been intensely debated, resulting in the formulation of a method for process costing based solely on exergy. This method should be called exergoeconomics, and it is described as such here. However, since many engineers use TE and EE as interchangeable terms with the same meaning, it has been published under the name of extended exergy accounting (EEA).

7. EXERGOECONOMICS AND EXTENDED EXERGY ACCOUNTING

If we want to unify the TE costing method and express all expenses by means of a single quantifier, how can we convert monetary expenses into exergy fluxes? The answer has been provided by a controversial energy-accounting theory, emergy (energy memory) analysis, formulated in the 1970s by Howard Odum and mainly used to study the energy cascade of biological systems. Odum maintains that the monetary capital that circulates in a society (a town, county, or nation) is entirely supported by, and therefore equivalent to, the amount of solar energy that maintains life in the environmental niche in which that society thrives. This idea, not developed to its full potential in emergy theories, has been echoed in Herman Daly's critical assessment of the economic theories of growth: An economist by trade, Daly (echoing and developing concepts formulated by others, such as Nicholas Georgescu-Roegen, Lotka, and Robert Costanza) distinguishes between natural capital and monetary capital and demonstrates that the two are not completely substitutable for each other but rather complementary. The

conclusion is that it is the amount of resources we avail ourselves of, and not our capital intensity, that is the key to our survival as an industrial society on Earth. From a completely different point of view, Szargut reached similar conclusions. He devised a procedure to track all amounts of exergy used in the production of a commodity from the mining of the raw materials to the final distribution and disposal, and he proposed to associate a cumulative exergy content to each good or service to express its value in purely exergetic terms. However, both Szargut and Daly left unanswered the problem of how to convert nonenergetic expenditures into resource consumption indices. Extended exergy accounting is the first theory to provide a unified treatment of these issues, along the guidelines discussed here.

EEA adopts the standard exergy accounting method of Szargut to embody into a product all of the exergetic expenditures incurred during its production: Extraction, refining, transportation, preprocessing, final processing, distribution and disposal activities are computed in terms of exergy consumption. Exergy, unlike energy, is not conserved, and in each step of the extended production line a portion of it is irrevocably destroyed in irreversible entropy generation. Thus, the exergetic production factors can be accounted for in full. Regarding the three nonenergetic externalities (labor, capital, and environmental remediation costs), EEA proposes the treatment discussed in the following sections.

7.1 Capital

With regard to including capital and general financial costs in the balance sheet of an energy conversion system, there seems to be a general agreement: We employ money and its time value as the sole quantifier for goods, services, labor, resources, etc. This paradigm of money as a basic metric for energy-related activities is so deeply rooted in our culture that most industrial energy balances are expressed in monetary price per unit of product rather than per energetic (not to mention exergetic) content. There are two reasons to support the necessity of maintaining a purely monetary criterion:

1. The society within which energy conversion systems operate consists of a complex network of related systems, and all exchanges among them are already assessed on a monetary basis.
2. On an average world basis, the contribution of energy-related costs to the global gross national product varies between 2 and 9%; therefore, money (capital), and not energy, is the main quantifier of human activities.

It is perfectly logical to reverse this point of view by considering that economic systems are ecosystems that function only because of the energy and material fluxes that sustain human activities. All agricultural, industrial, and economic activities can only exist as long as they exploit (use) biophysical resources taken from a reservoir of noninfinite mass capacity but of practically infinite exergy capacity. From this point of view, it clearly appears that exergetic content, and not capital, is the correct measure for the value of a commodity or a service, and that the monetary price should reflect this new scale of values.

Naturally, to support the cancellation of monetary prices would be unrealistic and destabilizing: The very structure in which we live and function demands the conservation of the "price-tag" concept in everyday economic activities and on a worldwide scale. EEA advocates that this tag be calculated on the basis of the extended exergetic content (EEC) of a good or service. The numerical relation between the EEC and the price of a product is also immediately clear: The conversion factor is the ratio of some measure of the monetary circulation to the global exergetic input; just as the monetary flux is the driving agent of societal development according to the current paradigm, the exergy flow is its physical driving force. The choice of a proper indicator for the monetary flux, of course, is somewhat arbitrary: EEA adopts the absolute measure of the global monetary circulation ($M2$), which for each country is computed and published by the central bank (or other organization):

$$e_{\text{Cap, Sector}} = \frac{E_{\text{in, Sector}}}{M2} \quad [D\text{J}/€]. \tag{25}$$

When processes are analyzed, it is the exergetic equivalent of the financial expenditures that must be inserted in the balance as an input, and the same applies to the revenues. It is noteworthy that for most state-of-the-art processes the substitution of the equivalent exergetic value for the monetary price causes a significant discrepancy in the exergy balance: the reason is clearly the over- or underestimation of the real extended exergetic content of materials, feed stocks, labor, and energy flows. For the EEA method to be optimally applicable, it is necessary that the economic and exergetic values become locally consistent in the long term, allowing the two value scales to reach a sort of local fixed parity. The same definition of the exergy equivalent implies that different countries may have different

e_{Cap} due to their different productive and economic structures and lifestyles, and that for a country e_{Cap} may vary over time due to an evolving social structure.

7.2 Labor

The capability of attaching a properly computed exergetic value to a labor input (taken here to include all service-related, blue- and white-collar human activities) is perhaps the most relevant novelty of EEA. In all practical applications of engineering cost accounting, including TE, labor is accounted for on a purely monetary basis, but very reasonable alternative approaches have been formulated. Odum's previously mentioned emergetic approach, for instance, computes a value for labor on the basis of the total time-averaged embodied energy content of the human life in the particular area where a worker lives and works. The problem is that the attribution of a purely monetary value to labor is unsatisfactory because it assigns a higher weight to market conditions and financial considerations than to social, technical, and environmental issues that although properly valued may so distort the objective function that new solutions emerge.

EEA proposes to assign labor, and human services in general, in each portion of a society an exergetic value computed as the total (yearly averaged) exergetic resource input into that portion divided by the number of working hours generated therein:

$$e_{L,Sector} = \frac{E_{in,Sector}}{n_{work\ hours,Sector}} \quad [J/man\text{-}hour]. \qquad (26)$$

7.3 Environmental Impact

All methods for assigning a monetary cost to environmental damage in essence suggest that once a substance is acknowledged to be (in some sense) harmful, it become regulated (i.e., legal upper limits are set for its free release into the environment). This is equivalent to setting, for a given technology, an upper price for the cleanup costs for that particular effluent. For many pollutants, however, the environmental situation has deteriorated to a point at which the overall balance of the biosphere has already been affected, and even a small amount of each one of the pollutants is, strictly speaking, intolerable. Therefore, to make a nonzero limit acceptable, the risks to humans are assessed in terms of monetary health- and life-expectancy parameters, and an upper bound is set a priori to the expenditures in such a way so as to remain below a certain statistical probability of incurring that risk. It is claimed that the consequent economical burden is transferred both ways in the economy: downwards, affecting the price of resources that are perceived to be more or less clean, and upwards, increasing the price of products seen as less environmentally friendly. The fallacy of this assertion may be exposed by considering that willingness to pay and the attitude toward a sustainable resource exploitation are different in different countries and may well vary in time. Therefore, in reality, the disturbances caused by a local modification in the environmental regulations affect regions possibly far away from the point of origin, and the method actually promotes an unfair transfer of not only the pollution but also the health risks from a region to another. A solution to this situation has been sought by linking the monetary structure of the environmental levies to energetic considerations: This is the rationale behind pollution commodity trading and the exergy tax. These are remedial measures, aimed at a fairer redistribution of the environmental pressure on a global scale, and they do not address the issue of how high the actual environmental cost is (all methods use the currently regulated values as a basis for their calculations).

EEA advocates a substantially different approach. Consider a process P (Fig. 11A), and assume that its only effluent is a stream that contains hot chemicals, some of which are not at their standard environmental concentration. To achieve a zero environmental impact, these chemicals would have to be brought to both thermal and chemical equilibrium with the surroundings. Thus, the real exergetic cost of the zero impact is proportional to the physical exergy of the effluent because it corresponds to the extended exergy (the sum of the physical exergy spent in the cleanup process plus the invested exergy—labor and capital—required by the installation and operation of the effluent cleanup devices) ideally required to cool the effluent to T_0 and break it up into its constituents such that each one is in equilibrium conditions with the surroundings. A possible representation of such an effluent treating process is shown in Fig. 11B: The additional process P_t requires an energetic input—possibly some auxiliary materials, labor, and invested exergy—but its output will have a zero physical exergy. The additional exergetic expenditures required by P_t must be charged to the effluent O_2, whose extended exergy will now be higher than its original one. Therefore, the overall conversion efficiency of the joint process $(P + P_t)$ is decreased. There may be

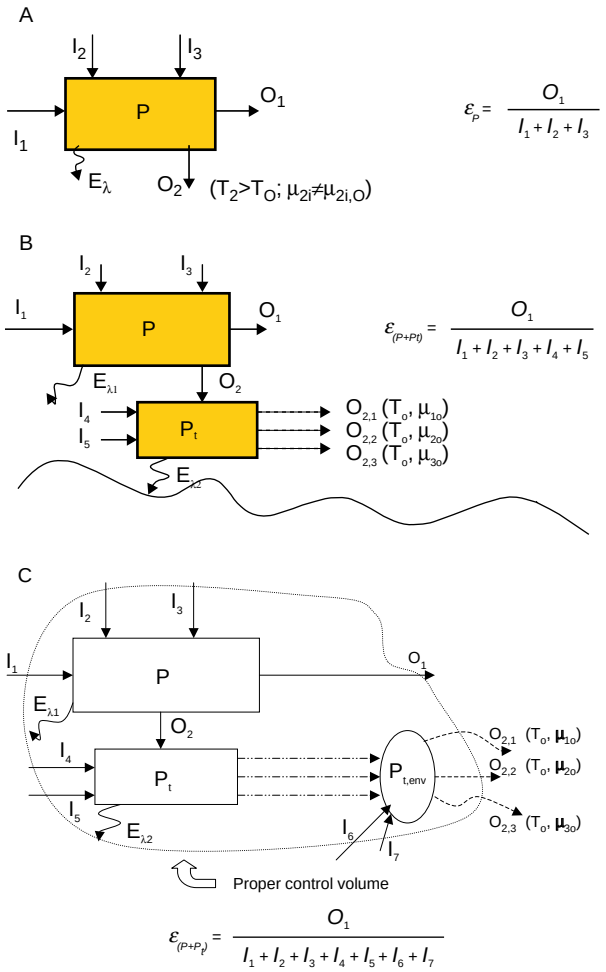

FIGURE 11 Environmental cost assessment in EEA. (A) The effluent O_2 is not at reference conditions. (B) Treatment of the effluent O_2. Each final effluent is at its reference conditions. (C) Only a portion of the cleanup is performed by man-made treatment processes; the remainder occurs spontaneously by biodegradation in the immediate surroundings.

effluents for which some of the chemical decomposition reactions take place spontaneously, in a short time and in the immediate surroundings of the emitting source. In such cases (Fig. 11C), the reactions must draw on some exergy source within the environment (a certain particular chemical catalyst, oxygen, water, solar radiation, or even a biological system), and this exergy flow must be accounted for as well.

EEA thus allows for a consistent incorporation of the effects of effluent treatment in the extended exergetic balance of a process, and it provides an absolute order-of-magnitude estimate of the minimum exergy consumption necessary to achieve zero impact. If an acceptable level of pollutant is specified, then the minimum exergetic expenditure will be proportional to the difference between the values of the physical exergies of the effluent stream between the point of its release and the regulated state point. Here, we use one of the desirable features of environmental cost estimates and at the same time effectively avoid the considerable effort required to determine what the "tolerable environmental impact limit" for a certain pollutant would be.

Once all fluxes (which can be equally regarded as production factors) have been computed in terms of exergy equivalents, EEA makes use of the same structured representation of TE to compute the costs of the final products and to study their dependence on a variation of process parameters. With all terms now expressed in terms of a uniform quantifier, the procedure is somewhat simpler and, more important, absolutely independent of external factors such as market fluctuations or time-varying currency exchange levels.

8. CONCLUSIONS

Current engineering practice uses a mixed energy–monetary formulation to study the cost-formation process of industrial products. TE represents a substantial improvement because its exergy–monetary procedures allow for an exact treatment of irreversibilities and for a better (more precise) accounting of the real causes of exergetic waste, which is equivalent to production cost (if we could find abundant amounts of a certain finished product in nature, its cost would be zero). EE, or EEA, broadens the objective and bases its treatment on a purely exergetic paradigm. TE is becoming increasingly popular, and modern production lines are designed according to its dictates. It is hoped that in the near future, EEA will constitute the basis for our cost-accounting procedure. When (and if) this occurs, we will be able to assess our industrial processes on performance indicators that correctly reflect the resource to final use (including disposal, in a omnicomprehensive cradle-to-grave approach) of our exergy resources.

Glossary

energy Motion or ability of motion (e.g., the disordered motions of the hot molecules in a cup of coffee); measured in joules (J).
entropy A physical concept of disorder; measured in joules per kelvin (J/K).
exergy Work (i.e., ordered motion) or ability of work (e.g., the motion of a falling object); measured in joules.
exergy analysis Calculation of the total input and output of exergy of a product or service.
exergy destruction Exergy that vanishes in an irreversible process; also called irreversibility.
information Physical capacity of carrying a message; measured in binary units (bits).
irreversible Real processes are always irreversible (i.e., exergy is destroyed) in order to occur.

The exergy concept has its roots in the early work of what would later become thermodynamics. In 1824, N. L. Sadi Carnot stated that the extractable work of a heat engine is proportional to the temperature difference, which led to the definition of the second law of thermodynamics. Willard Gibbs introduced the notion of available work, including the diffusion term, in 1873. He simply stated the following: We will first observe that an expression of the form

$$-\varepsilon + T\eta - Pv + M_1m_1 + M_2m_2 + \ldots + M_nm_n \qquad (1)$$

denotes the work obtainable by the formation (by a reversible process) of a body of which ε, η, v, m_1, $m_2,\ldots,m_n$ are the energy, entropy, volume, and the quantities of the components, within a medium having the pressure P, the temperature T, and the potentials M_1, M_2, …, M_n. (The medium is taken to be so large that its properties are not sensibly altered in any part by the formation of the body.)

Equation (1), originally referred to as Eq. (54) in Gibbs' work, is in exact correspondence with the present definition of exergy. Exergy is a thermodynamic potential; it is a general measure of "difference" or contrast. Thus, two states must be defined—the actual state and an equilibrium or a reference state, often defined by the environment. In 1953, the term exergy was first expressed by Z. Rant to denote "technical working capacity." In 1961, Tribus linked classical thermodynamics with information theory through the entropy concept. In 1977, a concise theory of exergy was offered and exergy was introduced as a useful concept not only for engineering but also for resource accounting in order to reduce environmental destruction. The term exergy is gaining in popularity and gradually replacing terms such as availability, available energy, essergy, utilizable energy, work potential, available work, and convertible energy.

1. THERMODYNAMICS AND EXERGY

Thermodynamics provides the concepts of temperature T, pressure P, heat Q, work W, internal energy U, entropy S, and four laws of thermodynamics. First, the zeroth law establishes the concept of temperature. Second, the first law defines energy as a conserved quantity (i.e., added heat ΔQ is equal to the increase of internal energy ΔU and the extracted work ΔW):

$$\Delta Q = \Delta U + \Delta W. \qquad (2)$$

The extracted work is force times distance, or pressure times volume change (i.e., PdV). Pressure is an intensive variable (i.e., independent of the amount of matter). Volume is an extensive quantity that obviously depends on size or amount of matter:

$$dW = PdV, \qquad (3)$$

TABLE I

Energy versus Exergy

Energy	Exergy
The first law of thermodynamics	The second law of thermodynamics
Nothing disappears.	Everything disperses.
Energy is motion or ability to produce motion.	Exergy is work (i.e., ordered motion) or ability to produce work.
$\Delta Q = \Delta U + \Delta W$ (2)	$E = T_0 \Delta S^{\text{tot}}$ (6)
where ΔQ is the total heat supplied to the system, ΔU is the total increase in the internal energy U of the system, and ΔW is the total increase in the external energy of the system or the total work done by the system.	where E is exergy, T_0 is the temperature of the environment, and ΔS^{tot} is the change of the entropy of the total system S^{tot} (i.e., the system and the environment).
$U = mc^2$ (7)	$E = k \ln 2 T_0 I$ (8)
Energy U and matter m are "the same thing."	Exergy and information I is "the same thing."
Everything is energy.	Contrast is exergy.
Energy is always conserved (i.e., in balance); it can neither be produced nor consumed.	Exergy is only conserved in a reversible process but partly consumed in an irreversible process, (i.e., real processes). Thus, exergy is never in balance for real processes.
Energy is a measure of quantity.	Exergy is a measure of quantity and quality.

where V is the volume. Third, the second law defines the concept of entropy through heat:

$$dS \geq 0,\ dS_{\text{reversible}} = 0 \tag{4}$$

$$dQ = TdS, \tag{5}$$

analogous to Eq. (3). Finally, the third law defines the zero level for entropy.

Thermodynamics only treats reversible processes (i.e., nonreal processes) and systems in equilibrium states. Thus, dynamics is not treated and a more proper name is thermostatics. Even so, thermodynamics remains one of the most successful pieces of physics, particularly in engineering.

The first law (i.e., energy is conserved) generally fails to identify losses of work and potential improvements or the effective use of resources (e.g., in an adiabatic throttling process). The second law of thermodynamics shows that for some energy forms, only a part of the energy is convertible to work (i.e., the exergy). Thus, exergy is a very useful tool in engineering. Table I summarizes the main differences between energy and exergy.

1.1 Calculation of Exergy

The exergy of a system is expressed by the formula

$$E = U + P_0 V - T_0 S - \sum_i \mu_{i0} n_i, \tag{9}$$

where U, V, S, and n_i denote extensive parameters of the system (energy or internal energy, volume, entropy, and the number of moles of different chemical materials i), and P_0, T_0, and μ_{i0} are intensive parameters of the environment (pressure, temperature, and chemical potential). This expression is exactly what Gibbs stated in 1873 (Eq. 1). The chemical potential μ_{i0} may be generalized to also include exergy from electromagnetic forces, stress, nuclear forces, etc. This makes exergy the most general concept of work or ability of work. The situation is illustrated in Table II. System A is surrounded by the environment A_0 that is assumed to be much larger than the system (i.e., almost infinite in size). These two systems define two unique thermodynamic states—a difference or a contrast (Table II).

TABLE II

System A in a Much Larger Environment A_0

Intensive quantities	Extensive quantities
T_0 = temperature	U = internal energy
P_0 = pressure	V_0 = volume
μ_{i0} = chemical potential for substance i	S_0 = entropy
	n_{i0} = number of moles of substance i

System A_0 is assumed to be unchangeable in order to initially also define the final state (i.e., the equilibrium state), when both systems have interacted in such a way that the contrast is exhausted. In

the real world, the situation is often like this. The ambient is usually so immense that it may be regarded as unchangeable. Each system is described by intensive and extensive quantities. The intensive quantities are actual measures of the contrast, such as the temperature T, the pressure P, and the chemical potential μ for every substance i. These quantities are not affected by the size of the system but only by the level of contrast. The extensive quantities, on the other hand, are directly proportional to the size of the system. However, it has been determined that human action (e.g., from combustion of fossil fuels) has a destructive impact on the environment in terms of changing its intensive quantities, such as temperature and composition, through the so-called greenhouse effect. The unpredictable dynamics of the environment makes this a dangerous activity.
