It would be difficult to overstate the importance of Appalachian coal in propelling America into the industrial age. Prior to World War II, virtually all coal mined in the United States came from the Appalachian fields. In 1925, for example, the Appalachian region produced 92% of the total amount of coal mined in the United States, with Pennsylvania alone accounting for approximately one-third of this output. Between 1880 and 1930, Pennsylvania consistently ranked as the leading producer of both bituminous and anthracite coal. By the mid-1920s, however, it had become apparent that all was not well with the coal industry in Appalachia.

2.2 The Decline of King Coal

Several years in advance of the stock market crash of 1929, the coal industry in general and miners in particular felt the first tremors of the Great Depression. In Appalachia, overexpansion stimulated by World War I, interstate competition with midwestern states, and competition between "union" and "nonunion" mines led to market gluts, falling prices, spiraling unemployment, and labor unrest. Although mining had weathered economic downturns in the past, most notably in the mid-1890s, nothing compared with the depression that beset the industry during the 1920s and 1930s. West Virginia, which lost 33,000 coal jobs as production fell from 146 million tons in 1927 to 83.3 million tons in 1932, was hit particularly hard.

In subsequent years, the rising popularity of new energy sources—petroleum, natural gas, and electricity—challenged coal's dominance of the domestic heating market. Although World War II provided a boost to the region's coal-based economy, it was only temporary. When railroads completed the conversion from coal to diesel after the war, the industry received another blow, contributing further to the industry's recent history of boom and bust. The coal operators' response was to accelerate the process of mechanization begun in earnest during the 1930s and to opt for surface mining over underground mining wherever feasible. Economic instability coupled with widespread utilization of new labor-saving machinery, typified most noticeably by the introduction of enormous electric-powered shovels to surface operations, forced many miners and their families to leave the region altogether in the post-World War II era.

Since the 1960s, the only major growth market for coal has been to supply electric power producers and for export abroad. With respect to the former, coal remains an important player. Today 52% of U.S. electricity is generated by coal-fired plants. However, increased production from western states starting in the late 1950s, but gaining momentum especially during the 1980s and 1990s, has further eroded Appalachia's share of coal markets. Compliance with environmental laws since the 1970s, including the Clean Air Act and its amendments, the Clean Water Act, and the Surface Mining Control and Reclamation Act (SMCRA), not to mention various state-level regulations, has also contributed to a rise in coal production costs. By 1999, more than half of the coal mined in the United States was coming from states located west of the Mississippi River, and far and away the largest single producer was Wyoming, not Pennsylvania. Nevertheless, coal mining has managed to remain viable in some portions of the Appalachian region due in large part to controversial mining techniques such as mountaintop removal.

3. BREAKING GROUND

Given the increase in demand for coal spurred on by industrialization, the existence of coal so near to the Atlantic seaboard aroused early interest among local boosters, land speculators, foreign investors, and others wishing to purchase mineral lands and mine them for profit. Before large-scale coal-mining operations could commence, however, certain obstacles had to be surmounted. First, coal lands had to be surveyed and evaluated, and the rights to the coal purchased or leased. Equally important, a reliable and cost-effective means of transporting the coal to eastern and Great Lakes markets, as well as to the steel mills of the North and South, had to be financed and developed. As historian Crandall A. Shifflett has pointed out: "All of the land and coal was worthless… if it could not be gotten out of its mountain redoubts. There was no use to open mines if the coal could not be transported to distant markets."

3.1 Railroads Usher in the Industrial Era

As early as the 1820s, coal mining had become an important, albeit seasonal, activity in some remote locations. During the first decade of the 19th century, for example, small quantities of coal, along with lumber and a variety of agricultural goods, were sent down the Potomac River via flatboat to Georgetown. On arrival, the large rafts were dismantled and their crews walked home. Such trade could only take place during the spring season when floodwaters raised the level of the river. Without significant investment in transportation improvements, it was clear that coal could not be mined profitably on a large scale.

Although coal and coke (fuel derived from coal) were slow to replace wood and charcoal in the manufacture of iron prior to the Civil War, coal found an early use in blacksmith shops and as a domestic heating fuel. After about 1840, coal gradually began to replace charcoal in the furnaces of the burgeoning iron industry. By this time, it was also being recognized as an important source of power for steam engines. After the Civil War, it would play an indispensable role in the manufacture of steel.

Initially, it was the anthracite fields of northeastern Pennsylvania that attracted great attention. Once problems associated with the burning of hard coal were resolved, production rose sharply. Between 1830 and 1860, production of Pennsylvania anthracite, much of it destined for the Northeast, increased more than 40-fold. As Andrew Roy put it in 1903, "the 'black rocks' of the mountains, heretofore deemed useless, at once rose in public estimation." Miners' villages sprouted wherever new mines were opened as English, Welsh, Irish, Germans, and, in later years, eastern and southern Europeans entered the region in search of high wages and a new beginning in America.

Before America's Industrial Revolution could "take off," another revolution—this one in the transportation sector—was needed. As the country grew in geographic extent, government officials became increasingly aware that improvements in communication and trade depended largely on the development of new, more efficient modes of travel. In 1808, Albert Gallatin, Secretary of the Treasury under Thomas Jefferson, envisioned a system of roads and canals crisscrossing the country and financed by the federal government. Although the Gallatin Plan was never carried out, great changes were in the works. The spectacular success of New York's Erie Canal served as a catalyst. Indeed, the completion of the Erie Canal in 1825 ushered in a period of canal building in the United States as eastern cities competed with one another in a race to expand their hinterlands and capture market share. Government officials and businessmen in Pennsylvania, Maryland, Ohio, and Virginia soon unveiled plans for canal systems they hoped would allow them to remain competitive with New York. In the end, none of the canal systems to the south could match the financial success of the Erie Canal and its branch connections. Difficult terrain and competition from a new form of transportation, the railroad, ensured that the reign of the canal would be relatively short (Fig. 2).

On the eve of the Civil War, large parts of northern Appalachia had established outlets for coal via rivers, canals, and railroads. In addition to the anthracite fields of eastern Pennsylvania, bituminous coal from the great "Pittsburgh" seam in western Pennsylvania, western Maryland, northern West Virginia, and Ohio was now being tapped. In contrast, central and southern Appalachia remained relatively unaffected by the transportation revolution that had seized the north. After the Civil War, an already impressive network of railroads in the Appalachian north was expanded. As these railroads, and to a lesser extent canals, penetrated the mountains, operations were expanded in western Maryland, western Pennsylvania, northern West Virginia, and southeastern Ohio, contributing to the growth of the iron industry and, especially after the introduction of the Bessemer hot-blast furnace in the 1860s, the nascent steel industry. Following the steady progress of the railroads, new fields were opened up in southern West Virginia, northeastern Tennessee, and northern Alabama, and finally, by the 1890s, southwestern Virginia and eastern Kentucky. As was the case with Pennsylvania's anthracite fields, the opening of mines in these areas was accompanied by a flurry of coal town construction and an influx of immigrant labor. As historian Richard Drake reminds us, in addition to carrying a great deal of coal, rail lines such as the Baltimore and Ohio, Chesapeake and Ohio, Norfolk and Western, Louisville and Nashville, and the Southern Railway, to name but a few, figured prominently in the growth of major industrial centers concentrated in the northern and southern extremities of the region. Of particular importance was the development of Pittsburgh and its industrial satellites—Johnstown, Altoona, Morgantown, and Fairmont—and the "A.B.C." triangle of the Deep South—Atlanta, Birmingham, and Chattanooga.

3.2 Clearing the Way

Long before the new transportation lines reached their destinations, however, land speculators were clearing the way for this initial wave of industrialization. During the first half of the 19th century, corporations interested in mining coal and iron ore

and cutting timber, and backed by capital from centers of commerce such as New York, Baltimore, Boston, and London, dispatched geologists and engineers into the mountains to measure the size and evaluate the quality of coal and iron ore deposits. When favorable reports were returned, they began accumulating property rights, a process that was often mediated by land speculators. Some of these speculators and businessmen were outsiders who entered the region as representatives of mining interests headquartered in the east. Others were local residents who recognized the value of coal and accumulated property rights based on the assumption that the arrival of the railroad would cause real estate values to soar. Still others were opportunistic politicians—men like Henry Gassaway Davis, Johnson Camden, and Clarence Watson—who used their power and influence in the chambers of the U.S. Senate and in various state capitols to finance railroads, purchase coal lands, and amass personal fortunes. Invariably the result was the same. By the time the railroad arrived, the coalfields were controlled for the most part by outside interests eager to begin the mining process.

One of the best known of these early entrepreneurs was Pike County, Kentucky native John C. C. Mayo. During the 1880s and 1890s, Mayo traveled throughout eastern Kentucky purchasing land or mineral rights from local farmers. Using the infamous "Broadform Deed," which permitted the mountain farmer to retain rights to the surface while authorizing the owner of the mineral rights to use any means necessary to extract the minerals, Mayo acquired thousands of acres of land that he eventually sold to companies such as the giant Consolidation Coal Company. As late as the 1980s, coal companies in Kentucky could count on the courts to accept the binding nature of Broadform Deeds signed in the late 19th and early 20th centuries. However, rather than extract the coal using underground mining techniques, as was the practice during the 19th and early 20th centuries, companies were now employing surface mining techniques. Essentially, the Broadform Deeds permitted coal operators to destroy the surface to reach the mineral deposits. The stability of many rural communities was sorely tested. In 1988, the citizens of Kentucky passed an amendment to the state constitution requiring coal companies to obtain permission from surface owners before strip mining land. Five years later, the Kentucky Court of Appeals accepted the constitutionality of this amendment.

4. LIFE IN THE COMPANY TOWN

A vexing problem that confronted coal operators in the early stages of mine development was a shortage of labor. Because exploitable seams of coal were often found in sparsely populated areas, operators were forced to recruit and import labor. Although some coal operators used prison labor, as in northern Alabama, or drew from the pool of displaced mountain farmers, by far the greater number chose to lure white labor from Europe or, in the years leading up to World War I, to enlist black migrants from the South. Thus, in addition to mine development and railroad construction, coal companies had to provide housing and other amenities for newly arrived miners and their families.

These company towns, as they came to be known, played an especially important role in central and southern Appalachia during the 19th and early 20th centuries. In eastern Kentucky, southern West Virginia, and southwestern Virginia during the 1920s, for example, an estimated two-thirds to three-fourths of all miners and their families resided in such communities. In southern West Virginia, the figure approached 98%. Beginning in the 1930s, the company town's usefulness began to fade. A number of factors contributed to this decline, including the diffusion of the automobile, which greatly enhanced worker mobility; the introduction of labor-saving devices, which made workers redundant; and, later, the adoption of surface-mining techniques, which further reduced the need for a large labor force. No longer profitable, by the 1950s and 1960s most mining firms had sold or otherwise disposed of company housing.

4.1 A Distinctive Feature of the Mining Landscape

There can be little doubt that the company town is one of the most distinctive features associated with Appalachia's historic mining districts. Although some scholars have argued that company towns were a necessity, at least at the outset, and that many companies treated their workers with respect and fairness, others contend that these carefully planned and controlled settlements allowed companies to exert an objectionable level of power over miners and other residents. Considering the extent to which some companies dominated local law enforcement, monitored educational and religious institutions, curtailed personal liberties, and influenced worker

behavior, their power was pervasive. As Shifflett reminds us, however, some miners' families, especially the first generation to leave hardscrabble farms in rural Appalachia, may have favored life in the company town, especially the more durably constructed "model" towns: "Contrary to the views that the coal mines and company controlled towns led to social fragmentation, disaffection, and alienation of the workforce, many miners and their families found life in them to be a great improvement over the past. Miners viewed the company town, not in comparison to some idyllic world of freedom, independence and harmony, but against the backdrop of small farms on rocky hillsides of Tennessee, Kentucky, and Virginia, or a sharecropper's life in the deep South states."

Company towns in Appalachia generally shared several distinguishing features (Fig. 3). First, the town bore the stamp of the company in every conceivable way. Everything in the town, from the houses and the company store to the schools, churches, hospitals, and the recreational facilities, if such "frills" even existed, was provided by the company. Second, housing generally conformed to a standard design. In general, one worker's house was identical to the next with respect to style and construction. A third trait was economy of construction. Companies typically limited their investment in towns because they knew they were not likely to evolve into permanent settlements. Renting houses to workers ensured that even a substantial investment in housing would be recovered quickly. Because companies generally preferred to hire married men with families over single men, believing they were less inclined to quit their jobs, single- and two-family dwellings were far more common in the coalfields than were large boarding houses. A fourth feature was that the company houses and other structures were usually laid out in a standard gridlike pattern, with long, narrow lots lined up along the railroad tracks. Finally, there was an outward manifestation of socioeconomic stratification and segregation according to racial and ethnic group expressed in the landscape. With respect to the former, sharp distinctions could be found in the size and quality of housing occupied by miners and company officials. Regarding the latter, historian Ronald Lewis notes that some companies sought a "judicious mix" of whites, blacks, and immigrants as a means of maintaining order and fending off the advances of union organizers. Thus it was not unusual to find distinct "neighborhoods"—an immigrant town, a Negro town, and an "American" town—existing side by side in the same town, each with its own separate facilities and social and cultural life.

One of the most controversial features of the typical coal mining town was the company store. Indeed, it represented both the best and worst of company town life. Often doubling as a meeting hall, lodge, and recreation facility, while also housing the company offices, the store carried a great variety of goods, including food and clothing, mining supplies, tools, and durable household goods. It also served as an important informal gathering place for both miners and managers alike. Given the remote location of many towns, the company store was often the only commercial retail establishment to which the mining population had regular access. In some cases, coal companies prohibited the establishment of other stores; in other cases, they penalized miners for making purchases in neighboring towns. Customer loyalty was achieved through the issuance of company scrip. Paying wages at least partially in scrip ensured that a portion of a worker's paycheck would be funneled back to the company. Although company officials claimed that such an arrangement protected families, critics have argued that companies charged higher prices in an attempt to keep the cost of coal production down. It is not surprising, then, that charges of debt peonage, coercion, price gouging, and differential pricing were leveled at the company store.

Some companies encouraged the planting of vegetable and flower gardens to improve the appearance of towns and to supplement food supplies. With the men at work in the mines, primary responsibility for the planting and care of the gardens rested on the

FIGURE 3 Railroad station, Fleming, Kentucky, ca. November 1915. Reprinted from the Smithsonian Institution, National Museum of American History, with permission.

shoulders of women and children. While they contributed significantly to the miners' larder, the gardens may have served another purpose. By encouraging miners to grow much of their own food, company officials could justify paying lower wages. Such a strategy enabled companies located at a considerable distance from major coal markets to keep the price of coal low and remain competitive with companies located nearer to centers of industry and population.

4.2 Culturally Diverse Communities

Coal towns in Appalachia often exhibited a high degree of cultural diversity. During the first half of the 19th century, immigrants to the minefields typically came from England, Wales, Scotland, Ireland, and Germany. By the end of the century, large numbers were being recruited from southern and eastern Europe, a trend that continued well into the first two decades of the 20th century (Fig. 4). When immigration from Europe plummeted during the war years, the door was opened wide for large numbers of African-Americans to enter the mines. Discouraged by low wages in the mines of northern Alabama or in search of seasonal work when there was a lull in activities on the family farm, this group made up a significant proportion of the workforce in places such as southern West Virginia and eastern Kentucky from approximately 1910 to the 1930s.

Cultural heterogeneity in the company town manifested itself in many and varied ways. It was not uncommon to find safety instructions posted at the mine opening written in several languages. Nor was it uncommon to find a diversity of religions represented in a single company town. Although some have argued that building churches and paying ministers' salaries allowed company officials to exercise even greater control over residents of the company town, others, citing low attendance, have downplayed the importance of religion in these communities.

FIGURE 4 Miners in front of Oakdale or Jumbo Mine No. 311, Ohio, 1887–1907. Reprinted from the Buhla Collection, Ohio University, Archives and Special Collections, with permission.

Although some coal operators looked on their creations with a certain measure of pride, believing them superior to anything one might find in outlying areas, living and working conditions, in fact, varied considerably from one location to the next. The time and money an operator was willing to invest in the development of a town depended on several factors, including the projected life of the mine, the number of houses that needed to be built, and the amount of capital the company had at its disposal. Towns constructed of durable materials and offering a range of amenities were clearly meant to last. Ramshackle housing, on the other hand, was a sure sign that a company's investment in a mine site was limited. According to contemporary theories of corporate paternalism and welfare capitalism, well-built towns equipped with electricity and indoor plumbing, and offering a wide range of amenities, such as churches, recreation buildings, meeting halls, ballparks, and stores, attracted a more dependable and loyal breed of miner—one who, in the end, would reject the temptation to join a union. Because the company maintained ownership of housing, the threat of eviction was never far from the mind of the miner. In the years following the First World War, companies fought off the advances of the unions by equating union membership with communist sympathy or radicalism. Companies employing a high number of foreign-born workers kept their workforce in line by equating loyalty to the company with patriotism and "Americanism." Eager to prove they were good American citizens and avoid persecution, recent immigrants were often reluctant to participate in union activities.

5. WORKING IN A COAL MINE

For the most part, coal miners during the 19th and early 20th centuries worked side by side in a dark, damp, and often dangerous environment, regardless of their cultural or ethnic background (Fig. 5). Given the stressful nature of their work and the dangers they faced, it was absolutely essential that safety and teamwork take precedence over all other matters in the mines. Dust and gas accumulations, roof falls,

FIGURE 5 Miner loading car at Mine No. 26, West Virginia. Reprinted from the Smithsonian Institution, National Museum of American History, with permission.

and heavy equipment malfunctions and accidents were just a few of the hazards miners dealt with on a daily basis. Under such conditions, even the most safety-conscious miner could be caught off guard. If a miner was fortunate enough to avoid a serious lost-time injury over the course of his career, black lung, a condition caused by the inhalation of coal dust, could cut his life short. Aboveground, miners went their separate ways. As Robert Armstead recently detailed in an autobiographical account, segregation and Jim Crow were a fact of life when the shift was over.

The coal mining industry in Appalachia has witnessed a great many changes since the days when miners toiled underground with picks and shovels and hand-loaded coal into wagons for transport to the surface. Although many of these changes have had a positive effect on the lives of miners and their families, e.g., improved safety, wage increases, and retirement benefits, to name just a few, others, such as the introduction of labor-saving equipment, have had the effect of putting miners out of work. Indeed, the effect that mechanization had on miners and mining communities during the middle years of the 20th century was far reaching.

5.1 Social Relations among Miners

Although relations between whites, blacks, and European immigrants were sometimes strained, especially when blacks or immigrants were brought in as strikebreakers, antagonism appears to have been the exception rather than the rule, at least on the job. According to Ronald Eller, "[a] relatively high degree of harmony existed between the races at a personal level. Working side by side in the mines, the men came to depend upon each other for their own safety, and the lack of major differences in housing, pay, and living conditions mitigated caste feelings and gave rise to a common consciousness of class." If integration typified relations in the mines, segregation characterized relations on the surface. When the workday was over, blacks and whites showered in separate facilities (if such facilities were, in fact, available) and then walked or drove home to their own neighborhoods. Foreign-born miners and their families were often subjected to similar, albeit more subtle, forms of discrimination.

Although small numbers of women worked in small "country bank" mines, they were generally discouraged from engaging in such work. In some states, such as Ohio, they were prohibited by law from coal mining work unless they actually owned the mine. Their absence is frequently attributed to the superstitious belief that a woman's presence in the mines was sure to bring bad luck. Starting in the early 1970s, small numbers of women were hired to join the ranks of male coal miners. Hiring peaked in 1978 and then tailed off again during the 1980s. The historical record seems to support geographer Richard Francaviglia's statement on the matter: "mining has traditionally been 'man's work', and no amount of neutralized language can…conceal that fact."

5.2 Mechanization

Coal mining was one of the last major industries in America to mechanize production. From the beginning of the 19th century through the first two decades of the 20th century, the manner in which coal was extracted from underground mines and brought to the surface changed very little. Before the advent of the mechanical loading machine in the 1920s, miners typically broke coal from the mine face using picks and wedges and shoveled it by hand into coal cars. Loaded cars were then pushed to the surface by miners or pulled by horses or other animals. By the end of the 19th century, miners were "undercutting" the seam and using drills and explosives to increase productivity. Considering that a miner's pay was directly linked to the amount of coal he mined and the number of cars he filled, new methods of mining that saved labor and increased productivity were quickly adopted.

As demand for coal increased over time, companies sought to overcome bottlenecks in the production process. When overexpansion and competition began

to cut into profits, and unionization forced the cost of coal production to go up, the drive to mechanize underground mining gained momentum. The logical starting point was to replace the hand-loading system with one that emphasized the use of mechanical loading machines. From the 1930s to the 1970s, the introduction of mechanical loaders, cutting machines, continuous miners, and longwall mining changed forever the way coal would be mined.

Another aspect of mining transformed by mechanization was in the area of haulage. During the pick and hand-loading era, miners shoveled coal into wagons and pushed them to the surface. Drift mines were generally constructed so that they pierced the hillside at a slight upward angle to allow for drainage and to facilitate the transport of loaded cars to the tipple. As mines grew in size and the distance to the tipple increased, companies turned to animal power as the principal means of haulage. When larger coal cars came on the scene, mechanical and electrical haulage, including conveyors, became increasingly necessary.

From the vantage point of the coal operator, mechanization offered several advantages. It allowed for more easily loaded coal, reduced the need for explosives, and lowered timbering costs. Most important, mechanization permitted greater amounts of coal to be mined. Mechanization had its drawbacks, however, at least from the perspective of the miner, for the introduction of laborsaving equipment greatly reduced the need for a large workforce. The introduction of the mechanical coal-loading machine, for instance, reduced the need for coal miners by approximately 30% industrywide between 1930 and 1950. According to Ronald Lewis, black miners bore the brunt of layoffs during this period because they were disproportionately employed as hand loaders. The continuous miner, which combined cutting, drilling, blasting, and loading functions in one machine, had a similar impact. After the introduction of the continuous miner, the number of miners working in West Virginia was cut by more than half between 1950 and 1960. The impact of mechanization also shows up clearly in production and employment figures for Ohio. Between 1950 and 1970, coal production in this state climbed steadily despite a 90% decrease in the number of underground mines and an 83% decline in the size of the labor force. Starting in the 1970s, longwall mining cut even further into employee rolls.

Mechanization presented miners with other problems as well. In mining's early days, miners walked to and from the mine face and relied on natural ventilation to prevent the buildup of mine gas. As mines expanded in size, miners had to walk greater distances to get to work, and problems with ventilation and illumination arose. To facilitate the movement of men, electric trolleys were introduced to the mines. Dust and gas problems were alleviated somewhat by the installation of mechanical fans. Meanwhile, illumination was improved when safety lamps and electric lights were substituted for candles. While solving some problems, these and other solutions contributed to others. In the words of one authority on the matter, now workers could be "crushed, run over, squeezed between cars, or electrocuted on contact with bare trolley wires." In addition, some of the new machinery generated sparks and produced tremendous amounts of ignitable coal dust.

5.3 Health and Safety

Coal mining has always been and continues to be a hazardous occupation. Indeed, fatalities and serious nonfatal injuries occur still. The risks miners face today, however, pale in comparison to the perils miners faced prior to World War II. Accidents resulting from roof falls, ignition of mine gas and coal dust, the handling of mechanical haulage equipment, and the operation of electric-powered equipment of all types contributed to a high accident rate in the United States. Increased demand, fierce competition, advanced technology, negligence on the part of miners, and a poorly trained immigrant workforce have all been blamed for the high accident and fatality rates. Coal operators must share a portion of the blame as well. Opposed to unions and wary of burdensome safety regulations, operators often stood in the way of meaningful safety reform.

Initially, enactment of mine safety legislation rested with the states. In 1870, Pennsylvania passed the first substantive mine safety law. Over the next 25 years, several states passed mine inspection laws of their own. By the mid-20th century, 29 states had mine safety laws on the books. Unfortunately, these laws were often poorly enforced. Although the U.S. Bureau of Mines had been created in 1910, it was primarily an "information-gathering" agency. Authority to inspect underground mines was not conferred until 1941. Enforcement powers were not granted until 1953. Continued high fatality rates eventually sparked an effort to pass comprehensive federal legislation. Proponents of federal legislation had to wait until 1969 before such measures were enacted.

By far, the greatest number of deaths was caused by roof falls. Nevertheless, it was the ignition of methane gas and coal dust that captured the attention of the news media. Wherever miners used candles or open-flame safety lamps for illumination and black powder to break coal from the face, and where the mine was deep, "gassy," and poorly ventilated, conditions were ripe for an explosion. During the 10-year period from 1891 to 1900, 38 major explosions rocked American mines, resulting in 1006 deaths. Some of the worst explosions occurred during the first decade of the 20th century, including the worst one in American history, the dreadful Monongah mine disaster. On December 6, 1907, 362 miners employed by the Fairmont Coal Company of West Virginia were killed when the company's No. 6 and No. 8 mines blew up. Previously, Andrew Roy had noted that "more miners are annually killed by explosions in West Virginia, man for man employed, or ton for ton mined, than in any coal producing State in the Union or any nation in the world." It was clear that much needed to be done to improve mine safety in the United States.

Discovering the cause of mine explosions was of paramount importance to officials at the fledgling U.S. Bureau of Mines. Several causes were identified. First, as mines grew deeper, providing fresh air to miners and dispersing mine gas became more of a challenge. Given that miners typically used candles or open-flame safety lamps to light their way, this was a particularly serious problem. There was also a preference on the part of the miners to use greater amounts of explosives to "shoot off the solid," that is, to blast without first undermining the coal. As with the open flame, explosives were another source of ignition. Finally, there was the widely held belief that coal dust alone could not set off an explosion. Disproving this belief was particularly important (one that Europeans had confirmed by a much earlier date) given the increasing amounts of dust being produced by new mining machinery. The adoption of new technologies eventually reduced the risk of explosion. Improved ventilation, electric cap lamps, rock dusting, safer mining machinery, first-aid and mine rescue training, and passage of legislation permitting federal inspection of mines combined to improve conditions considerably. Although the frequency of mine explosions diminished considerably after the 1930s, the Farmington, West Virginia disaster of 1968, in which 78 miners were killed, served as a reminder that mine explosions were still a potential threat. With respect to roof falls, more effective supervision, systematic timbering, and roof bolting would, in time, reduce the frequency of these accidents.

5.4 Coal Mine Unionism

No history of coal mining in Appalachia would be complete without mentioning organized labor. Given the conditions that coal miners often had to work under, it is not surprising that they were among the first workers in the United States to organize. Given the power and control coal companies wielded throughout the better part of the 19th and early 20th centuries, it is also not surprising that coal operators fought the unions at every turn. Proponents of corporate paternalism and welfare capitalism believed that company benevolence could effectively stave off the unions, but others believed that coercion and intimidation would more effectively produce the desired results.

Although coal mine unionism in Appalachia can be traced to the early 1840s, the modern era of unionism began in 1890 when two groups, the National Progressive Union of Miners and Mine Laborers and the National Assembly Number 135 of Miners of the Knights of Labor, joined forces in Columbus, Ohio to form the United Mine Workers of America (UMWA). After winning recognition from Central Competitive Field Operators in 1897, the UMWA set out to stake a middle ground between ineffectual "company" unions and more radical unions, such as the National Miners Union. Under the able leadership of John Mitchell, the UMWA won strikes and concessions from the coal operators and built membership. Withdrawing from what they saw as a temporary truce with union organizers during the war years, coal operators sought to roll back the gains the UMWA had made during the first two decades of the 20th century. Citing a 1917 U.S. Supreme Court decision in which yellow-dog contracts forbidding union membership were ruled legal, coal operators set out to reclaim lost ground. An attempt by new union leader, John L. Lewis, to organize the southern coalfields during the middle of the decade was crushed. With demand for coal down and nonunion mines undercutting the cost of production in union mines, UMWA membership plummeted during the 1920s.

The 1930s, and more specifically President Franklin D. Roosevelt's New Deal legislation, breathed new life into the beleaguered union. Passage of the National Industrial Recovery Act (1933), the Bituminous Coal Code, or "Appalachian Agreement" (1933), the National Labor Relations, or "Wagner,"

Act (1935), and the first and second Bituminous Coal Conservation, or "Guffey," acts (1936 and 1937) shifted the advantage to the unions once again. Particularly important was the fact that the union had finally won the right to be recognized as a collective bargaining agent. Among the union's "victories" at this time was approval of an 8-hour workday, a 40-hour workweek, and higher wages. A minimum work age of 17 was also set, ending, in theory at least, the industry's long-standing practice of utilizing child labor. In addition, miners were no longer forced to use company scrip, to shop only at the company store, or to rent a company house, all mechanisms by which some companies attempted to keep up with the rising cost of production.

The gains of the 1930s and 1940s were replaced by the uncertainties of the 1950s and 1960s. The terms of the Love–Lewis agreement, signed in 1950 by Bituminous Coal Operators Association president George Love and UMWA president Lewis, reflect the ever-changing fortunes of the miners and their union. Although the agreement provided a high wage and improved health benefits for miners, it prevented the union from opposing any form of mechanization. The adoption of new technologies, including augering and stripping, resulted in layoffs and a decline in membership. Although certain gains were made, e.g., portal-to-portal pay, improved insurance and pension benefits, and passage of black lung legislation, the 1970s and 1980s saw many workers return to nonunion status.

Sometimes, relations between management and labor took a violent turn. Students of Appalachia know well the price that was paid in human life in places such as Matewan, West Virginia, "bloody" Harlan County, and at Blair Mountain, where 3000 UMWA marchers clashed on the battlefield with an army of West Virginia State Police, company mine guards, and assorted others representing the interests of the coal operators. In more recent times, violence has flared up in places such as Brookside, Kentucky. In 1969, charges of fraud and the murder of a UMWA presidential candidate tarnished the reputation of the union.

Although unions, the UMWA in particular, can take justifiable pride in improving the lot of miners, some scholars have argued that the higher labor costs associated with these victories ended up increasing the cost of coal production and accelerating the move toward mechanization. Thus, an impressive and hard-earned package of benefits was eventually passed down to an increasingly smaller pool of beneficiaries.

Glossary

ash A measure of coal purity that consists of the noncombustible residue that remains after coal is completely burned.
coking coal A coal product having properties that make is suitable for consumption by the metallurgical market for the manufacture of steel.
cut point The density corresponding to a particle that has an equal probability of reporting to either the clean coal or reject product of a density-based separator.
cut size The particle size that has an equal probability of reporting to either the oversize or undersize product of a sizing device such as a screen or hydraulic classifier.
heavy media An aqueous suspension of micron-sized particles (usually magnetite) that is used to create an artificial, high-density fluid that is passed through various coal washing processes to separate coal from rock based on differences in density.
middling A composite particle containing both organic and inorganic matter.
open area The percentage of the total cross-sectional area of a screening surface that is open for particles to pass. A larger open area improves screen capacity and efficiency.
organic efficiency An indicator of separator performance (usually expressed as a percentage) that is calculated by dividing the actual clean coal yield by the theoretical maximum yield that could be achieved at the same ash content according to washability analysis.
steam coal A coal product having properties that make it suitable for consumption by the power industry for the production of electricity.
throw The maximum displacement created by the rotary vibrator of a screening mechanism.
washability analysis A laboratory procedure used to assess the potential cleanability of coal that uses dense liquids (usually organic) to partition a particulate sample into various density fractions (also called float-sink tests).
washing A generic term used to describe the process by which mined material is treated by various particulate separation processes to remove unwanted impurities from the valuable organic matter (also called *cleaning*).
yield An indicator of separation performance (usually reported as a percentage) that is calculated by dividing the clean coal tonnage by the feed coal tonnage.

Coal preparation is the process in which mined coal is upgraded to satisfy size and purity specifications that are dictated by a given market. The upgrading, which occurs after mining and before shipping to market, is achieved using low-cost unit operations that include screening, cleaning, and dewatering. The process is typically required for economic reasons that are driven by a desire to improve utilization properties, reduce transportation costs, or minimize environmental impacts.

1. INTRODUCTION

1.1 Why Process Coal?

Mined coal is a heterogeneous mixture of both organic (carbonaceous) and inorganic (mineral) matter. The inorganic matter is comprised of a wide range of mineral components including shale, slate, and clay. During combustion, these impurities reduce the heating value of the coal and leave behind an ash residue as waste. The impurities also influence the suitability of the coal for high-end uses such as the

 © 2004 Elsevier Inc. All rights reserved.

manufacture of metallurgical coke or generation of petrochemicals. Some of the mineral impurities, such as pyrite, form gaseous pollutants when burned that are potentially harmful to the environment. The impurities may represent a significant portion of the mined coal weight and, as a result, need to be removed to minimize the cost of transporting the coal to the customer. For these reasons, a tremendous incentive exists for the removal of inorganic impurities prior to the downstream utilization of the coal. Coal purchasing agreements commonly include limitations on ash (mineral matter), sulfur, and moisture.

1.2 Brief History

Little attention was given to coal preparation in the early industrial years. Hand sorting of rock and sizing by screening were the major methods of preparing mined coals for market. Most of the fine (<0.5 mm) coal was either discarded or sold for very low prices. More recently, increased emphasis has been placed on coal preparation because of the depletion of higher quality reserves and increased levels of out-of-seam dilution resulting from mechanized mining. Consumers in the steam (utility) and metallurgical (coking) coal markets have also placed new demands on coal producers to provide consistent high-quality products. The combined influence of these factors has made coal preparation far more important than it was in the past. There are estimated to be more than 2000 plants operating worldwide with capacities ranging from as little as 100 ton per hour to more than several thousand ton per hour. In terms of annual production, coal preparation facilities produced just over 1.3 billion tons of the 3.5 billion tons of coal sold by the top 10 coal-producing countries in 1998. The United States produced more than one-third of this tonnage (35%), followed by China (20%), South Africa (14%), and Australia (13%). The average plant capacity in North America is approximately 750 ton per hour.

1.3 Typical Systems

Despite the perception of coal preparation as a simple operation, it has become far more complicated than most people realize. Modern coal preparation plants can be as complex and sophisticated as processing facilities used in the chemical industries. However, for simplicity, plant flowsheets can be generically represented by a series of sequential unit operations for sizing, cleaning, and dewatering (Fig. 1). This sequence of operations, which is commonly called a circuit, will be repeated several times since the processes employed in modern plants each have a limited range of applicability in terms of particle size. Modern plants may include as many as four separate processing circuits for treating the coarse (plus 50 mm), intermediate (50×1 mm), fine (1×0.15 mm), and ultrafine (minus 0.15 mm) material. Although some commonalities exist, the selection of what number of circuits to use, which types of unit operations to employ, and how they should be configured are highly subjective and largely dependent on the inherent characteristics of the coal feedstock.

2. COAL SIZING

2.1 Background

Run-of-mine coal produced by mechanized mining operations contains particles as small as fine powder and as large as several hundred millimeters. Particles too large to pass into the plant are crushed to an appropriate upper size or rejected where insufficient recoverable coal is present in the coarse size fractions. Rotary breakers, jaw crushers, roll crushers, or sizers are used to achieve particle size reduction. Crushing may also improve the cleanability of the coal by liberating impurities locked within composite particles (called middlings) containing both organic and inorganic matter. The crushed material is then segregated into groups having well-defined maximum and minimum sizes. The sizing is achieved using various types of equipment including screens, sieves, and classifying cyclones. Screens are typically employed for sizing coarser particles, while various combinations of fine coal sieves and classifying cyclones are used for sizing finer particles. Figure 2 shows the typical sizes of particles that can be produced by common types of industrial sizing equipment.

2.2 Screening Principles

Screens are mechanical sizing devices that use a mesh or perforated plate to sort particles into an undersize product (particles that pass through the openings in the screen) and an oversize product (particles that are retained on the screen surface). In coal preparation, screens are used for a wide range of purposes including the extraction of large rock and trash prior to treatment and the production of optimum size

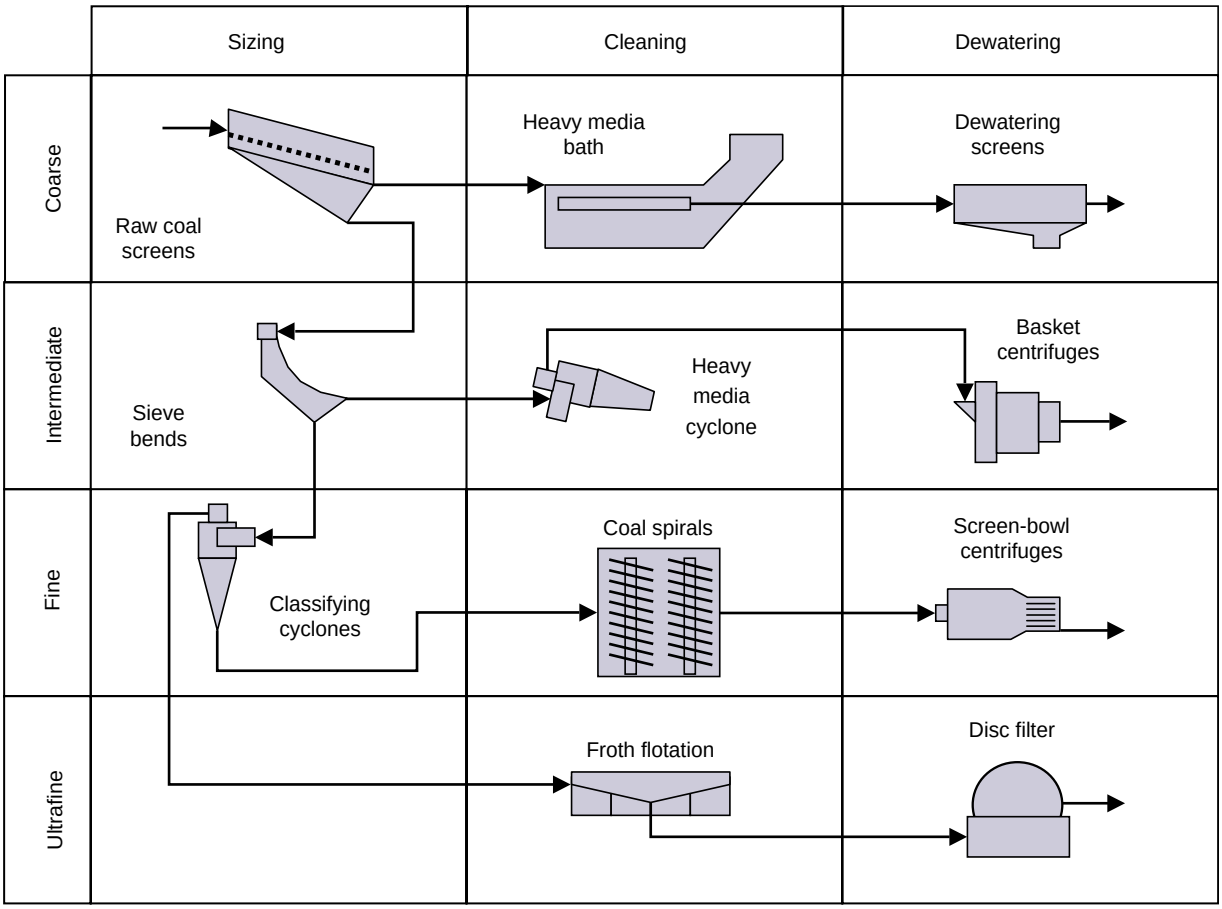

FIGURE 1 Conceptual preparation plant flowsheet subdivided according to unit operation and particle size.

fractions for separation devices. In addition, screens are commonly employed for the recovery of heavy media suspensions and the separation of water from solid particles. The efficiency of the screening operation is influenced by the material properties of the feed and the operating and design characteristics of the machine, particularly its size.

2.3 Types of Screens

Several types of screens are commonly used in coal preparation. These include the grizzly, vibrating screens and high-frequency screens. A grizzly is a series of evenly spaced parallel bars that are positioned in the direction of material flow. This simple device is used only for gross sizing of very coarse particles (>50 mm) and is generally applied only for the protection of equipment from large oversized material.

Vibrating screens are the most common equipment for sizing particles and are used in almost every aspect of coal preparation. These units utilize an out-of-balance rotating mechanism to create a vibrating motion to sort particles and to move material along the screen surface (called a deck). The three common versions of vibrating screens are the incline screen, horizontal screen, and banana screen. The operating characteristics of these units are compared in Table I. An incline screen uses a combination of gravity flow and machine movement to convey material along the screen by mounting the screen deck 15 to 20 degrees from horizontal. Incline screens are available in single-, double-, and triple-deck arrangements with dimensions up to 3 m (10 ft) wide and 7.3 m (24 ft) long. For a horizontal screen, material is conveyed without the aid of gravity, thus a higher speed and throw are required. These units may be as large as 3 m (10 ft) wide and 7.3 m (24 ft) long and are available in single-, double-, and triple-deck arrangements. Finally, banana screens are designed so that the slope of the screen surface changes along the length of the unit (Fig. 3). The slope at the feed end will typically be 30

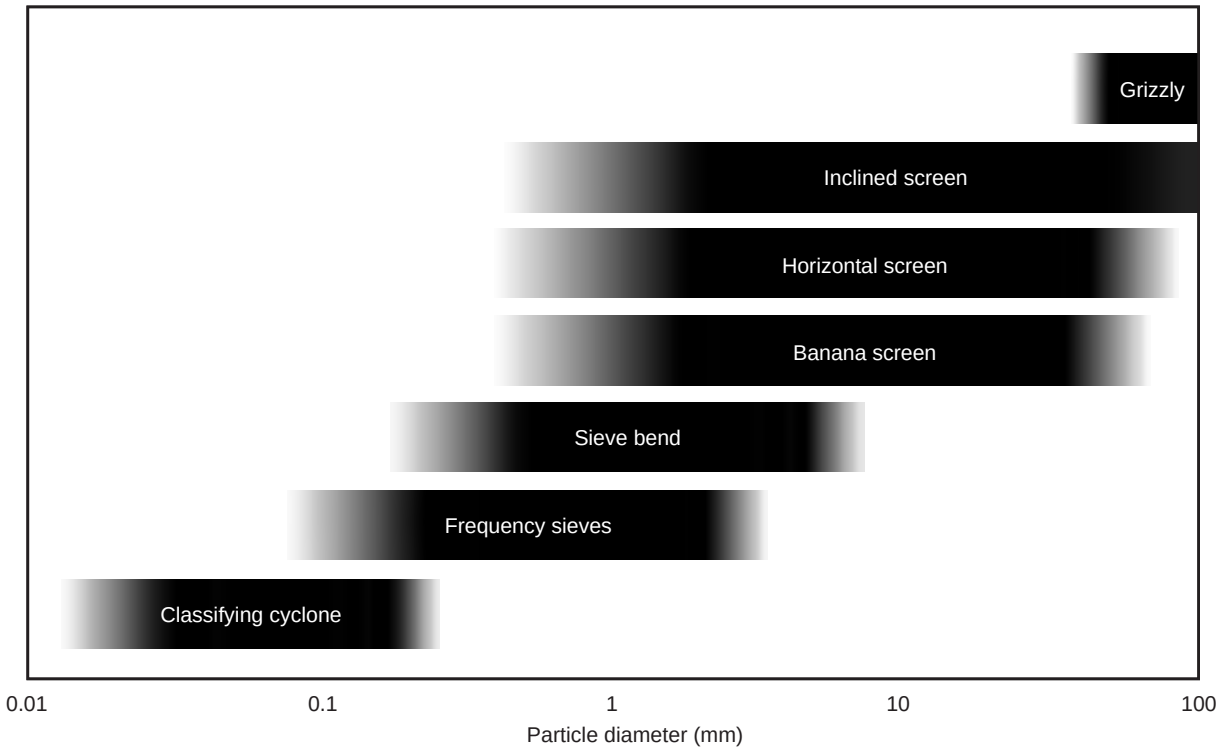

FIGURE 2 Typical ranges of applicability for various sizing equipment.

TABLE I

Typical Operating Characteristics of Vibrating Screens

	Incline	Horizontal	Banana	High frequency
Application	Raw coal sizing scalping	Raw coal sizing prewet drain and rinse dewatering	Raw coal sizing deslime drain and rinse dewatering	Dewatering fines recovery
Incline (degrees)	15–25	Horizontal	Variable	Opposing
Motion	Circular	Linear	Linear	Linear
Speed (rpm)	750–800	930	930	1200
Throw	9.6–11.2 mm (0.38–0.44 inch)	11.2 mm (0.44 inch)	11.2 mm (0.44 inch)	6.4 mm (0.25 inch)
Travel rate	0.5–0.6 m/s (100–120 fpm)	0.2–0.23 m/s (40–45 fpm)	0.9–1.0 m/s (180–200 fpm)	0.13–0.18 m/s (25–35 fpm)

to 35 degrees, while the slope at the discharge end can be 0 to 15 degrees. The steep initial slope enhances the ability of fines to pass since the higher rate of travel reduces the depth of the particle bed. The shallower slope at the discharge end of the screen increases screening efficiency by slowing the travel rate and providing more opportunities for near-size particles to pass. Commercial units are available with dimensions exceeding 3.7 m (12 ft) wide and 7.3 m (24 ft) long in single- and double-deck arrangements. Banana screens are becoming increasingly popular since they offer increased capacity and lower capital and operating costs compared to conventional horizontal and inclined screens.

High-frequency screens are normally used for dewatering fine coal or refuse (Fig. 4). These screens are designed to retain feed slurry between two opposing inclines. The screen motion transports dewatered cake up a gradual slope to the discharge end of the screen. The screen vibrator, which may be an unbalanced rotor or linear exciter, operates at a higher speed and with a shorter thrown than vibrating

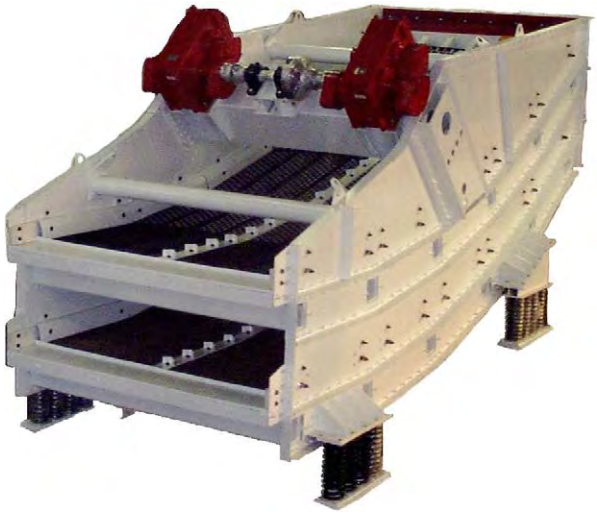

FIGURE 3 Production-scale banana (multislope) screen. Courtesy of Innovative Screen Technologies.

FIGURE 4 Production-scale high frequency screen. Courtesy of Innovative Screen Technologies.

screens. The operating characteristics are beneficial for the efficient dewatering of fine solids. Commercial units are now available in single-deck configurations that exceed 2.4 m (8 ft) wide and 3.7 m (12 ft) long.

2.4 Screen Surfaces

A wide variety of screen surfaces are commercially available for coal sizing. The most common types of media include punch plate, woven wire, rubber, urethane, and profile wire (Fig. 5). The selection of the most appropriate media is dictated by type of

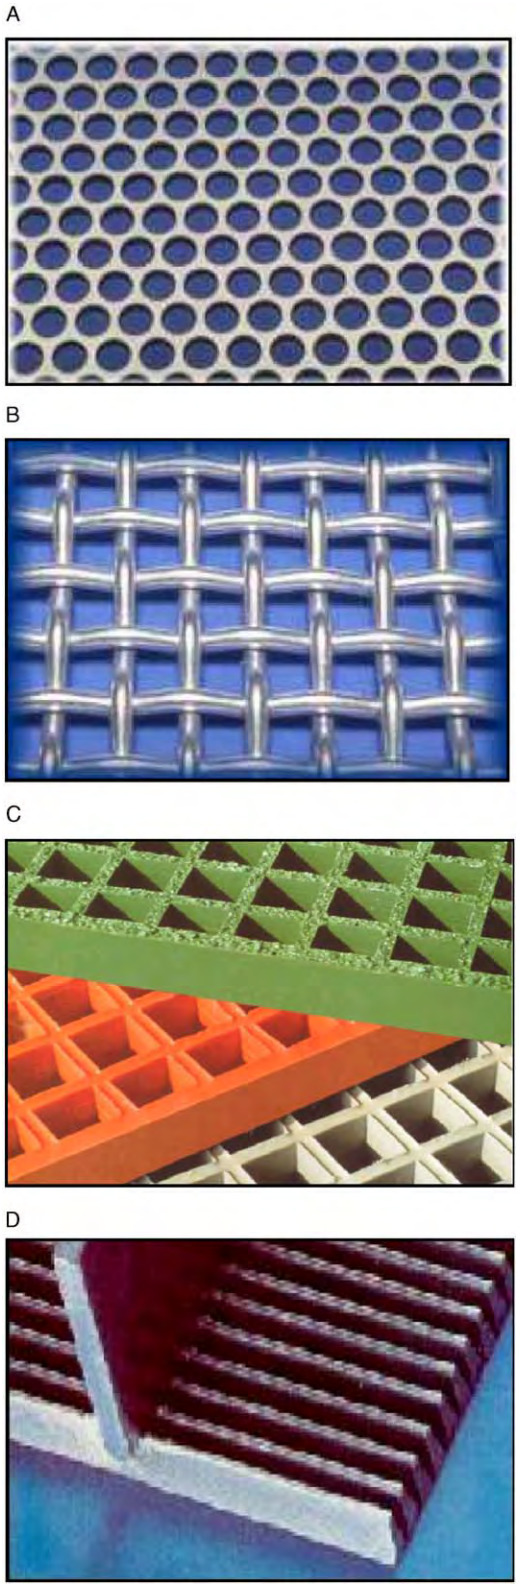

FIGURE 5 Common types of screening media. (A) punch plate, (B) woven wire, (C) polyurethane, and (D) profile wire.

application and considerations associated with wear and maintenance. Punch plate typically consists of steel sheets that are perforated with square, round, or rectangular holes. This type of media is used for primary sizing. Woven wire media consists of fine wires that are woven together to form a mesh pattern with the desired hole size. Also, the woven mesh must be strong and wear resistant (which requires larger wires) and still possess sufficient open area for the efficient passage of particles (which requires smaller wires). The final selection is usually based on an economic tradeoff between replacement frequency and sizing efficiency. Both rubber and urethane media can be manufactured in modular panels that can be easily installed and replaced. These materials offer a longer wear life and are less likely to become plugged than other types of screening media. Urethane panels can be manufactured with openings ranging from 0.15 to 100 mm. The major concern with this type of media is the loss of open area that normally occurs when they are used to replace woven wire media. In cases where fine (3×0.5 mm) sizing is performed, profile wire may be used to reduce problems with plugging and to increase the open area of the screen. The wires in this type of media are constructed with tapered cross sections (usually an inverted triangle or trapezoid) that allow particles to freely pass once they have cleared the top surface of the screen media. This type of screening media improves open area and screen capacity but typically has a shorter wear life.

2.5 Fine Coal Sieves

Sizing of fine coal is difficult due to the increased likelihood of plugging and the large number of particles that must pass through the screen surface. Fine sizing is typically performed either utilizing banana screens or sieve bends in conjunction with a horizontal screens. A sieve bend (Fig. 6) consists of a curved panel constructed from inverted trapezoidal bars (profile or wedge wire) placed at right angles to fluid flow. The capacity of the sieve is relatively high since the leading edge of the trapezoidal bars "slice" material from the flowing stream. Although the screen has no moving parts, passage of solids is also greatly enhanced by the centrifugal force created by the fluid flow along the curved sieve surface. Because of the unique geometry, the size retained by the sieve is approximately three-fourths the bar spacing (e.g., 0.5 mm spacing retains 0.38 mm particles). Sieve bends are commonly used for fine particle dewatering and are often used ahead of vibrating screens. A variation on the sieve bend theme incorporates the use of high-frequency vibration.

FIGURE 6 Production-scale sieve bend for fine coal sizing. Courtesy of Conn-Weld Industries.

2.6 Classification

Classification is used in coal preparation for fine sizing where conventional screening becomes impractical or too expensive. Classification is usually applied to dilute suspensions of <1 mm diameter particles. This technique is generally less efficient than screening or sieving since the separation can be influenced by particle shape and density, as well as particle size. The most common type of classification device used in the coal industry is the classifying cyclone (Fig. 7). In this device, dilute slurry is pumped under pressure to multiple parallel units (banks) of cyclones. The rotating flow field within the cyclone creates a centrifugal force that increases the settling rate of the particles. Larger particles are forced to the wall of the cyclone where they are carried to the discharge port (apex) at the bottom of the cyclone. Finer particles exit out the top of the cyclone (vortex finder). Classifying cyclones are commonly applied to size (cut) at 0.10 to 0.15 mm and represent the only practical option for sizing ultrafine particles (at a cut of 0.045 mm). Smaller

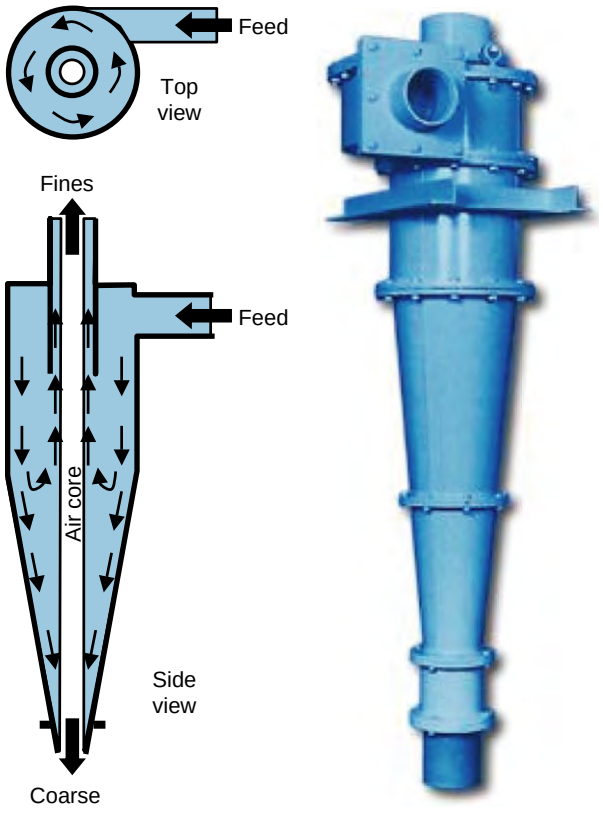

FIGURE 7 Illustration of a classifying cyclone. Courtesy of Krebs Engineers.

cyclones are typically used to size finer particles since these units provide a higher centrifugal force. Classifying cyclones have become very popular in the coal industry since they offer a high unit capacity, operational flexibility, and low maintenance requirements.

3. COAL CLEANING

3.1 Background

One of the primary goals of coal preparation is to separate the valuable carbonaceous material (organic matter) from contaminants in the surrounding host rock (mineral matter). The separation is typically accomplished using low-cost processes that exploit differences in the physical properties that vary according to mineralogical composition. Some of the common properties that are used to separate coal and rock include size, density, and surface wettability. The effectiveness of the separation depends largely on the characteristic properties of the feed material and the operational efficiency of the separator. The effectiveness of most separators is limited to a relatively narrow range of particles sizes (Fig. 8) due to limitations associated with processing efficiency and equipment geometry. Several different types of cleaning processes are incorporated into the plant flowsheet to treat the wide range of particle sizes present in the run-of-mine coal. Density separators, such as heavy media baths and cyclones, are commonly used to treat coarse and intermediate sized particles. Froth flotation, which separates particles based on differences in surface wettability, is the only practical method for treating very fine coal (<0.15 mm). Particles in the intermediate size range between 0.15 mm and 2 to 3 mm may be treated by a variety of processes including water-only cyclones, spirals, teeter bed separators, or combinations of these units. Each of these units is described in greater detail in the following sections.

3.2 Coal Washability

Most of the physical separation processes used in coal preparation take advantage of the differences in the density of coal and rock. Coal preparation terminology commonly interchanges density and specific gravity (a dimensionless parameter defined as the density of a substance divided by the density of water). The specific gravity (SG) for pure coal is approximately 1.3, while the SG for common coal contaminants such as shale and sandstone are in the 2.3 to 2.7 SG range. The density of pyrite ($SG = 4.8$) is significantly higher. Unfortunately, mined coal does not consist of pure coal and pure rock. Instead, middlings material consisting of composite particles of varying composition are also present to a greater or lesser extent. A typical distribution of the composite material is shown in Table II. There is an approximate linear relationship between the density of the composite particle and its ash (mineral matter) content. The SG at which preparation plants operate is adjusted to provide operating levels which satisfy customer quality constraints.

3.3 Coarse Coal Cleaning (Plus 12.5 mm)

One of the oldest forms of coarse coal cleaning is jigging. Jigging is the process of particle stratification due to alternate expansion and compaction of a bed of particles by a vertical pulsating fluid flow. A single jigging vessel can treat large particles (up to 200 mm) at capacities approaching 680 tonnes (750 tons) per hour. Common versions include the baum and batac designs. The baum jig, which is most common, uses a

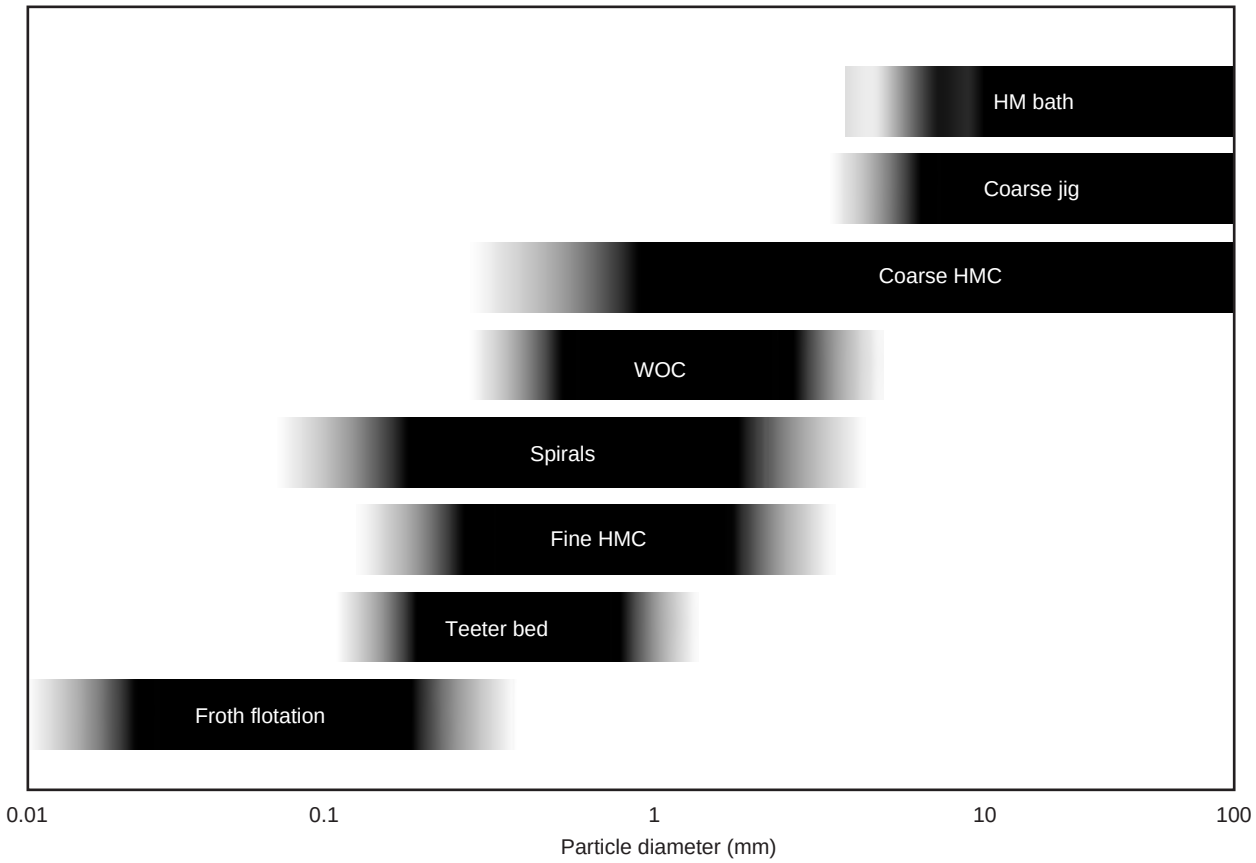

FIGURE 8 Typical ranges of applicability for various cleaning equipment.

U-shaped vessel that is open on one size and closed on the other (Fig. 9). Water is pulsed through the particle bed atop the perforated plate by sequentially injecting and releasing air in and out of the enclosed chamber. A batac jig is a variation of this design that uses an air chamber below the perforated plant to trap air and create the pulsing action. Jig installations require specific conditions in order to be effective and are significantly less efficient than competitive heavy media processes. As a result, the use of jigs for coal cleaning has declined rapidly. However, jigs can treat a wider size range than single heavy media processes and provide an obvious advantage in applications where capital is limited.

The most common process for upgrading coarse coal (>12.5 mm) is the heavy media bath. A common type of heavy media bath is the Daniels vessel (Fig. 10). This unit consists of a large open vessel through which an aqueous suspension of finely pulverized magnetite (SG = 5.2) is circulated. The magnetite creates a suspension with an artificial density that is between that of pure coal and pure rock. Lighter coal particles introduced into media float to the surface of the vessel where they are transported by the overflowing media to a collection screen. Waste rock, which is much denser, sinks to the bottom of the vessel where it is collected by a series of mechanical scrapers (called flights). The flights travel across the bottom of the vessel and eventually drag the waste rock over a discharge lip at one end of the separator. The unit is highly flexible, since the quality of the clean coal product can be readily adjusted by varying the density of the media from 1.3 to 1.7 SG by controlling the amount of magnetite introduced into the suspension. Sharp separations are possible even in the presence of large amounts of middlings, since SG can be controlled very precisely (as close as 0.005 SG units in some cases) using online instrumentation. A wide variety of different designs of heavy media baths exist, with the major differences being the mechanisms used to discharge the clean coal and waste rock products. Common examples include heavy media cones, drums, and several variations of deep and shallow baths. Drums, usually Wemco or Teska, are widely

TABLE II

Example of Coal Washability Data

Specific gravity		Individual		Cumulative float		Cumulative sink	
Sink	Float	Weight (%)	Ash (%)	Weight (%)	Ash (%)	Weight (%)	Ash (%)
	1.30	47.80	4.20	47.80	4.20	100.00	28.38
1.30	1.40	15.60	14.50	63.40	6.73	52.20	50.52
1.40	1.50	6.60	22.80	70.00	8.25	36.60	65.88

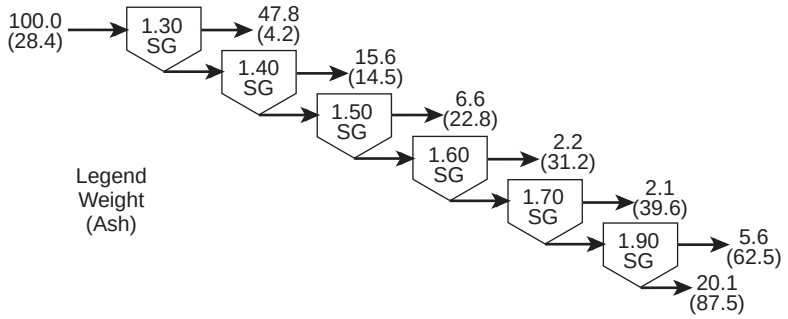
		100.00	28.38				



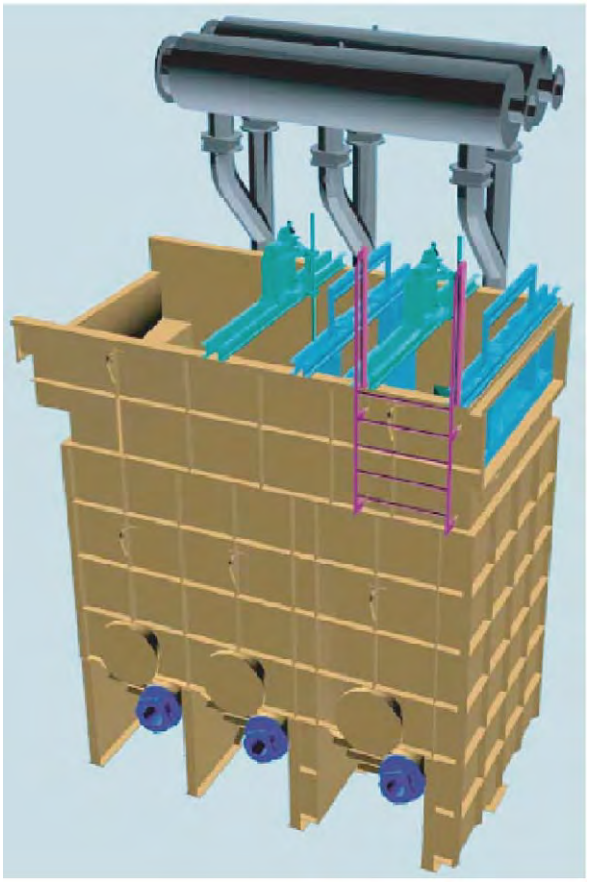
used in South Africa and to a certain extent in Australia. This is where coals are difficult to wash and very high efficiency levels are required.

The primary disadvantage of a heavy media process is the ancillary equipment that must be installed to support the operation of the separator (Fig. 11). A typical circuit requires that the clean coal and refuse products pass over drain-and-rinse screens to wash the media from the surfaces of the products and to dewater the particles. The media that is recovered from the drain section is circulated back to the separator by means of a pump, while media from the rinse section is diluted by spray water and must be concentrated before being fed back to the separator. Fortunately, magnetite is magnetic and can be readily recovered from a dilute suspension using magnetic separators. A rotating drum magnetic separator is commonly used for this purpose (Fig. 12). These devices are highly efficient and generally recover $>99.9\%$ of the magnetite to the magnetic product. For cost reasons, losses of magnetite must be kept as low as possible. Typical losses fall in the range of about 0.45 kg of magnetite loss per tonne (1 lb per ton) of feed coal treated. A portion of the circulating media from the drain section may also be diverted (bled) to the magnetic separator so that the buildup of contaminants such as ultrafine clay can be prevented. Such a build increases the viscosity of the circulating media and adversely impacts the separation efficiency.

Heavy media processes make use of a variety of instrumentation to monitor and control the performance of the separator. In most cases, this consists of a gamma (nuclear) density gauge or other device that continuously monitors the specific gravity of the circulating media. Automated controls are used to add water or magnetite so as to maintain a constant density in the circulating media.

3.4 Intermediate Coal Cleaning (12.5×1 mm)

Heavy media cyclones, which were originally developed by the Dutch State Mines, are the most effective method for treating coal particles in the size range between 1.0 and 12.5 mm. These high-capacity devices (Fig. 13) make use of the same basic principle as heavy media baths—that is, an artificial media is used to separate low-density coal from high-density rock. In this case, however, the rate of separation is greatly increased by the gravitational effect created by passing media and coal through



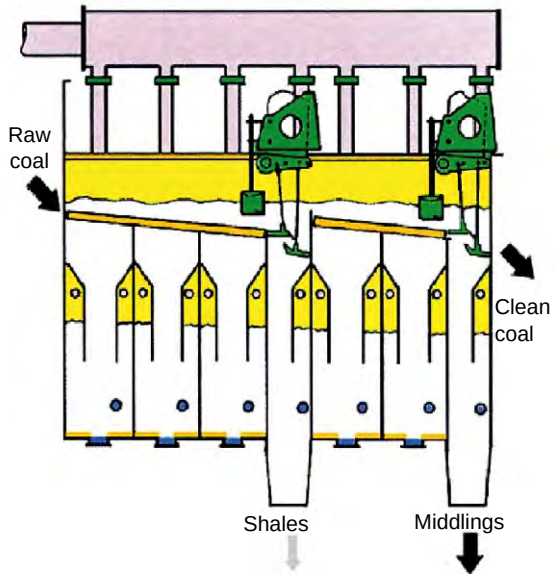


FIGURE 9 Illustration of a baum jig. Courtesy of Bateman.

one or more cyclones. Heavier particles of rock sink in the rotating media and are pushed toward the wall of the cyclone where they are eventually

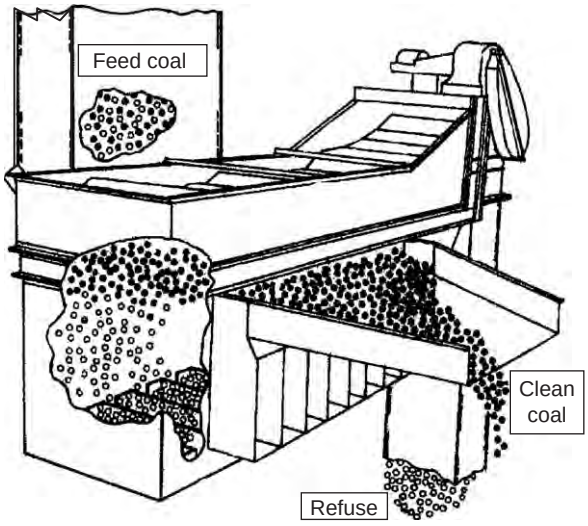

FIGURE 10 Illustration of a heavy media bath. Courtesy of Peters Equipment.

rejected out the bottom. Lighter particles of coal rise to the surface of the rotating media and are carried with the bulk of the media flow out the top of the cyclone. Major advantages of heavy media cyclones include a high separation efficiency, high unit capacity, and ease of control. As with baths, heavy media cyclones have the disadvantage of higher costs associated with the ancillary operations required to support the separator. Several different configurations are used to feed heavy media cyclones. These include gravity flow, pump fed, and wing tanks. Of these, the pump fed configuration (Fig. 14) offers the greatest operational flexibility. The circuit is similar in function to that employed by a heavy media bath.

Advances in cyclone technology and improved wear-resistant materials (ceramic linings) have allowed the upper particle size limit to increase in many applications to 60 to 75 mm. Massive

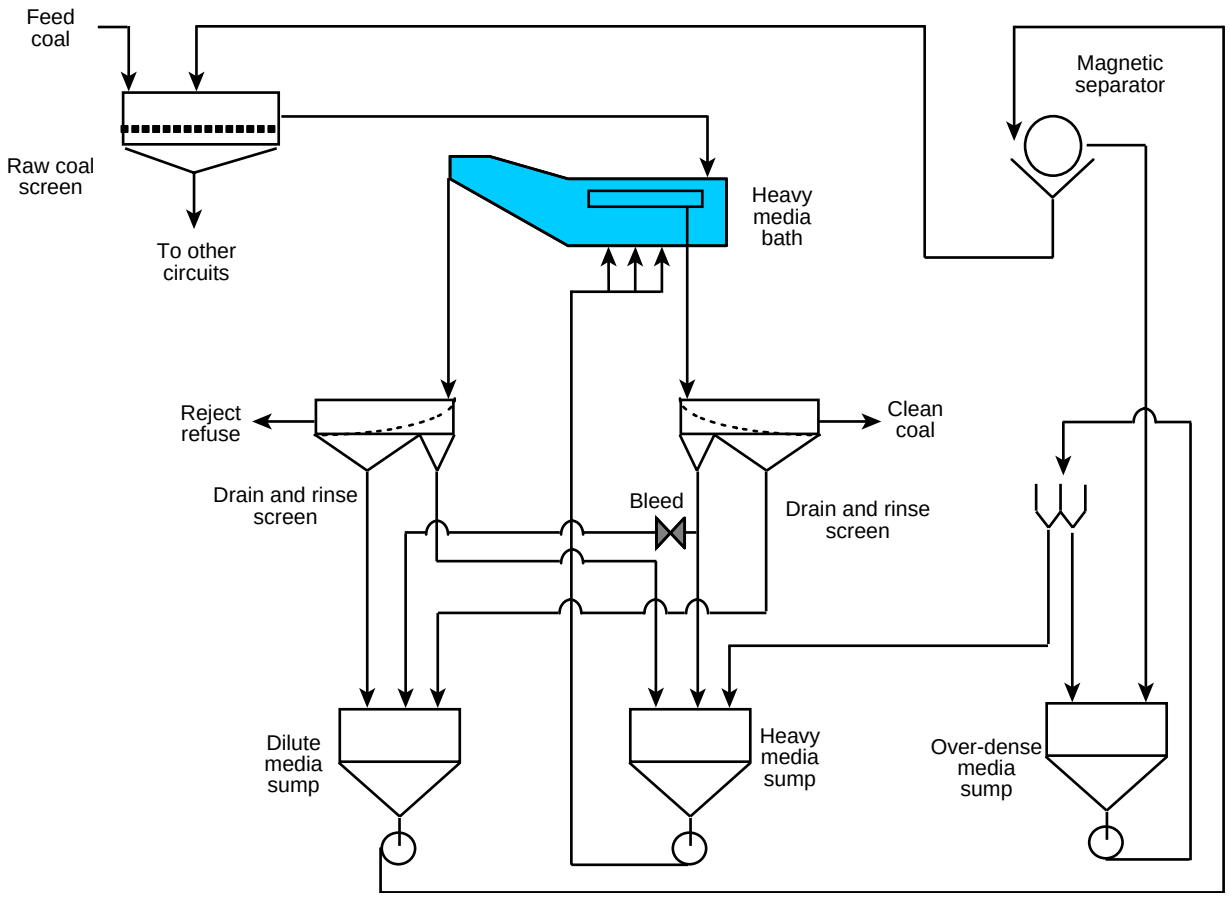

FIGURE 11 Simplified schematic of a heavy media bath circuit.

increases in throughput capacity have also been realized through the use of larger cyclones having diameters of 1.2 m and more. A single unit of this size is capable of treating more than 360 to 410 tonnes per hour (400 to 450 tons per hour) of feed coal. Unfortunately, increased diameter is accompanied with poorer efficiency, particularly in the finer size fractions. The ability to increase both throughput and the upper particle size for cyclones makes it possible to eliminate the heavy media bath in many new plants. This capability is particularly useful for those plant treating very friable coals containing minimal quantities of larger (>50 mm) particles. The simplified circuitry also has significant benefits in terms of capital cost and ease of maintenance. For high reject or hard coals, significant advantages are still present for the bath/cyclone circuit. This results from the reduced necessity for crushing, reduced wear in the plant, and improved total product moisture content. If low density separations are required (<1.4 SG), then the two circuit plant incorporating both baths and cyclones may be necessary since low density separations are easy in baths but difficult in cyclones.

Another option for cleaning coarse coal is a large coal dense media separator, known as a larcodem. This unit was originally developed to handle coal feeds in the size range between 0.6 and 100 mm. The device has the major advantage of being able to treat in one process what was traditionally processed in two separate heavy media devices (heavy medium bath and heavy medium cyclone). Larcodems can also clean far more efficiently what was previously fed to jigging operations. Capital and operating costs for circuits incorporating Larcodems are considerably less that would be the case for traditional heavy medium designs. Despite these advantages, Larcodems have not been widely used in the United States due to lower fine coal cleaning efficiency and the ability of the new generation of cyclones to handle similar top-size material.

FIGURE 12 Illustration of a drum-type magnetic separator. Courtesy of Eriez Manufacturing.

3.5 Fine Coal Cleaning (1 × 0.15 mm)

A wide variety of options are available for upgrading fine coal in the size range between 0.15 and 1 mm. Common methods include water-only cyclones, spirals, and teeter-bed separators. A water-only cyclone (WOC) is a water-based process that employs no extraneous media to separate rock from coal. Water-only cyclones were introduced in the early 1950s for the treatment of fine coal (< 5 mm). Water-only cyclones are similar to classifying cyclones, but typically have a somewhat stubby wide-angled conical bottom and are usually equipped with a long axially mounted vortex finder. Separations occur due to differences in the settling rates of coal and rock in the centrifugal field within the cyclone body. The separation is also enhanced by the formation of autogenous media created by the natural fines already present in the feed slurry. These units are often employed in two stages or in combination with other water-based separators to improve performance. Water-only cyclones do offer some advantages for selected applications including high throughput capacity, operational simplicity, and low operating and maintenance costs.

A separator that has grown tremendously in popularity is the coal spiral (Fig. 15). A spiral separator consists of a corkscrew shaped conduit (normally four turns) with a modified semicircular cross section. The most common units are constructed from polyurethane-coated fiberglass.

FIGURE 13 Illustration of a heavy media cyclone bank. Courtesy of Krebs Engineers.

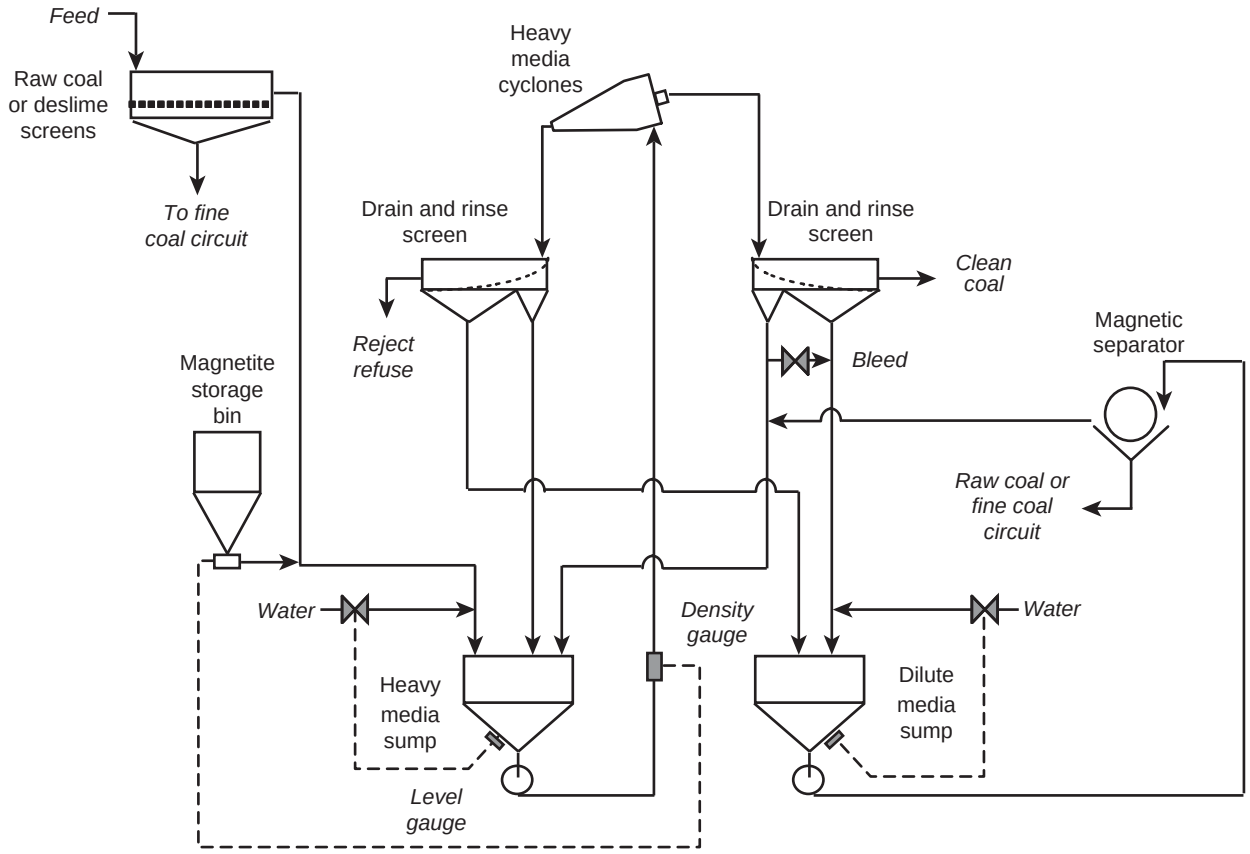

FIGURE 14 Simplified schematic of a pump fed heavy media cyclone circuit.

During operation, feed slurry is introduced to the top of the spiral and is permitted to flow by gravity along the helical path to the bottom of the spiral. Particles in the flowing film are stratified due to the combined effects of differential settling rates, centrifugal forces, and particle-particle contacts. These complex mechanisms force lighter coal particles to the outer wall of the spiral, whereas heavier particles are forced inward to the center of the spiral. The segregated bands of heavy to light materials are collected at the bottom of the spiral. Adjustable diverters (called splitters) are used to control the proportions of particles that report to the various products. A three-product split is usually produced, giving rise to three primary products containing clean coal product, middlings, and refuse. Because of the low unit capacity 1.8 to 3.6 tonnes per hour (2 to 4 tons per hour), spirals are usually arranged in groups fed by an overhead radial distributor. To save space, several spirals (two or three) may be intertwined along a single central axis. In practice, the middlings product should be retreated using a secondary set of spirals to maximize efficiency. The secondary circuit, which is often 10 to 20% of the size of the primary circuit, enables any misplaced material from the primary circuit to be captured. Circuits have been designed to use spirals in treating wider size ranges (e.g., 0.1×3.0 mm), but performance has been poor and efficient spiral cleaning at present would appear to be limited to the 0.15×1.5 mm size range. The main advantages of the spiral circuits are comparatively low capital and operating costs coupled with ease of operation. A major drawback of spiral circuitry is the inability to make a low gravity separation since spirals normally cut in the 1.7 to 2.0 SG range. A consistent volumetric feed rate and minimum oversize (>2 mm) and undersize (<0.1 mm) in spiral feed are also essential requisites to good operation. Spirals have been successfully utilized in combination with water-only cyclones to improve the efficiency of separating fine coal. Latest spiral technologies incorporate primary and secondary cleaning in a single unit. Clean coal and middlings being produced in the upper section are reprocessed in an extended spiral totaling seven turns.

Heavy media cycloning of fine coal is practiced, but usually only where a low SG of separation is required. High efficiencies and low impurity levels

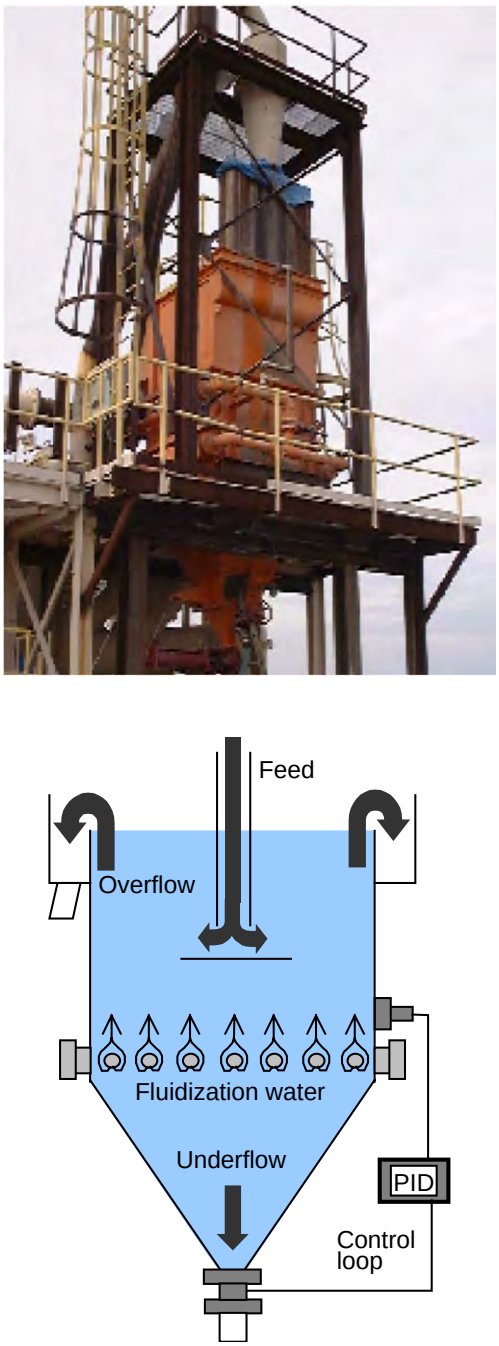

FIGURE 16 Illustration of a teeter-bed separator. Courtesy of Eriez Manufacturing.

(ash) are possible. Operating and capital costs are high.

Teeter bed separators (Fig. 16) are gaining popularity, particularly in Australia. Separation is achieved as a result of the different setting rates of coal and rock in water currents. These units have high capacity and can make lower SG cut points than

spirals. The major unit disadvantage is the limited size range which can be efficiently treated (4:1 top size to bottom size).

3.6 Ultrafine Coal Cleaning (<0.15 mm)

The most widely accepted method for upgrading ultrafine coal is froth flotation. Froth flotation is a physicochemical process that separates particles based on differences in surface wettability. Flotation takes place by passing finely dispersed air bubbles through an aqueous suspension of particles (Fig. 17). A chemical reagent, called a frother, is normally added to promote the formation of small bubbles. Typical addition rates are in the order of 0.05 to 0.25 kg of reagent per tonne (0.1 to 0.5 lb per ton) of coal feed. Coal particles, which are naturally hydrophobic (dislike water), become selectively attached to air bubbles and are carried to the surface of the pulp. These particles are collected from a coal-laden froth bed that forms atop the cell due to the frother addition. Most of the impurities that associate with coal are naturally hydrophilic (like water) and remain suspended until they are discharged as dilute slurry waste. Another chemical additive, called a collector, may be added to improve the adhesion between air bubbles and coal particles. Collectors are commonly hydrocarbon liquids such as diesel fuel or fuel oil. In the United States, flotation is typically performed on only the finest fractions of coal (<0.1 mm), although coarse particle flotation (<0.6 mm) is practiced in Australia where coal floatability is high and the contaminants in the process feed low. The removal of clay slimes (<0.03 mm) is carried out ahead of some flotation circuits to minimize the carryover of this high ash material into the froth product. The ultrafine clay slimes are typically removed using large numbers of small diameter (15 mm or 6 inch) classifying cyclones (Fig. 18).

Most of the industrial installations of flotation make use of mechanical (conventional) flotation machines. These machines consist of a series of agitated tanks (four to six cells) through which fine coal slurry is passed. The agitators are used to ensure that larger particles are kept in suspension and to disperse air that enters down through the rotating shaft assembly. The air is either injected into the cell using a blower or drawn into the cell by the negative pressure created by the rotating impeller. Most commercial units are very similar, although some variations exist in terms of cell geometry and impeller design. Industrial flotation machines are now available with individual cell volumes of 28.3 m^3 (1000 ft^3) or more. Coal flotation is typically performed in a single stage with no attempt to reprocess the reject or concentrate streams. In some cases, particularly where high clay concentrations are present, advanced flotation processes such as column cells have been used with great success. Conventional flotation cells allow a small amount of clay slimes to be recovered with the water that reports to the froth product. A column cell (Fig. 19) virtually eliminates this problem by washing the clay slimes from the froth using a countercurrent flow of wash water. This feature allows columns to produce higher quality concentrate coals at the same coal recovery.

4. SOLID-LIQUID SEPARATION

4.1 Background

Practically all of the processes employed in coal preparation use water as the medium. After treatment, the coal must be dewatered. The purpose of dewatering is to remove water from the coal to provide a relatively dry product. A coal product with an excessively high moisture content possesses a lower heating value, is subject to freezing, and is more costly to transport.

4.2 Mechanical Dewatering

A variety of methods are used to mechanically dewater the different sizes of particles produced by coal cleaning operations (Fig. 20). Dewatering of coarse coal is predominantly carried out using screens or centrifugal dryers. For screens, the prime force involved in dewatering is gravity. This is a relatively simple process for particles larger than approximately 5 mm. Dewatering screens have the advantage of being simple, effective, and inexpensive. Disadvantages include blinding and poor performance for smaller particles. Finer particles, which have a much higher surface area, tend to have correspondingly higher moisture content and are typically dewatered by centrifugal methods.

Centrifugal dryers are comprised of a rotating screen or basket, an entrance for feed slurry, a power drive for rotation, and a mechanism for solids removal. Centrifugal dewatering equipment utilizes sedimentation and filtration principles that are amplified by centrifugal forces. Centrifuges can be used to dewater particles from 50 mm to a few microns. However, no single unit can effectively treat this entire size range (Fig. 20). For coarser fractions, two popular units are the vibratory centrifuge and the screen-scroll centrifuge. Both are available in horizontal or vertical configurations. The primary difference in these units is the mode by which solids are transported. The vibrating centrifuge uses a reciprocating motion to induce the flow of solids across the surface of the dewatering basket (Fig. 21a). The screen-scroll centrifuge uses a screw-shaped scroll that rotates at a slightly different speed than the basket to positively transport the solids through the unit (Fig. 21b). The vibratory centrifuge works best for coarser feeds up to 30 to 50 mm. Both the screen-scroll and the vibratory centrifuges are appropriate for intermediate sizes, although the screen-scroll centrifuge typically provides lower product moistures. For finer material (<1 mm), both the screen-scroll centrifuge and another popular design, called a screen-bowl centrifuge, may be used. The screen-bowl centrifuge is a horizontal unit that consists of a solid bowl section and a screen section

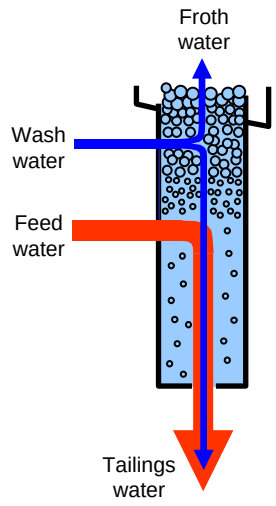

FIGURE 19 Illustration of column flotation technology.

(Fig. 22). Feed slurry is introduced into the bowl section where most of the solids settle out under the influence of the centrifugal field. A rotating scroll transports the settled solids up a beach and across the screen section where additional dewatering occurs before the solids are discharged. Solids that pass through the screen section are typically added back to the machine with the fresh feed. This unit is capable of providing low product moistures, although some ultrafine solids are lost with the main effluent that is discarded from the solid bowl section. This process has become dominant in the United States for drying combined fine and ultrafine coal due to low operating cost and ease of maintenance.

If high coal recovery is desirable, then higher-cost filtration processes may be used to dewater fine coal. Filtration involves the entrapment of fine solids as a cake against a porous filtering media. Traditionally, flotation concentrates have been dewatered using some form of vacuum filtration. These units are capable of maintaining high coal recoveries (>97%) while generating product moisture contents in the 20 to 30% range. One of the most popular types of vacuum filters is the disc filter (Fig. 23). This device consists of a series of circular filtration discs that are constructed from independent wedge shaped segments. At the beginning of a cycle, a segment rotates down into the filter tub filled with fine coal slurry. Vacuum is applied to the segment so that water is drawn through the filter media and a particle cake is formed. The resultant cake continues to dry as the segment rotates out of the slurry and over the top of the machine. The drying cycle ends when the vacuum is removed and the cake is discharged using scrapers and a reverse flow of compressed air.

More recently, horizontal belt vacuum filters have become increasingly popular for dewatering fine coal (particularly in Australia). This device consists of a continuous rubber carrier belt supported between two end rollers (Fig. 24). Filter fabric is placed along the top surface of the belt to serve as filter media. Coal slurry is introduced at one end of the moving belt and is dewatered by the vacuum that is applied along the entire length of the underside. As the belt reaches the end roller, the vacuum is removed and the dewatered cake is discharged. A significant advantage of this design is the ability to clean the filter cloth on the return side using high-pressure sprays. Other advantages include the ability to control the cake thickness (by varying belt speed) and the independent control of cake formation and drying cycle times.

4.3 Thermal Drying

Thermal drying is used when mechanical dewatering is incapable of producing a coal moisture content that is acceptable for market. Although many types of thermal dryers have been tried including indirect heating dryers, fluidized bed dryers have become prominent in drying coals of bituminous rank, often producing product moistures in the 5 to 6% range. Fuel used is most often coal either in a pulverized form or as a stoker product. As far as lower rank coal drying is concerned, numerous thermal drying

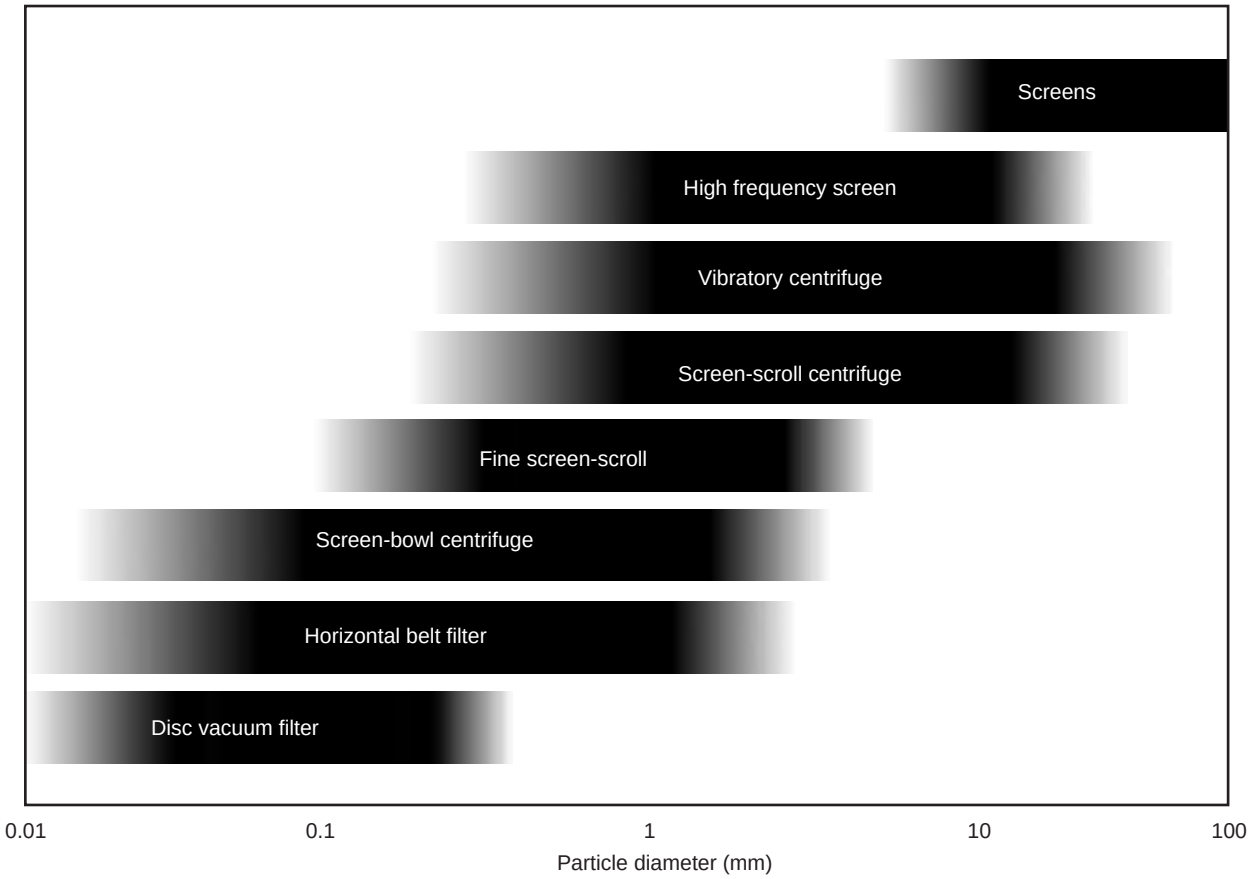

FIGURE 20 Typical ranges of applicability for various dewatering equipment.

processes have been developed, several of which include some degree of surface pyrolysis to reduce the tendency of the coal to reabsorb water or to be subject to spontaneous combustion. Briquetting is also utilized in several processes to deal with the fines inevitably generated in the drying process. Advantages of thermal drying include the ability to achieve very low moistures and the potential to improve other coal properties (e.g., coking). Disadvantages include high operating and capital costs, fugitive dust emissions, and safety hazards associated with potential fires and explosions.

4.4 Thickening

The process of cleaning coal is a wet one, using large quantities of water (i.e., thousands of gallons per minute). As a result, vast quantities of dirty (fine rock-laden) water are produced. Beneficiation processes require clean water. Consequently, dirty water is processed, solids removed, and clean water recycled for further use in the plant. This process is called thickening. A thickener is simply a large tank in which particles (usually flocs) are allowed to settle, thereby producing a clean overflow and a thickened underflow (Fig. 25). Thickeners are typically fed dilute slurry (<5 to 10% solids) that is rejected from the fine coal cleaning circuits. The clarified water that overflows along the circumference of the thickener is recovered and reused as process water. The thickened underflow, which typically contains 20 to 35% solids, is transported to the center of the thickener by a series of rotating rakes. The thickened sludge is typically pumped to an appropriate disposal area or is further dewatered prior to disposal. Chemical additives are usually introduced ahead of the thickener to promote the aggregation of ultrafine particles so that settling rates are increased. The pH levels are also monitored and controlled.

Conventional thickeners, which are typically 15 to 60 m (50 to 200 ft) diameter, require constant monitoring to ensure that overflow clarity and underflow density is maintained and the rake mechanism is not overloaded. A torque sensor on

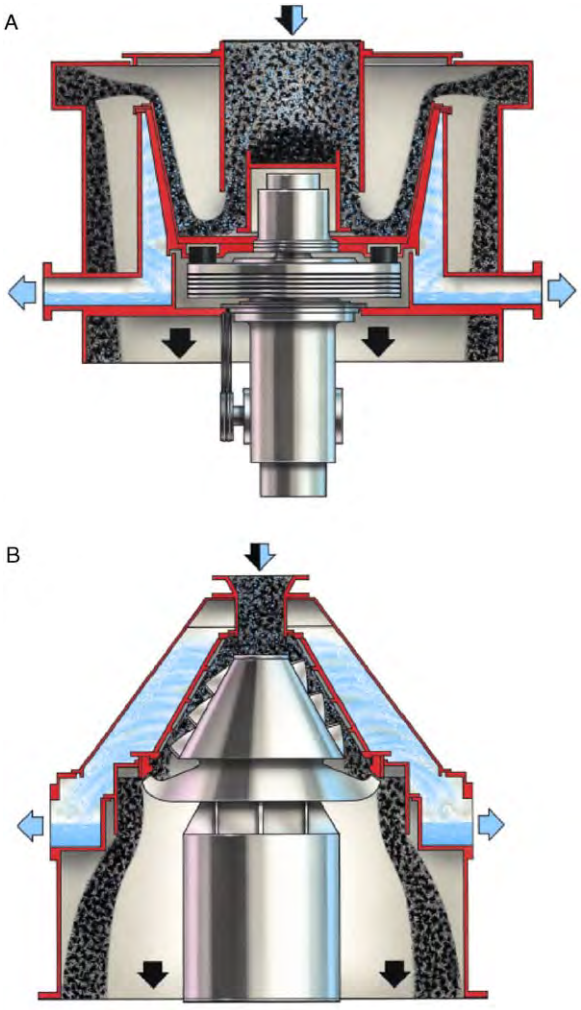

FIGURE 21 Illustrations of (A) vibratory and (B) screen-scroll centrifugal dryers. Courtesy of Centrifugal Machines, Inc.

the central drive is typically used to monitor rake loading, while a nuclear density gauge is used to monitor underflow density.

5. MISCELLANEOUS

5.1 Process Control

A state-of-the-art coal processing facility typically uses a programmable logic controller (PLC) as the heart of the plant control system. The PLC is a computer based controller that acquires data (input) representing the status of all the units and control loops in the plant, makes decisions based on the data input and programmed instructions, and sends data (output) to the plant units reflecting the decisions.

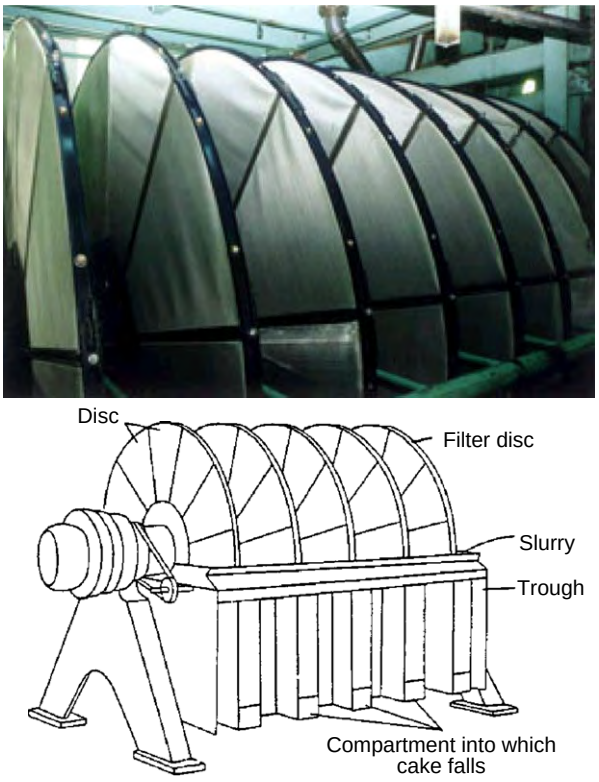

FIGURE 23 Illustration of a conventional disc filter. Courtesy of Peterson Filters.

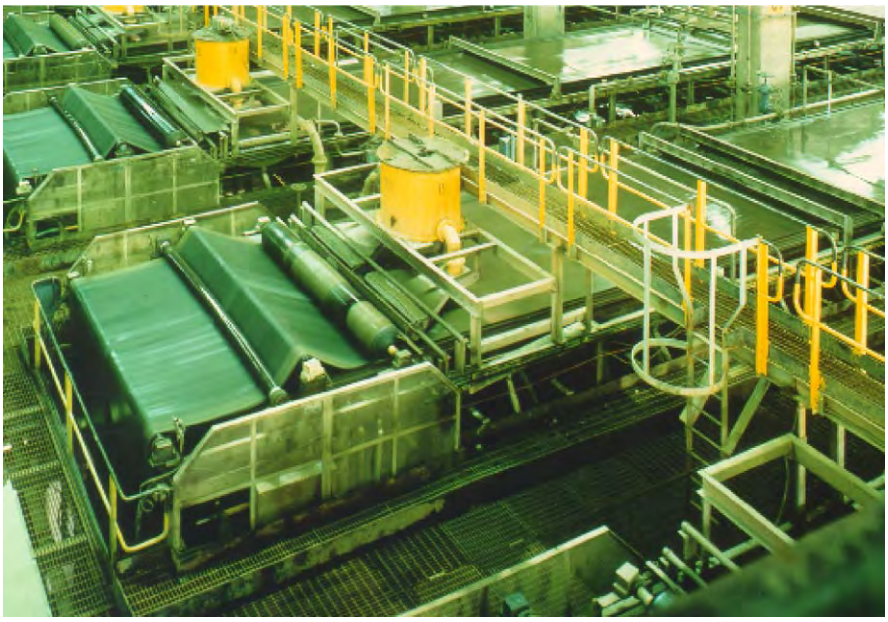

FIGURE 24 Production-scale horizontal belt filter. Courtesy of Delkor Pty, Ltd.

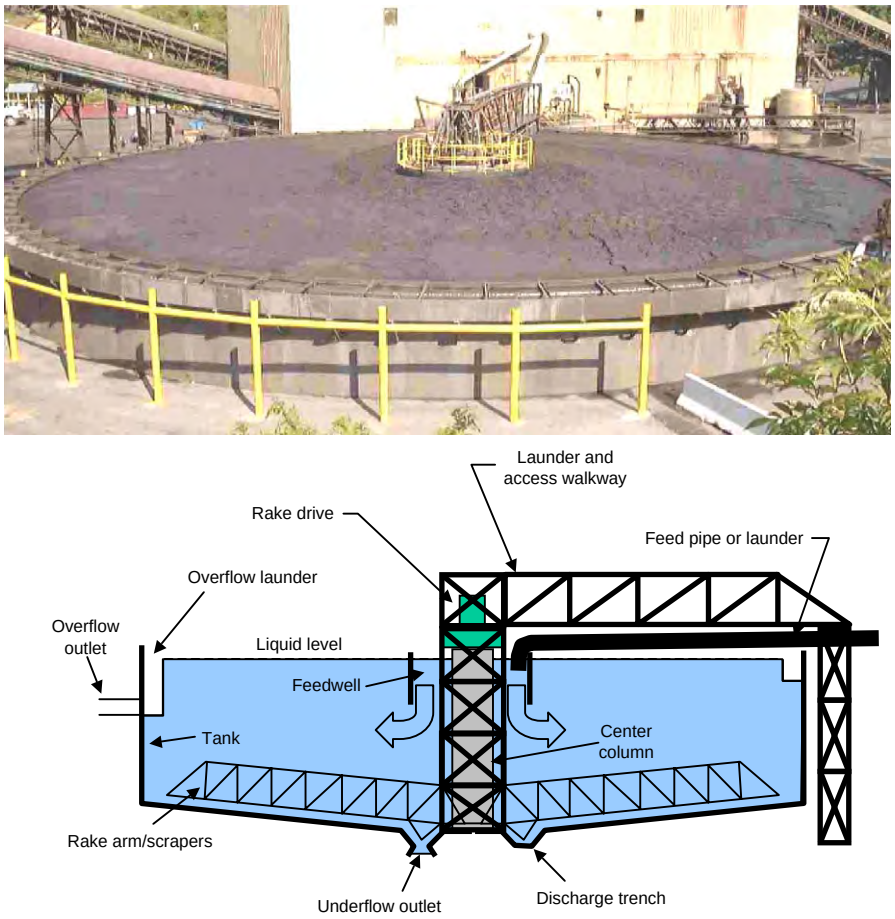

FIGURE 25 Illustration of a refuse thickener.

Inputs include a wide variety of data such as the electrical status of motor control circuits, operating/position status of moving equipment, electrical and mechanical faults, and operating status of control loops (levels, temperatures, flow rates, pressure, etc.). Field devices that provide input to the PLC include electronic transmitters for levels, temperature, pressure, position, and flow rates. Nuclear devices are used for determining online measurements for specific gravity and solids content of slurry streams, for mineral and elemental analysis of process streams, and for flow rates. Digital (microprocessor-based) equipment is becoming available that provides faster communication, less hard wiring, and more reliable data. Digital equipment is also being used to replace standard motor control circuits, which provides better monitoring for those circuits. Outputs include various instructions to field devices such a start/stop signals to motors, open/close or position signals to process equipment (valves, gates, etc.), and signals to the control loops (valves, diverters, feeders, gates, etc.). Field devices that translate PLC output instructions into control actions include standard relay based or digital motor control circuits; electric or electro-pneumatic actuators for valves, gates, and so on; and electronic or digital variable speed controllers for feeders, pumps, conveyors, and so on.

The PLC in conjunction with a full color graphical interface (typically based on a personal computer) provides the operator with all relevant data concerning the operation of the facility. The capabilities of the system includes real time monitoring and control. A major advantage of the PLC system in is the ability to modify the program quickly to change interlocks, startup/showdown procedures. Two other techniques being used to enhance monitoring and control are fiber optics communications and radio frequency telemetry systems. The use of fiber optics for data transmission over long distances provides faster communications and immunity to electrical (lightning) interference. Radio frequency telemetry (direct and satellite relay) provides communications where it is impractical to install long runs of wires and conduits for remote monitoring and control.

During the past decade major enhancements in online analysis of coals have occurred. A variety of ash analyzers are now commercially available for monitoring the quality of the clean coal products produced by a preparation plant. These analyzers are typically mounted on a conveyor belt for the through-the-belt analysis of process streams or at the coal loadouts where the product streams are intercepted. These units can be used to monitor product quality, but more usually in the blending of coals of different qualities. This is done to meet customer quality specifications. They can use the principle of measuring the attenuation of a beam of nuclear radiation as it passes through a process stream. There are also slurry ash analyzers available, including one that uses submersible probes and another than is similar to a nuclear density gauge.

Several commercial monitors are also available of online determination of product moisture content. The principle of measuring the attenuation of a beam of nuclear or microwave radiation as it passes through a process stream is utilized in moisture determination. Accuracy for the microwave analyzers decreases as the variability in the size consists of the process stream increase.

5.2 Waste Disposal

Coal washing processes produce large volumes of waste rock that must be discarded into refuse piles or impoundments. Refuse piles are designed to receive coarse particles of waste rock that can be easily dewatered. This material is relatively easy to handle and can be transported by truck or belt haulage systems to the disposal area. In contrast, impoundments are designed to retain fine waste rock that is difficult to dewater. The waste is normally pumped from a thickener to the impoundment as slurry containing water, coal fines, silt, clay, and other fine mineral particulates. In most cases, the slurry is retained behind a embankment (earthen dam) constructed from compacted refuse material. The impoundment is designed to have a volume that is sufficiently large to ensure that fine particles settle by gravity before the clear water at the surface is recycled back to the plant for reuse. In some cases, chemical additives may be used to promote settling and to control pH. Impoundments, like any body of water contained behind a dam, can pose a serious environmental and safety risk if not properly constructed, monitored, and maintained. Potential problems include structural failures, seepage/piping, overtopping, acid drainage, and black water discharges. In the United States, strict engineering standards are mandated by government agencies to regulate the design and operation of impoundments. In some countries, combined refuse systems are employed in which both coarse and fine refuse are

disposed together as a solid product or alternatively as a pumped slurry.

Glossary

ASTM Abbreviation for American Society for Testing and Materials.
coalification Geochemical process by which buried peat is converted into increasingly higher ranking coal.
coal rank American Society for Testing and Materials-adopted coal classification system, accepted in the United States, that includes brown coal, lignite, subbituminous, bituminous, and anthracite as increasingly higher coal ranks.
lithology Characterization of the structural aspects of the coal bed and the coal texture obtained from the macro- and microscopic observation of the coal.
macerals The altered plant remains, classified into three groups: vitrinite, liptinite, and inertinite.
peatification Biochemical conversion of plant material by anaerobic bacterial action.
petrography Systematic quantification of different bands of material in coal and their characteristics by microscopic study.
petrology Study of the origin, composition, and technological application of different bands of material in coal.

Coal is defined by the American Society for Testing and Materials (ASTM) as "brown to black combustible sedimentary rock composed principally of consolidated and chemically altered plant remains." Coal, formed by biological and geological processes over millions of years, is a heterogeneous and nonuniform material containing macromolecular organic compounds, mineral matters, elements, moisture, gases, and oily and tarry material. Its properties are the result of types of plants, geological age, and biological and geological processes to which plants are subjected.

1. ORIGIN OF COAL

An understanding of coal origin and factors influencing coal formation is important because the demand for electricity, a large fraction of which comes from coal-fired power plants, is increasing. Locating coal sources, assessing their extent and quality, and using coal in an environmentally sound manner are aided by such an understanding.

1.1 Influence of Age

The first plants to grow on land made their appearance toward the end of the Silurian period. These were the earliest vascular plants, leafless shoots that transported nutrients and water throughout the plant. Extensive forests existed by the middle of the Devonian period from which the oldest coal comes. The environment was warm and humid, allowing club mosses, scouring rushes, and horsetails to flourish.

1.1.1 Carboniferous Period

During this period, under a worldwide tropical/subtropical climate with long growing seasons and moderate to heavy rainfall, plants extended their geographic coverage and increased in size. A forest could cover 20,000 to 25,000 square miles, and more plant species existed than do today. Ground pines and club mosses were 30 to 75 feet tall. Giant forerunners of today's horsetail and scouring rushes were abundant. Forests were in swampy areas located on low-lying flat land near shallow seas or rivers. Periodic flooding or drought conditions altered the nature of the forests and led to the formation of anthracite or bituminous coal.

1.1.2 Permian Period

A cooler climate and seasonal changes characterized this period. Except in China, deposition leading to formation of coal in the North declined. In the South, important deposits leading to bituminous coal were laid down in South Africa and Australia.

1.1.3 Cretaceous Period

During this period, the climate was so mild that vegetation grew even in the polar regions, leading to the formation of coalfields there. A major shift in vegetation occurred, namely, plants emerged with seeds having protective coverings. Because of its relatively young age, the coal of this period is of low rank.

1.1.4 Tertiary Period

Deposition of plant materials continued during this period. Ashes, willows, and maples were among the common plants. The younger age of these deposits led to lignite formation.

A strong relationship is found between the rank of coal and the geological age of plant deposition. For example, Texas lignite deposits are from the Tertiary Ecocene period, whereas subbituminous coal in the Big Horn basin and eastern Wyoming was formed during the Paleocene epoch and bituminous coal in western Pennsylvania and eastern Ohio came from the Carboniferous period. However, age alone does not determine the rank. For example, brown coal and lignite found near Moscow, Russia, were formed from plant deposits of the Carboniferous period. However, the plants were not buried deeply. Thus, the temperatures and pressures to which the plant materials were subjected were not high enough to form high-ranking coals.

1.2 Influence of Geology

In spite of seeming abundance in various regions of the world, coal beds form only a very small percentage of the total thickness of the overall sedimentary deposits termed "coal measures" in coal-bearing areas. In a simplified description of coal formation, there are two sequential processes: peat formation (peatification) by biological processes and conversion of peat to coal (coalification) by geological processes. Geological activities also play an important role during the peatification phase. The composition, thickness, hardness, and regularity of the strata both below and above coal beds are created by geological processes over millions of years. These characteristics must be considered in assessing coal mineability and its economics and in selecting mining approaches. For example, in underground mining, the weight and strength of the overlying material ("roof") have a significant bearing on the underground support structure needed for safe operation. Similarly, the "seat" rock on which a coal bed lies may become unduly soft or sticky when wet or excessively plastic when under pressure, causing problems in mining operation.

Under some geological conditions, peat-forming material accumulated at or close to the place of plant growth (autochthonous origin). Under different conditions such as along beaches, along river streams, or when flooding occurs, plant material was moved to a different location, where it was deposited (allochthonous origin) possibly on top of existing plants. Coals formed by the allochthonous mechanism are relatively rare and have less commercial value because of their higher mineral contents.

During peatification, lasting 10,000 to 15,000 years, biochemical activities predominated. Plants and partially decomposed plants were subjected to varying environments (e.g., flooding, drought), addition of plants from other locations, and so on. The extent to which plants were buried under water had a large effect on the type of biochemical activity (e.g., anaerobic vs aerobic fermentation). Some geological changes destroyed swamps and halted the formation and accumulation of peat. Long periods of drought promoted aerobic action, leading to inferior coalfields.

The aerobic process, if it proceeds unimpeded, destroys plant material completely. The anaerobic process leads to peat, and eventually to various ranks of coal, depending on the prevailing geological conditions. If lightning strikes during peatification, fires set by it lead to the formation of charcoal. The charcoal may be incorporated in the coal to a lithotype form of coal called fusain, also termed mineral charcoal or mother-of-coal. An alternate theory for fusain formation also has a geological basis: a drier environment is claimed to lead to the formation of fusain. Cannel coal is theorized to be formed in aerated water, which decomposes all but the spores and pollen.

In stagnant water, the concentrations of acids increase as microbial activities proceed. These acids tend to kill bacteria and short-circuit peatification. In rushing water, this mechanism is less important because acids formed by microbial activities are removed or diluted. Water itself acts as a shield against attack by atmospheric oxygen. Thus, a freshwater environment is most favorable for coal formation.

Coalification primarily involves the cumulative effects of temperature and pressure over millions of years. The sediment covering the peat provides the pressure and insulation, and heat comes from the earth's interior. (Temperature increases ~4–8°C each 100 m.) The change from bituminous coal to anthracite coal involves significantly higher pressure (as in mountain building activity under tectonic plate movements) and higher temperatures than does the formation of bituminous coal. Pressure affects the physical properties of coal (e.g., hardness, strength, porosity). Higher temperatures can be the result of several factors: (1) relative proximity of the earth's magma to formative coal seams, (2) close approach, or contact with, igneous intrusions/extrusions, (3) volcanic activity, and (4) depth of burial. Tectonic plate movement itself creates additional heat. Volcanic activity near the peat or partially formed coal can have a negative impact such as sulfur, mercury, and other environmentally undesirable mineral matters being incorporated into the coal bed. Rapid coalification may lead to parts of coalfields to have natural coke.

The kinds of sediments surrounding the coals are also important. For example, clays do not resist pressure well and deform relatively easily. Thus, a peat deposit in contact with clays reflects the results of pressure more. Although rare, geological processes introduce in some coal beds relatively narrow, vertical, or steeply slanting veins of clay, sometimes partially pyritized.

Several geological phenomena have an impact on the coal bed placement underground:

- *Partings*. Partings are formed when plants buried in a swamp get covered with layers of mud, silt, or clay material followed by additional plant accumulation trapping nonplant materials in between two coal seams. Often, the partings are not uniform and, instead, form a wedge shape that is progressively thicker toward the source of deposited material. Partings impair the mining procedures and, especially if pyritized, decrease the quality of the mineable coal.
- *Concretions*. Formations, perhaps several feet in diameter, that impede mining operations are formed during the overlaying of nonplant material (lenticular masses composed of pyrite, calcite, or siderite or their combinations).
- *Heterogeneity*. During coal bed formation, valleys are formed by the downward erosion caused by nearby streams, occasionally leading to exposure of existing coal beds during their formative stages. The beds are then covered with additional plants or a different type of sedimentation.
- *Geological stresses*. These stresses induce folding and sharp deformation and lead to specific dislocation ("faults"). Such dislocations may range up to hundreds of feet vertically and thousands of feet laterally.

Throughout coalification, formative coal beds are subjected to the action of ground waters. Most of the mineral constituents in the coal bed, such as pyretic material and gypsum, are brought in by ground water either as suspension or by ion exchange. During the bituminous coal stage, the beds develop vertical or nearly vertical fractures that are often filled with coatings of pyrite, calcite, kaolinite, or other minerals deposited by circulating ground water. Similar deposition occurs during peatification, but with a difference. Peat tends to be highly porous and acts as a filter. Secondly, living organisms within peat interact with dissolved minerals such as sodium, potassium, and calcium to exchange ions.

1.3 Influence of Microbes

Microbial activity leads to peat formation (peatification). Microbial activity continues for many years even after the geochemical phase gets under way so long as pressure and temperature are not excessive.

Microbial activity can be of fungal, aerobic, or anaerobic type. The first two need oxygen and cause complete plant decay. If the plant is submerged in water, anaerobic activity dominates. Decomposition of plant material by microbes can be classified as shown in Table I. For the formation of a commercially viable product (coal), peatification or putrefaction is required. Attacks of microbes, oxygen, dissolved oxygen, enzymes, and water-borne chemicals cause degradation of plant material, forming new organic macromolecules so that the original plant structure is not recognizable. Methane and carbon dioxide are also generated under these conditions, hence the term "marsh gas" for methane.

Different parts of plant material have different levels of resistance to microbial activities. Also, their products have different levels of toxicity. For example, cellulose, a major constituent of cell walls, and protein are more susceptible to microbial attacks than are plant constituents such as lignin, tanins, fats, waxes, and resins. Humic acids and other humic substances are important peatification products. Woody material passes through a plastic gel-like

TABLE I

Decomposition of Plant Material via Microbial Actions

Type of action	Type of product
Disintegration (aerated)	Gases, liquids, limited resins
Mouldering (aerobic bacteria and fungi)	Inertinite
Peatification (anaerobic/aerobic bacteria and fungi)	Vitrinite
Putrefaction (anaerobic bacteria)	Exinite

stage before solidifying to huminite and eventually vitrinite. Formation of other maceral structures, such as liptinite and inertinite, is also the result of microbial activities.

2. FORMATION OF COAL

2.1 Petrology, Petrography, and Lithotypes

Careful visual examination of a coal sample shows that it is layered; that is, it consists of bands of different materials with distinct entities distinguishable by optical characteristics. Coal petrology is the study of the origin, composition, and technological application of these materials, whereas coal petrography involves systematic quantification of their amounts and characteristics by microscopic study. Lithological characterization of coal pertains to (1) the structural aspects of the coal bed and (2) the coal texture obtained from the macro- and microscopic observation of the coal.

The texture of the coal is determined by the type, grain, and distribution of its macro- and microscopic components. Banded coals composed of relatively coarse, highly lustrous vitrain lenses (6 mm or more in thickness) are labeled as coarsely textured. As the thickness narrows, the texture becomes fine-banded and then microbanded. Coals with homogenous texture are rare and regarded as nonbanded or canneloid coals. The lithotype nomenclature is often not suitable for lignite due to the presence of plant pieces.

Some geologists consider coal to be a rock that has microscopically identifiable altered plant remains and minerals. The altered plant remains are called macerals, which are classified into three groups: vitrinite, liptinite, and inertinite. Vitrinite is derived from coalified plant tissues and gels. Liptinite is formed from plants' protective coatings, reproductive organs, and resinous cell fillings. Inertinite is produced from oxidation of vitrinite and liptinite precursors. Lithotype classification is partly independent of coal rank. In spite of the similarity of naming conventions, macerals are not minerals because they do not have definite chemical compositions and are not crystalline.

The quantities of various types of macerals in coal can be estimated petrographically. Bulk chemical data can be used to assess the influence of macerals on coal composition. Petrographic analysis involves the use of a microscope to measure optical properties. A widely accepted method is called vitrinite reflectance.

2.1.1 The Stopes–Heerlen System

The Stopes–Heerlen system has been codified by the International Committee for Coal Petrology. In this system, coal is classified either as hard coal or brown/lignite coal on the basis of visual appearance. The hard coals are further divided into banded/humic coals and saporpolic coal (nonbanded coal with large concentrations of algae or spores). The coal types are further divided into four lithotypes based on visual observation of features greater than 3 mm:

- *Vitrain:* bright, black, brittle
- *Clarain:* semi-bright, black, finely stratified
- *Durain:* dull, black–gray, black, hard, rough
- *Fusain:* charcoal-like, silky, black, fibrous, friable

The lithotypes are further divided into microlithotypes, which must be at least 50 microns wide and contain at least 5% of the minor components. The combination of individual macerals in a particular coal sample identifies it and determines whether it is mono-, bi-, or trimaceral. Table II provides a list of the combinations of macerals found in coal and the names of their resultant hybrids. The optical classification of brown and lignite coals has recently been standardized along lines similar to those used for hard coals.

2.1.2 Impact of Lithotype on Utilization Potential

Lithotype descriptions are primarily used to characterize coal beds in geological investigations. This includes the study of lateral variabilities in thickness and structure. They are used as the principal basis for coal resource and reserve determination, but not to predict specific coal properties such as ash content and coal rank.

A wide range of petrographic applications have been developed to assess coals for their specific use,

TABLE II
Characteristics of Hard Coal

Group maceral	Maceral	Submaceral	Maceral variety	Cryptomaceral	Occurrence (percentage)	Reflectance class
Vitrinite	Telinite	Telinite 1	Cordeltetelinite		75–98	T0–T21
			Fungotelinite			
			Xylotelinite			
		Telinite 2	Lepidophytotelinite			
			Sigillariotelinite			
	Collinite	Telocollinite		Cryptotelenite		C0–C21
		Gelocellinite		Cryptocorpocollinite		
		Desmocollinite		Cryptogelocollinite		
		Corpocollinite		Cryptovitrodetrinite		
	Vitrodetrinite					
Exinite or liptinite	Sporinite		Tenuisporinite		0–10	St0–St15
			Crassisporinite	Cryptoexosporinite		
			Microsporinite	Cryptointosporinite		
			Macrosporinite			
	Cutinite				0–1	Ct0–Ct15
	Resinite				0–5	R0–R15
	Suberinite					
	Alginite				0–1	At0–At15
	Liptodetrinite					
	Fluorinite					
	Bituminite					
	Exudatinite					
Inertinite	Micrinite				0–10	M0–M18
	Macrinite				0–10	
	Semifusinite				0–20	SF00–SF21
	Fusinite	Pyrofusinite			0.1–10	
		Degradofusinite				
	Sclerotinite			Plectenchyminite	0–1	
				Corposclerotinite		
				Pseudocorposclerotinite		
	Inertodetrinite				Common

predict potential problems in their application, and solve problems when they are encountered. Petrographic data are used for determination of seam correlations, geological history, and ease of coal oxidation as well as for measurements of rank, interpretation of petroleum formation from coal deposits, and prediction of coke properties. For example, constituents of seams can be measured over considerable distances apart, and these measurements can then be used to establish profiles for entire seams or coal basins. The vitrinite reflectance histogram can provide a quantitative measure of the ease of coal burning.

A vital role is played by petrographic analyses of various coals under consideration as potential feed material to form metallurgical coke. The coking behavior of the coal depends on the rank, maceral constituents, and their relative proportions. Sometimes, as many as eight different coals have to be

blended, maintaining a balance between "reactive" and "inert" maceral constituents, to attain the desired coking properties. Vitrinite has good plasticity and swelling properties and produces an excellent coke, whereas inertinite is nearly inert and does not soften on heating. Exinite becomes extremely plastic and is nearly completely distilled as asphaltenes (tar). By carefully controlling the blends of coals based on their petrological compositions, behavior during carbonization can be controlled.

Petrographic analyses are also useful for the evaluation of coals for liquefaction and gasification. Bituminous and lower ranking coals that are rich in exinite and vitrinite macerals are desirable for liquefaction. Based on microscopic analysis of dispersed "coaly" materials in shales and other sedimentary rocks, geologists can identify favorable areas for oil and gas exploration.

Extensive work has been carried out to correlate elemental composition, functional forms in which elements are present, and physical properties of coal with maceral forms and their proportions in the coal.

2.2 Factors Influencing Formation of Coal

The net result of peatification and coalification is reduction in hydrogen, oxygen, and free moisture and a corresponding increase in fixed carbon content of the original plant material.

2.2.1 Components of Plants

A perspective of the biochemical degradation leads to three plant components:

a. Structural components meant for the plant's rigidity and form include cellulose (polymerized glucose), hemicellulose (polymerized xylose, or wood sugar), lignin (polymerized *n*-propyl benzene), and calcium pectate.

b. Stored food includes carbohydrates, starch, fats and oil, and proteins. Carbohydrates tend to decompose earlier during peatification.

c. Specialty materials are meant to provide various services to the plant. These materials, functioning to protect the plant, include resin, cutin (protection of leaf surfaces), waxes (moisture retention), and sporopollenin (protective outer layer of spores and pollen). They are relatively resistant to biochemical degradation.

2.2.2 Biochemical Phase (Peatification)

Although bacteria and fungi attack all parts of plants simultaneously, the first ones to succumb are carbohydrates, starch, and calcium pectate. This is followed by decomposition of hemicellulose and then decomposition of cellulose. Lignin is more resistant, specialty materials are even more so, and sporopollenin is the most resistant.

Brackish or saline water often contains enough sulfur to support bacterial activities that lead to conversion of sulfate ions to hydrogen sulfide or elemental sulfur. These two by-products, instead of escaping formative peat, may be incorporated into preexisting pyrites or into the organic structures in the peat.

As peatification proceeds, more plants may be dumped on top of the previously buried plant material, compacting the peat-like material underneath, squeezing out some of the trapped water, and increasing its density. Degradation of cellulose under bacterial attack opens up cell walls and helps to disintegrate the large pieces of plant tissue. The structure of coal itself changes drastically during this phase, increasing carbon content from 50 to 60%.

2.2.3 Geochemical Phase (Coalification)

The geochemical phase begins when sedimentation such as silt, mud, sand, and clay is placed on top of the peat or partially formed peat. The weight of the sedimentation compresses the peat and buries it deeper as more sedimentation is piled up.

Transformation of peat into brown coal, lignite, subbituminous, bituminous, and (finally) anthracite is a sequential and irreversible process. The primary factors that determine coalification progress are temperature, pressure, and duration of coalification to which peat is subjected. With a shorter time, coalification does not proceed beyond the rank of brown coal or lignite. Incomplete coalification produces coal that has recognizable plant fragments.

Higher temperatures are critical for the metamorphosis of peat to increasingly higher ranks of coal. The coalification of brown coals and lignite occurs at temperatures less than 100°C. These coals retain much water and volatile matter and more of the functional groups of the original plant. Temperatures in the range of 100 to 150°C yield bituminous coals through the loss of moisture, aliphatic and oxygenated groups, and hydrogen. In the process, there is a decrease in the pore structure and an increase in the carbon and heat content of the coal. Low- and medium-volatile coals are produced by further exposure to temperatures in the range of 150 to 180°C. Anthracites are produced at temperatures greater than 180°C, with further loss of hydrogen and organic functional groups. Loss of hydrogen during this stage actually decreases slightly the

heating value of coal. Anthracite formation also increases the fine pore structure of the coal. Anomalous coal of higher ranking has been produced during relatively short coalification periods when peat is subjected to magma intruding near it.

2.3 Structure of Coal

Because coal is the result of the partial decay and deposition of vegetation, it consists mostly of organic material. In addition, inorganic matter is incorporated in the coal bed, some of which becomes an integral part of the organic material in coal. Coal also contains free water (inherent moisture). The percentage of inherent moisture ranges from 40 to 50% in lignite to less than 5% in anthracite. Coal composition and structure vary substantially as the rank changes from lignite to anthracite. As rank increases, fixed carbon increases and oxygen and inherent moisture/volatile matter decrease.

In general, rank and maceral composition are viewed as substantially fixed for a particular coalfield, certainly within a particular coal seam. The structure of the coal seam/bed is itself highly irregular, depending on its geological history. Thus, the height of the seam and its horizontal spread are often unpredictable.

2.3.1 Bonding within a Macromolecule

A variety of macromolecules with different molar masses, proportions of functional groups, and structural features exist in any coal piece. These molecules consist of planar fused ring clusters linked to nonpolar hydroaromatic structures. The overall structure is complex, irregular, and open. Entanglement between macromolecules occurs, as does cross-linking of hydrogen-bonded species. These different molecular shapes and sizes in coal lead to irregularities in packing and porosity in coal and make it amorphous. In the extracted material of the coal, the average molar mass is 1000 to 3000 for 5 to 50% fraction. Unextractable coal contains even larger macromolecules. The magnetic resonance technique was applied to coals of various ranks to generate the intramolecular functional group data given in Table III.

The structure of vitrinites, the major maceral groups in bituminous and anthracite coals, has been analyzed and found to have the following characteristics:

a. The organic molecules contain a number of small aromatic clusters, with each typically having one to four fused benzene rings. The average number of clusters depends on the rank, increasing slowly up to 90% fixed carbon and then rapidly for higher carbon content. (Lignites typically have 0.60 aromaticity, whereas anthracite has 0.95.)

b. The aromatic cluster linkage is, in part, by hydroaromatic, alicyclic, and ring structures, which also contain six carbons. On dehydrogenation, these ring structures can become part of the cluster through molecular rearrangement, increasing the average cluster size.

TABLE III

Carbon Structural Distribution: Fraction of Carbon Type

	Lignite	Subbituminous	High-volatile bituminous	Medium-volatile bituminous	Low-volatile bituminous
sp^2 hybridized carbon	0.61	0.63	0.72	0.81	0.86
sp^2 hybridized carbon in aromatic ring	0.54	0.55	0.72	0.81	0.86
Carbon in carbonyl	0.07	0.08	0.00	0.00	0.00
Protonated aromatic	0.26	0.17	0.27	0.28	0.33
Nonprotonated aromatic	0.28	0.38	0.45	0.53	0.53
Phenolic or phenolic ether carbon	0.06	0.08	0.06	0.04	0.02
Alkylated aromatic carbon	0.13	0.14	0.18	0.20	0.17
Aromatic bridgehead carbon	0.09	0.16	0.22	0.29	0.34
sp^3 hybridized carbon	0.39	0.37	0.28	0.19	0.14
CH or CH_2 aliphatic carbon	0.25	0.27	0.16	0.09	0.08
CH_3 aliphatic carbon	0.14	0.10	0.12	0.10	0.06
Oxygen-bound aliphatic carbon	0.12	0.10	0.04	0.02	0.01

Source. Vorres, K. S. Coal. *In* "Encyclopedia of Chemical Technology" (J. Kroschwitz, Ed.), 4th ed. John Wiley and Sons, New York.

c. Clusters can also form linkages employing short groups such as methylene, ethylene, and ether oxygen.

d. A large fraction of hydrogen sites on the aromatic and hydroaromatic rings are substituted by methyl or larger aliphatic groups.

e. Oxygen is usually present in phenolic and ether groups, substituting for hydrogen on the aromatic ring.

f. In a small fraction of the aromatic and hydroaromatic rings, oxygen replaces carbon in the ring, making the ring heterocyclic. (Some of these rings are five-membered.)

g. Compared to oxygen in phenolic groups, a lesser fraction of oxygen appears in the carbonyl structure (quinone form on aromatic and ketone form on hydroaromatic rings). In both cases, oxygen is apparently hydrogen bonded to adjacent hydroxyl groups.

h. Nitrogen, which is less abundant in vitrinite than is oxygen, is usually present as a heteroatom in a ring structure or as a nitrile.

i. Most of the sulfur, especially if its content exceeds 2%, is in the form of inorganic material. Organic sulfur occurs in both aliphatic and aromatic forms. Sulfide and disulfide groups are involved in linking clusters.

2.3.2 Bonding between Macromolecules

Individual macromolecules in coal structure are bonded to each other by a variety of forces and bonds to form a solid, three-dimensional coal structure. Aromatic clusters are linked by connecting bonds through oxygen, methylene or longer aliphatic groups, or disulfide bridges. The proportions of the various functional groups change with rank. Acid groups decrease early in the rank progression and other groups follow, leaving ether groups to act as cross-linking groups. Another type of linkage involves hydrogen bonds that, for example, hold hydroxy and keto groups together in solids.

3. DESCRIBING AND CLASSIFYING COAL

Coal samples from around the world show differences in appearance and properties—soft, moist, and brownish; very hard, glossy, and black solid; or numerous variations in between. Coal is primarily used for electric power generation. Other coal uses include drilling fluids, briquettes, and formation of coke for iron smelting. For more than a century, it supplied hundreds of chemical intermediates to prepare medicines, dyes, paints, and perfumes. These coal applications require different physical, chemical, and other properties of coal.

A number of classification systems have been developed to facilitate the production, sale, and use of coal and to satisfy the needs of major stakeholders. They seek a systematic way by which to assess performance and economic value of coals in particular applications and to facilitate assessing potential operational problems.

3.1 The Ranks of Coal

In the United States in 1938, the American Society for Testing and Materials (ASTM) adopted classification of coals "by rank" as a standard means of coal specifications (D388), parameters of which are provided in Table IV. Lower ranking coals are classified by their calorific values on a moisture- and mineral-free basis. Higher ranking coals are specified in terms of percentage of fixed carbon ($\geq 69\%$) or volatile matter ($\leq 31\%$) on a moisture- and mineral-free basis. ("Volatile matter" is defined by the ASTM D3175 procedure.) Many properties of coal vary in a fairly regular way with rank. This allows one to judge the properties of a particular coal on the basis of its rank alone.

Anthracite, bituminous, subbituminous, and lignite are ranks of coal in descending order. Peat itself is not considered coal. Less mature lignite is called brown coal. A further distinction is made within bituminous and subbituminous coals on the basis of volatile matters and agglomerating properties. Lignite and subbituminous are low-ranking coals, whereas bituminous and anthracite are high-ranking coals.

3.1.1 Descriptions of Coals by Their Ranks

3.1.1.1 Brown Coal Geologically least mature, brown coal has high moisture, sometimes more than 60%. On drying, it tends to disintegrate. Although susceptible to spontaneous ignition, it has a low heating value ($\sim$3000 BTU/pound as mined).

3.1.1.2 Lignite Geologically not mature, with easily recognizable plant parts present, lignite has less than 75% carbon on a moisture- and ash-free basis and moisture as high as 40 to 42%. Because of its high volatile matter, it ignites easily, but with a smoky flame. It has a low heating value and tends to disintegrate on drying.

TABLE IV
Classification of Coals by Rank

	Fixed carbon (percentage)[a]		Volatile matter (percentage)[a]		Gross calorific value (kJ/kg)[b]		
	≥	<	≥	<	≥	<	Agglomerating character
Coal rank							
Anthracite							
Meta-anthracite	98			2			Nonagglomerating
Anthracite	92	98	2	8			Nonagglomerating
Semi-anthracite[c]	86	92	8	14			Nonagglomerating
Bituminous							
Low volatile	78	86	14	22			Commonly agglomerating[e]
Medium volatile	69	78	22	31			Commonly agglomerating[e]
High volatile							
A		69	31		32,500[d]		Commonly agglomerating[e]
B					30,200[d]	32,500	Commonly agglomerating[e]
C					26,700	30,200	Commonly agglomerating[e]
					24,400	26,700	Agglomerating
Subbituminous							
A					24,400	26,700	Nonagglomerating
B					22,100	24,400	Nonagglomerating
C					19,300	22,100	Nonagglomerating
Lignite							
A					14,600	19,300	Nonagglomerating
B						14,600	Nonagglomerating

Source. Vorres, K. S. Coal. *In* "Encyclopedia of Chemical Technology" (J. Kroschwitz, Ed.), 4th ed. John Wiley and Sons, New York.
[a] Dry, mineral-matter-free basis.
[b] Moist, mineral-matter-free basis (i.e., contains inherent moisture)
[c] If agglomerating, classify in low-volatile group of the bituminous class.
[d] Coals having 69% or more fixed carbon on the dry, mineral matter-free basis are classified according to fixed carbon, regardless of gross calorific value.
[e] There may be nonagglomerating varieties in the groups of bituminous class, and there are notable exceptions in high-volatile C bituminous group.

3.1.1.3 Subbituminous Coal ("Black Lignite") Geologically more mature, as manifested by the absence of woody texture, subbituminous coal has a tendency to disintegrate and spontaneously ignite like lignite, but it burns more cleanly. Since the 1970s, environmental concerns have increased interest in low-sulfur subbituminous coal.

3.1.1.4 Bituminous Coal Bituminous coal is black and often appears to be banded with alternating layers of glossy and dull black colors. It has a higher heating value and lower moisture and volatile matters than does subbituminous coal. It has little tendency to disintegrate or ignite spontaneously.

3.1.1.5 Anthracite With very low volatile matter, sulfur, and moisture, anthracite burns with a hot clean flame and no smoke or soot. Stable in storage, it can be handled without forming dust. Hardest and densest of all the coal ranks, anthracite is jet black and has a high luster.

Although not part of the standard ASTM classification, some coals, with 25 to 50% ash by weight on a dry basis, are termed "impure coal." The mineral matter is introduced during deposition, mostly as clay or as fine-grained detrital mineral matter (bone coal) or later by secondary mineralization (mineralized coal). Other deposits in which mineral matter predominates, such as oil shale, coaly carbonaceous shale, and bituminous shale, are also not classified as coal.

3.2 The International Systems for Coal Classification

Many countries have official national organizations that develop and maintain standards for analyzing coal and classification schemes that are used in the coal trade and compilation of coal resource and reserve data. In the United Kingdom, the British Standards Organization serves this purpose, as does the ASTM in the United States.

3.2.1 National Coal Board Classification for British Coals

Proposed in 1946 by the Department of Scientific and Industrial Research, this classification is based on (1) volatile matter on a dry, mineral-free basis and (2) coking power, as measured by the Gray–King assay. Classification of lower ranking coals is based primarily on the Gray–King assay. Because this classification is applied to coals having less than 10% ash, high-ash coals need to be first cleaned by methods such as a float–sink separation.

3.2.2 International Classification (Hard Coal)

The rapid increase in the international coal commerce since 1945 necessitated an international system of coal classification. In 1956, the Coal Committee of the European Economic Community agreed on a system designated as the International Classification of Hard Coal by Type. Among the parameters considered are volatile matter and gross calorific value on a moisture- and ash-free basis. Table V provides various national classifications and their relationships to the classes of the international system.

In coal classification, most countries use volatile matter as the primary criterion, with a secondary criterion being coking properties. Criteria employed by some countries are as follows:

- Belgium: none
- Germany and The Netherlands: appearance of coal button
- France and Italy: Free Swelling Index (FSI)
- Poland: Roga Index
- United Kingdom: Gray–King assay

The International Organization for Standardization (ISO) based in Geneva, Switzerland, formed a committee to develop international standards. These standards, which incorporate both coal rank and coal facies parameter, replaced the UN Economic Commission of Europe's classification for hard coal.

A three–digit classification of the international system combines rank (class), caking (group), and coking (subgroup) parameters into a three-code system, as shown in Table VI. The first digit indicates the class or rank (higher digits for lower ranks). Coals having less than 33% volatile matter are divided into classes 1 to 5, and those with higher volatile matter are divided into classes 6 to 9. The second digit is based on the caking properties such as the Roga Index and the FSI. The third digit defines a subgroup based on coking properties.

3.2.3 International Classification (Brown Coal and Lignite)

These types of coals are defined as those having less than 23,860 kJ/kg heating values. Their classification employs a four-digit code. The first two digits (class parameter) are for total moisture content of freshly mined coal on an ash-free basis. The third and fourth digits are defined by the tar yield on a dry, ash-free basis.

4. CONSTITUENTS OF COAL AND THEIR IMPACTS

4.1 Organic Components in Coal

The functional groups within coal contain primarily elements C, H, O, N, and S. The significant oxygen-containing groups found in coals are carbonyl, hydroxyl, carboxylic acid, and methoxy. The nitrogen-containing groups include aromatic nitriles, pyridines, carbazoles, quinolines, and pyrroles. The sulfur-containing groups are thiols, dialkyl and aryl-alkyl thioethers, thiophenes, and disulfide.

The relative amounts of various functional groups depend on coal rank and maceral type. In vitrinites of mature coals, the principal oxygen-containing functional groups are phenolic and conjugated carbonyls as in quinones. In exinites, oxygen is present in functional groups such as ketones (unconjugated carbonyls).

The aromaticity of macromolecules in coal increases with coal rank. Calculations based on several coal models indicate that the number of aromatic carbons per cluster varies from 9 for lignite to 20 for low-volatile bituminous coal, and the number of attachments per cluster varies from 3 for lignite, to 4 for low-volatile bituminous coal, to 5 for subbituminous through medium-volatile bituminous coal.

4.2 Inorganic Constituents in Coal

To determine inorganic constituents in coal, a variety of instrumental techniques are available, including

TABLE V

The International System and Corresponding National Systems of Coal Classes

International system			National classifications							
Class number	Volatile matter (percentage)	Calorific value (kJ/g)[a,b]	Belgium	Germany	France	Italy	The Netherlands	Poland	United Kingdom	United States
0	0–3					Anthraciti Speciali		Meta-antracyt		Meta-anthracite
1A	3.0–6.5		Maigre	Anthrazit	Anthracite	Anthraciti Comuni	Anthraciet	Antracyt	Anthracite	Anthracite
1B	6.5–10.0							Polantracyt		
2	10–14		$\frac{1}{4}$ Gras	Magerkohle	Maigre	Carboni Magri	Mager	Chudy	Dry steam	Semianthracite
3	14–20		$\frac{1}{2}$ Gras	Esskohle	Demigras	Carboni Semigrassi	Esskool	Polkoksowy meta-koksowy	Coking steam	Low-volatile bituminous
4	20–28		$\frac{3}{4}$ Gras	Fettkohle	Gras à Courte flamme	Carboni Grassi Corta fiamaa	Vetkool	Orto-koksowy	Medium volatile coking	Medium-volatile bituminous
5	28–33		Gras	Gaskohle	Gras Proprement dit	Carboni Grassi Media fiamma		Gazowo koksowy		High-volatile bituminous A
6	>33(33–40)	32.4–35.4				Carboni da gas	Gaskool			
7	>33(32–44)	30.1–32.4			Flambant gras	Carboni grassi da vapore	Gasvlamkool	Gazowy	High volatile	High-volatile bituminous B
8	>33(34–46)	25.6–30.1		Gas flammkohle	Flambant scc	Carboni Secchi	Vlamkkol	Gazowoplomienny		High-volatile bituminous C

X-ray diffraction, infrared spectroscopy, differential thermal analysis, electron microscopy, and petrographic analysis. Typically, the coal sample has to be first prepared by low-temperature "ashing" to remove the organic material. Analyses have shown the presence of nearly all of the elements in coal, at least in trace quantities. Certain elements (e.g., Ge, Be, B, Sb) are found primarily with organic matter, whereas others (e.g., S, P, Na, K, Ca, Mg) are found in both inorganic and organic components of coal. The primary elements forming inorganic constituents are Al, Si, Ca, Mg, Na, and S, with the secondary elements being Zn, Cd, Mn, As, Mo, and Fe.

The presence of inorganic constituents in coal is a result of several separate processes. These include (1) natural occurrence in plants as, for example, silica in cell walls of scouring rushes, (2) incorporation by ion exchange (cations linking with carboxylic acid groups or formation of chelating complexes), and (3) incorporation by mechanisms such as filtration. Some come from the detrital minerals deposited during peatification, whereas others come from secondary minerals that crystallize from water that percolates through the coal seams. During the early stages of coal development, minerals can be deposited in the peat either allogenically (minerals carried and deposited unaltered from outside the peat bed) or authigenically (minerals altered during the deposition in the peat bed).

4.3 Minerals Mixed with Coal

Table VII provides a list of different minerals that have been found in coal. Mineral matter in coal can be classified as inherent mineral matter, included mineral matter, and excluded mineral matter. Inherent mineral matter is bound to organic matter in the coal's structure. Included mineral matter is that which forms an inorganic entity within pulverized coal particles. Excluded mineral matter is that which is external to the coal seam, taken in accidentally.

Mineral matter occurs in coal seams as layers, nodules, fissure fillings, rock fragments, and small particles finely distributed throughout. These are classified as inherent (plant derived), detrital, syngenetic, or epigenetic. Inherent minerals contribute less than 2% to the coal ash.

Detrital minerals are those that were washed into the peat swamp by water streams or blown in by wind. The various clay minerals are the most common detrital minerals. Other common detrital minerals include quartz, feldspar, garnet, apatite, zircon, muscovite, epidote, biotite, augite, kyanite, rutile, staurolite, topaz, and tourmaline. The secondary minerals are kaolinite, calcite, and pyrite.

Syngenetic minerals are formed *in situ* from colloidal, chemical, and biochemical processes as organic matter accumulates in swamps. Pyrite is the most common type, and in some coals certain clay materials are syngenetic in origin. Epigenetic minerals are formed during later stages of coalification. These include calcite, dolomite, ankerite, siderite,

TABLE VII
Minerals Found in Coals

Clay minerals		**Chloride minerals**	
Montmorillonite	Common	Halite	Common
Halloysite	Rare	Sylvite	Rare
Illite-Sericite	Abundant	Bischofite	Rare
Kaolinite	Dominant	**Silicate minerals**	
Mixed layer	Common	Quartz	Dominant
Clay minerals/smectite		Tourmaline	Rare
Sulfide minerals		Staurolite	Rare
Pyrite (isometric)	Common	Sanidine	Rare
Chalcopyrite	Rare	Hornblende	Rare
Millerite	Rare	Biotite	Rare
Sphalerite	Rare	Garnet	Rare
Pyrrhotite	Rare	Epidote	Rare
Arsenopyrite	Rare	Orthoclase	Rare
Galena	Rare	Topaz	Rare
Marcasite (orthorhombic)	Rare	Zircon	Rare
Carbonate minerals		Kyanite	Rare
Calcite	Common	Albite	Rare
Siderite	Rare	Augite	Rare
Dolomite	Common	Feldspar	Common
Witherite	Rare	**Oxide and hydroxide minerals**	
Ankerite (ferroan dolomite)	Common	Hematite	Rare
Sulfate minerals		Limonite	Rare
Barite	Rare	Lepidocrocite	Rare
Bassanite	Rare	Magnetite	Rare
Rozenite	Rare	Goethite	Rare
Roemerite	Rare	Rutile/Anatase	Rare
Sideronatrite	Rare	Diaspore	Rare
Gypsum	Common	**Phosphate minerals**	
Jarosite	Rare	Apatite	Rare
Melanterite	Rare		
Mirabilite	Rare		
Anhydrite	Rare		
Szomolnokite	Rare		
Coquimbite	Rare		
Kieserite	Rare

pyrite, marcasite, sphalerite, barite, certain clay minerals (especially kaolinite), gypsum, carbonates, and chlorides. They commonly precipitate from solutions as they percolate through the peat or along joints and pores in the coal. Sometimes, they are coarsely crystalline or in the shape of nodules.

4.3.1 Impact of Mineral Matter on Coal Use

Mineral matters in coal cause major problems in coal-fired power plants. Hard minerals cause erosion and wear of equipment during handling, crushing, and grinding. Ash, produced by mineral matters, needs to be disposed of in an environmentally safe manner, adding to the power generation cost. High-temperature ash discharge as a molten slag involves substantial loss of sensible heat. Slagging and fouling on boiler and superheater walls reduce heat transfer efficiency, increase fan power requirements, and in extreme cases block passages in boilers. Major air pollution is caused by mineral matters such as sulfur and mercury. Minerals in coal can behave as poisons for a variety of coal conversion processes. For

example, titanium compounds in coal act as poisons in coal gasification and liquefaction.

Mineral matters do not always have a negative impact on coal use. A high sulfur content of feed coal in the synthetic fuels process is deemed to be best for catalysis. A high calcium carbonate content in combustion promotes self-cleaning of emissions. The presence of sodium in flue gas enhances the performance of electrostatic precipitators.

To assess the potential adverse effects of minerals in the coals, it is insufficient to depend on the "ultimate and trace element" analyses. The forms in which various elements are present in coal are also important. For example, sulfur in coal can have 30 different forms. Organically bound sulfur exists in a variety of functional forms. Selenium occurs in pyrite and sphalerite or as organically bound selenium, lead selenide, and ion-exchangeable, water-soluble selenium.

In general, one needs to know four factors about mineral matters in the coal to assess their effects on coal use:

- Chemical composition of the minerals
- Particle size distribution of mineral matters
- Percentage compositions of minerals
- Extent of crystallanity of the minerals

4.3.2 Metallurgical Coke

The quality of metallurgical coke depends on ash yield and composition and the sulfur content of the coal in addition to its rank, maceral composition, and density. Phosphorus and vanadium in coal are undesirable in the coke-forming process. Depending on the maceral and other properties, cokes of various types and strength are generated. Therefore, to produce cokes of a specific strength to support the iron ore in a blast furnace, coal blending is necessary.

4.3.3 Fouling

The buildup of sintered ash deposits ("fouling") on the heat exchange surfaces of coal-fired boilers is one of the most costly problems. Fouling drastically reduces boiler efficiency and also promotes corrosion and erosion. The size and strength of these deposits depend on the configuration and operation of the boiler and the mineral contents of the coal. Although sodium is often cited as the primary cause of fouling, the formation of sintered ash deposits is the result of the interaction of many inorganic constituents. Research indicates that ash yield and sodium, calcium, and magnesium concentrations in ash are the most important factors influencing the fouling behavior of low-rank coal.

4.3.4 Slagging

Slag is a molten ash deposited on boiler walls in zones subjected to radiant heat transfer. Minerals that have low melting points tend to stick to the boiler walls and accumulate to form massive fused deposits. Many slags reach a point at which the viscosity begins to rise rapidly with very small temperature changes. Above this "temperature of critical viscosity," slag becomes too viscous to flow and drain from the equipment.

The iron content of the coal ash has a major influence on the ash fusion temperature and the slagging potential of a coal. Iron sulfides tend to promote slagging more than do other iron-bearing minerals. Illite, a clay mineral, also may play a role in the slagging process by acting as an initiator.

4.3.5 Corrosion

Corrosion is enhanced by nonsilicate impurities in coal that volatilize and collect on the metal walls. Low-temperature corrosion can be caused by acidic gases (chlorine and sulfur oxides) or condensing acids (sulfuric acid), leading to most severe damage of the boiler's coolest parts. Therefore, the flue gas temperature needs to be above the acid dew point to minimize sulfur corrosion effects. High-temperature corrosion is caused by oxidation, sulfidation, or chlorination of the metal. Sodium and potassium sulfates play an important role in the corrosion process. High levels of chlorine (>1000 ppm) and (to a lesser extent) fluorine are considered to be potentially corrosive. At high levels ($>0.6\%$), chlorine, normally associated with sodium and complex sulfate deposits, initiates deposition on superheater tubes and also initiates stress corrosion cracking of tubes.

Although the elements arsenic, lead, boron, and (perhaps) zinc are typically present in trace quantities, they also enhance corrosion under certain conditions. Under high-firing temperature conditions, phosphorus at levels greater than 0.03% leads to phosphate deposits.

4.3.6 Erosion and Abrasion

Erosion and abrasion lead to wear. They cause wear in boilers and in mining and grinding equipment. Abrasive minerals in coal include quartz and pyrite. Particle size and shape affect the extent of erosion and abrasion. Coal technologists use the silicon/aluminum ratio as an indicator of abrasiveness, based on the assumption that the higher the ratio, the greater the quartz content. Ratios greater than 3 are deemed abrasive.

4.3.7 Environmental Impact

There are many ways by which coal use can negatively affect the environment. Coal mining involves blasting, dredging, and excavation that leads to air pollution by particulate matter being discharged into the atmosphere. Waste material dumped in local streams contaminates them. Coal dust explosions, mining accidents, and black lung disease among miners are some of the major health, safety, and hazard issues of mining. During coal transportation in open railroad cars, some coal particles fly off and spread over the land.

The 1990 Amendments to the Clean Air Act (CAAA) cited 12 elements in the Hazardous Air Pollutant List (P, Sb, As, Be, Cd, Cr, Co, Pb, Mn, Hg, Ni, and Se), several of which are present in coal. Many of the same elements (As, Be, Cd, Cr, Pb, Hg, and Se) appear in the U.S. Environmental Protection Agency's (EPA) list of potential pollutants in drinking water.

The EPA found that most coal wastes are not hazardous as defined by the Resources Conservation and Recovery Act. However, it reported the presence of groundwater contamination in the vicinity of waste disposal sites. At one site, nearby drinking water wells were contaminated with vanadium and selenium. The release of selenium from coal combustion wastes has caused extensive fish kills at two sites in North Carolina and at one site in Texas. Small amounts of selenium can be potentially toxic to livestock. Although coals in the Powder River Basin contain less than l ppm selenium, coal mining there releases selenium in sufficient quantity to exceed the permissible groundwater selenium concentration limit for livestock drinking water.

In power plants, mineral matters are collected as bottom or fly ash. Sometimes, they are sluiced up for environmentally sound disposal. To collect fly ash, electrostatic precipitators, bag houses, or cyclones are employed. Roughly 20 million tons of ash, or 25% of all particulate matter discharged into the air from all sources, is generated each year. Much of the ash is discarded as waste, is returned to the mines, or is dumped in the ocean. Ash has been used to make concrete. It is also a potential raw material to make aluminum. Some ashes contain valuable quantities of gallium, gold, and silver, making them attractive revenue sources.

4.3.7.1 Sulfur Pollution Sulfates in coal, constituting approximately 15% of the sulfur, are retained as ash. Pyritic and organically bound sulfur is combusted to form sulfur oxides, which in the absence of emission controls escape to the atmosphere. Sulfur oxides and sulfurous and sulfuric acids are corrosive and harmful to the health of humans, animals, and plants. Acid rains have caused deforestation and damaged buildings and monuments.

To comply with increasingly stringent government regulations, power plants have had to resort to a variety of actions. They include (1) switching from coal to alternate fuels, (2) switching from high-sulfur to low-sulfur coal, (3) blending coals, (4) beneficiating coal to lower its sulfur content, and (5) desulfurizing flue gas. Low-sulfur subbituminous coal from eastern Wyoming has come into high demand to lower sulfur emissions.

4.3.7.2 Mercury Pollution Mercury in flue gases can be present simultaneously as elemental mercury, oxidized mercury, and/or "particulate mercury," the form of which has not been determined by current methods. No reliable methods that can control mercury regardless of its form are yet available. The leading candidate is injection of activated carbon. Currently, U.S. power plants are exempt from having to control mercury pollution resulting from their operations. With the 2002 "Clear Skies" initiative, the U.S. government proposed to reduce mercury emissions from power plants by approximately 70% by 2018. The EPA is also separately considering mercury regulations under the CAAA. Thus, some mercury emission regulations can be expected, but their timing and stringency are not known.

4.3.7.3 Radionuclides Pollution Less known is the fact that coal contains trace quantities of radionuclides such as uranium, polonium, thorium, and radium. They are removed by wet scrubbers and electrostatic precipitators, and they tend to concentrate in the ash that is disposed. The use of ash in building materials has led to radon problems in residential and commercial buildings in some cases. Based on a U.S. Department of Energy's (DOE) comprehensive study showing emission values at or below the crustal values of the earth, the EPA concluded that levels of radionuclide emissions are not harmful to the ecosystem or humans and exempted power plants from reporting them.

5. COMPOSITIONAL ANALYSIS AND PROPERTIES OF COAL

5.1 Sampling Issues

Assessment of coal resources and their efficient use require knowing the coal properties in sufficient

detail. The sample must be representative and large enough for all planned testing procedures and their replications. To ensure integrity of the analyses, the sample must be properly handled. The most widely accepted authority on sampling methods is U.S. Geological Survey (USGS) bulletin 1111-B. The procedures for taking a sample, reducing the particle size of the sample, and separating a smaller portion for later analysis are in ASTM procedures D2234, D2013, and BS 1017.

5.2 Proximate Analysis (ASTM D3172)

In this analysis, a coal sample is gently heated at 105°C in an inert atmosphere, and loss of weight is attributed to "moisture" in the coal (D3173). However, this loss is also due to the evolution of gaseous matter trapped in coal.

When loss of weight at 105°C stabilizes, coal is further heated at 750°C, again under inert atmosphere. The loss in weight under these conditions is assigned to volatile matter consisting of gases, organic oil, and tar, which normally is not further analyzed (D3175).

In the last step of proximate analysis, the remaining char is burned off, leaving behind ash (D3175, D388). By subtraction of moisture, volatile matter, and ash masses from the original sample mass, the fixed carbon mass is obtained (D3174).

Although not part of the standard proximate analysis, low-temperature oxidation of fixed carbon (and organic combustible material) at 120 to 150°C using oxygen-rich plasma is employed to ensure that the original minerals remain essentially unaltered. The resulting ash is then subjected to a wide range of analyses such as X-ray diffraction.

Proximate analysis is easy and quick to perform and is of great practical value in making empirical predictions of the coal combustion behavior. The volatile matter/fixed carbon ratio predicts how the coal will burn, that is, the flame characteristics and ease of ignition. Because high-rank coals contain less volatile matter than do low-rank coals, the former are more difficult to ignite and have a shorter flame than do the latter. This makes low-rank coals more suited for cyclone burners in which rapid intense combustion leads to maximum carbon use and minimum smoke emissions. Ash data generated by the proximate analysis allow engineers to predict the frequency and quantity of ash disposal. The proximate analysis data can be used to (1) establish the ranks of coals, (2) aid in buying and selling decisions, and (3) evaluate the need for beneficiation and the like.

5.3 Ultimate Analysis (ASTM D3176)

This is an elemental analysis limited to carbon, hydrogen, sulfur, nitrogen, and oxygen. Carbon and hydrogen are measured by burning the coal and collecting the resulting carbon dioxide and water (D3178).

Because of increasingly stringent environmental restrictions on SO_x emissions, particular interest has developed in the total sulfur part of the ultimate analysis. Sulfur determination (the Eschka method) (D3177) is based on conversion of all types of sulfur in the coal (e.g., pyrite, sulfates, sulfides, organically bound sulfur) to sodium sulfate. A coal sample is ignited with magnesium oxide and sodium carbonate. The resulting sodium sulfate is then converted to water-insoluble barium sulfate, which is filtered, dried, and weighed. There are two additional sulfur determination methods. In the bomb-washing method, sulfur is precipitated as barium sulfate from the oxygen bomb calorimeter washings. In the high-temperature combustion method, the sample is burned in a tube furnace and sulfur oxides are collected and quantified by titration. Forms of sulfur are determined by the D2492 method.

Nitrogen is usually determined by first liberating elemental nitrogen from the sample by the digestion method (Kjeldahl–Gunning), converting the elemental nitrogen catalytically to ammonia, and (finally) titrating the resulting ammonia with acid (D3179).

There are no relatively simple analytical methods for oxygen determination. The most commonly used method requires a neutron source such as a nuclear reactor. Neutrons are bombarded on the sample to convert oxygen into nitrogen-16, a very unstable isotope of nitrogen. Nitrogen-16 decays rapidly by emitting beta and gamma rays that are counted. Because most laboratories do not have access to a neutron source, oxygen content is calculated by subtracting the masses of other elements from the mass of the sample (D3176).

Chorine may also be included in the ultimate analysis. It is determined by either the bomb calorimeter or the Eschka method (D2361, D4208).

5.4 Heating Value or Calorific Value

The heating value of coal is measured by an adiabatic calorimeter (D2015). The procedure gives the "gross heating value." The "net heating value" is based on the assumption that all of the water resulting from

combustion remains in vapor form (D407). The heating value of a coal determines the amount of coal a power plant needs.

5.5 Other Chemical Analysis Methods

Since the 1970s, environmental concerns have led to increasingly restrictive levels of permissible emissions of some of the trace elements in coal. A procedure has been adopted by USGS, outlined in Table VIII, to analyze trace mineral matters. MAS, ICP/AES, and ICP/MS analyses are performed on ash produced at 525°C.

5.6 Physical, Mechanical, and Other Properties of Coal

5.6.1 Physical Properties

Most of the physical properties of coal discussed here depend on the coal orientation and history of the piece of coal. Properties may vary from one coal piece to another coming from the same seam or mine.

The specific electrical conductivity of dry coal is in the semiconductor zone, 10^{10} to 10^{14} ohm.cm, increasing with rank and temperature. Moisture in coal also enhances conductivity.

The dielectric constant also varies with rank, with a minimum at about 88% carbon. Polar groups in low-rank coal and higher electrical conductivity in high-rank coal contribute to their dielectric constants.

Magnetic susceptibility measurements indicate that the organic part of coal is diamagnetic, with traces of paramagnetic behavior resulting from the presence of free radicals or unpaired electrons.

Thermal conductivity and diffusivity of coal depend on pore and crack structure. Conductivity ranges from 0.23 to 0.35 $W/(cm \cdot K)$, and diffusivity ranges from 1×10^{-3} to 2×10^{-3} cm^2/s. At 800°C, these ranges increase to 1 to 2 $W/(cm \cdot K)$ and $(1–5) \times 10^{-2}$ cm^2/s, respectively. The increases are due to radiation across pores and cracks at higher temperatures. The thermal conductivity of coal is influenced by moisture content, the chemical and physical nature of the coal during reaction, and convective and radiant heat transfer within the particle. Below 400°C, thermal conductivity of coal has been measured in the range of $(5–8) \times 10^{-4}$ $cal/(cm \cdot s \cdot K)$.

The specific heat of coal is estimated to be in the range of 1 to 2 $J/(g \cdot K)$ at 20°C to 0.4 $J/(g \cdot K)$ at 800°C. The specific heat is affected by the oxidation of the coal.

5.6.2 Mechanical and Other Properties of Coal

These properties have a much more direct bearing on the operations of power plants or other coal processing units.

5.6.2.1 Density The true density of coal, which increases with carbon content or rank, is most accurately obtained by measuring helium displacement. Values of 1.4 to 1.6 g/ml have been reported for greater than 85% carbon coal. The bulk density (D291), typically about 0.8 g/ml, depends on the void fraction. It affects coal's storage, hauling requirements, and sizing for its conveyance.

5.6.2.2 Porosity Fine porosity of coal restricts the access of oxygen to the internal structure. This retards combustion rates and depresses burnout in power plant boilers. Porosity is the result of the random arrangement of organic macromolecules within coal. Total porosity of coal ranges from 0.02 to 0.2%, with no apparent trends with carbon

TABLE VIII

Methods Employed by U.S. Geological Survey

Elements	Methods employed
Hg, F	Wet chemical analysis
Cl, P	X-ray diffraction
Se	Atomic absorption spectroscopy hydride ASS
Na, Be, Cu, Li, Th, Zn, Co, Mn, Ni, V, Cr, Sc, Sr, Y	Induced coupled plasma/atomic emission spectroscopy (acid digestion)
Si, K, Ba, Al, B, Ca, Ti, Zr, Mg, P, and Iron oxides	Induced coupled plasma/atomic emission spectroscopy (sinter)
Ag, As, Au, Bi, Cd, Cs, Ga, Ge, Mo, Nb, Pb, Sb, Sn, Te, Tl, U	Induced coupled plasma/mass spectroscopy (acid digestion)

content. Porosity is often subdivided into macropore ($d = 300\text{A}^\circ$), intermediate pores ($d = 12$–300A°), and micropores ($d < 12\text{A}^\circ$). Micropore volume appears to be low for low-rank coals and high for coals with carbon contents between 74 and 80% and greater than 90%. This is one reason why low-rank coals burn more easily.

5.6.2.3 Equilibrium Moisture Content Equilibrium or inherent moisture (D1412) is the moisture-holding capacity of coal at 30°C in an atmosphere of 97% relative humidity. The organic reflux moisture test (ISO R348) has been used to determine the residual moisture in the prepared sample.

Total moisture or "as received" moisture is determined by a two-step procedure (D3302, D3173) involving surface moisture measurement, reduction of gross sample, and determination of residual moisture.

Higher total moisture leads to a lower heating value of the coal and lower flame temperature, and it lowers the plant efficiency. It also causes higher haulage costs per million BTUs and causes the power plant to purchase more coal. A number of processes have been patented to dry coal at the mine site before its shipment, but none of them has been commercialized, due partly to excessive capital requirements.

5.6.2.4 Ash Fusibility (D1857) The ash fusibility test provides the "melting point" of ash. Although empirical, the procedure requires strict adherence to ensure reproducible results. Ash fusibility data are critical to power plants because they are used to assess operational difficulties encountered in using the coal (e.g., slagging, loss of heat transfer rate, frequency of boiler shutdown).

Ash fusibility under oxidizing conditions tends to be higher than that under reducing or neutral conditions. In the procedure, the condition of the starting cone of ash is reported as it undergoes several physical changes as temperature increases. These include (1) initial (cone tip) deformation, (2) softening (height/base = 1.0), (3) hemispherical shape formation (height/base = 0.5), and (4) fluid (puddle) formation.

A related criterion, namely T_{250}, the temperature at which slag has a viscosity of 250 poise, depends on base/acid and silica/alumina ratios. The lower the base/acid ratio and the higher the silica/alumina ratio, the higher the T_{250} of the ash.

5.6.2.5 Ash Analysis This term is applied to the analysis of the major elements commonly found in coal and coal ash (D2795). Oxides of Si, Al, Fe, Ti, Ca, Mg, Na, K, and P are measured. Phosphorus oxide has importance in the coke used in steelmaking processes. Two other ASTM methods for ash composition based on atomic absorption are D3682 and D3683.

The ASTM ash analysis is widely used to predict slagging and fouling. However, the way by which ash is produced in the boiler is considerably different from the way by which it is produced by the ASTM procedure.

5.6.2.6 Free Swelling Index This index is determined by quickly heating a coal in a nonrestraining crucible (D720). The values are assigned from 0 to 9, with noncaking, nonswelling coals being assigned the value 0. The higher the FSI value, the greater the swelling property.

The FSI is not recommended for predicting coal behavior in a coke oven. The index is not deemed important for pulverized coal-fired boilers. Some units (e.g., retort stokers) form coke in their normal operation. For certain coals, the FSI values reduce while in storage, indicating coal deterioration and partial oxidation.

Gray–King and ROGA tests, employed in Europe, serve a function similar to that of the FSI test in the United States.

5.6.2.7 Washability A large part of mined coal is cleaned to reduce its mineral contents before it is sold. Washability tests are performed to predict the effectiveness of coal cleaning. This is a float–sink test in heavy liquids that generates various gravity samples that are analyzed for their heating values, ash and sulfur contents, and so on. Sometimes, efforts to lower ash content by washing are uneconomical.

5.6.2.8 Strength and Hardness These are important coal properties in mine stability and comminution. Various tests are available to estimate coal's compressive and shearing strengths and hardness. On the Mohs hardness scale, lignites range from 1 to 3, bituminous from 2.5 to 3.0, and anthracite from 3 to 4.

5.6.2.9 Grindability The Hardgrove Grindability Index (HGI) method is used to determine the relative ease of coal pulverization in comparison with a series of standard coals (D409). The data can be used to determine power and sizing of grinding equipment and its expected wear rate. For low-rank coals, subbituminous and lignite, the HGI is found to depend on coal moisture, which decreases as grinding proceeds.

5.6.2.10 Friability The breaking of coal into dust during handling, transporting, and pulverizing causes explosion hazards, control of which requires special sensors and control equipment. The most friable coal contains approximately 90% carbon. This point also corresponds to the maximum HGI and minimum Vickers microhardness values. Charcoal-like fusain tends to be soft and friable.

5.6.2.11 Slaking Slaking causes coal disintegration during storage due to coal drying. This is an important phenomenon for lignite and subbituminous coals but not for high-rank coals, as lignite and subbituminous coals have high moisture content.

5.6.2.12 Spontaneous Ignition Temperature of a coal pile builds up slowly if it is not turned over. This triggers spontaneous ignition, which is a serious hazard requiring monitoring and preventive measures. Coal particle size distribution and its oxygen content have a great influence on spontaneous ignition. Other important factors include pyrite content, oxygen circulation in the pile, moisture, and rank of coal.

5.6.2.13 Coal Petrography/Vitrite Reflectance Test Extensive use has been made of vitrite reflectance measurements (D2797, D2798) and reflectograms along with the physical microscopic components (D2797, D2799) to assess coking coals. Vitrinite reflectance limits data for various coal rank classes are given in Table IX.

5.6.2.14 Gieseler Plasticity Plasticity measurement (D2639) gives the coal's tendency to fuse or soften and reach a fluid state on heating during simulated coking stages.

5.6.2.15 Audibert Arni Dilatometer/Sole Heated Oven Determination The dilatometer measures the contraction and expansion of coal during carbonization (ISO R349). The corresponding ASTM test is called Sole Heated Oven Determination (D2014). These data are important in predicting whether coke can be removed during production without damaging the equipment.

5.6.2.16 Other ASTM Tests for Coal Table X lists other ASTM tests that are relevant for coal characterization.

TABLE IX

Vitrinite Reflectance Limits Taken in Oil versus Coal Rank Classes

Coal rank	Maximum reflectance (percentage)
Subbituminous	<0.47
High-volatile bituminous	
C	0.47–0.57
B	0.57–0.71
A	0.71–1.10
Medium-volatile bituminous	1.10–1.50
Low-volatile bituminous	1.50–2.05
Semianthracite	2.05–3.00 (estimated)
Anthracite	$>$ 3.00 (estimated)

6. FRONTIERS OF COAL RESEARCH

6.1 Advanced Instrumental Methods of Measurements

The advanced measurements listed here overcome some of the limitations of the standard methods by providing more detailed and accurate characterization of specific coal. These methods can be grouped into (1) composition, (2) combustion characteristics, and (3) tests for improved correlations.

6.1.1 Composition

Table XI lists some of the advanced methods that have been used with some success, but much work still needs to be done to ensure their reliability and to assess the limits of their applicability. This is a

TABLE X

Other ASTM Tests for Coal

Test	ASTM method	Parameters	Plant performance
Calorific value	D3286, D2015	—	General combustion
Fineness	D197	75–1180 micron sieve	Burner
Sieve analysis	D410	3/8- to 8-inch sieve	Coal handling/ storage
Drop–Shatter test	D440	Friability	Pulverization
Tumbler test	D441	Friability	Pulverization
Dustiness	D547	Dustiness indices	Handling
Sulfur in ash	D1757	Sulfur	SO_x pollution

TABLE XI

Advanced Coal Composition Measurements

Method	Parameters
Electron microscopy	Ultra-fine granular structure
	Pore structure
X-ray diffraction	Size distribution of aromatic ring systems
	Diameter and thickness of lamellae
	Mean bond length
	Mineral phase evaluation
Mass spectroscopy	Molar mass and formulae
	Analysis to determine types of hydrocarbons
	Carbon number distribution
	Trace elements
Nuclear magnetic resonance	H_{ar}/H and C_{ar}/C ratios
	Distribution of isotopic tracers
Electron spin resonance	Stable free radicals
	Other species with unpaired electrons
Infrared absorption	Functional groups (e.g., OH, CH_{ar})
	Minerals
Ultraviolet–visible absorption	Difficult to apply to whole coal samples but can be used to identify components in extracts
Electron spectroscopy for chemical analysis	Elemental distribution and chemical state of surface
Optical emission spectroscopy	Elemental analysis
	Single-element and survey analysis
	Major, minor, and trace element analysis for metals and semi-metals
	Applies to coal ash only
X-ray fluorescence	Inorganic element analysis
Atomic absorption	Precise quantitative determinations of metals and semi-metals
	Single element analysis for minor and trace constituents
Mossbauer spectroscopy	Iron compounds and association with sulfur
Scanning electron microscope automatic image analysis	Size, shape, and composition of minerals in coal
Neutron activation analysis	Elemental analysis
Spark source mass spectroscopy	Semiquantitative elemental analysis of coal ash
Inductively coupled plasma spectroscopy	Quantitative multi-element analysis of coal ash
Electron microprobe analysis	Elemental analysis of micrometer-size areas
Thermometric techniques	Chemical characterization of coal ash
Optical microscopy	Identification of minerals in coal or coal ash
Ion microprobe mass analysis	Isotopic characterization of minerals or macerals
Extended X-ray analysis fine structure	Chemical environment of an atom

Electric Power Research Institute, Palo Alto, CA; Stanton, R. W., and Finkelman, R. B. Coal quality. *In* "Energy Technology and the Environment" (A. Bisio and S. Boots, Eds.), Vol. 1. John Wiley and Sons, New York.

dynamic area because new methods and applications are being developed continually. The methods are used to analyze microstructure, trace elements, organic material structure, and mineral matter composition and structure. They make it possible to characterize coal with more details and better accuracy. However, they require expensive instrumentation and highly skilled personnel to operate.

6.1.2 Combustion Characteristics

Although proximate analysis provides key coal data, it provides no data on devolatalization and combustion characteristics. These data are provided by

thermogravimetric analyses. Four important methods needed to design boilers and assess performance of existing boilers are the following:

- Burning profile (Babcock & Wilcox)
- Volatile release profile (Babcock & Wilcox)
- Thermogravimetric analysis of char (Combustion Engineering)
- Drop tube furnace system (Combustion Engineering)

6.1.3 Tests for Improved Correlations

Procedures have been developed to improve the correlation of coal properties with coal's performance in power plant systems. These include analysis of physical separation of pulverized coal (pulverizer wear and slagging), analysis of alkalies in coal ash (fouling), sintering strength of fly ash (fouling), free quartz index (pulverizer wear), and continuous coal grindability (pulverizer capacity).

6.2 Active Areas of Coal Research

Active coal research areas worldwide include the following:

- Advances in pollution controls for NO_x, SO_x, hazardous air pollutants (HAPs), and particulate matter
- Development of economically viable mercury emissions control technologies
- Advances in coal liquefaction and gasification
- Advances in power generation systems
- Studies in greenhouse gases sequestration
- Advanced studies to correlate physical structure, petrography, and properties
- Advanced processing studies (e.g., management of coal use by-products, coal chemicals, pyrolysis, and coal–oil–water interaction)
- Studies of coal gasification fundamentals

6.3 Carbon Sequestration

Major activities are under way worldwide to find economically viable means of sequestration of carbon dioxide, a major greenhouse gas. Although its emissions from fossil fuel power plants are only approximately 39% of its total emissions in the United States (32% from coal-fired plants), sequestration of these power plant emissions is the focus of research and development and analysis because they are localized. CO_2 use for enhanced resource recovery is being considered along with the use of underground saline formations, possibly oceans, and mineral carbonation for its sequestration. The United States has not signed the International Climate Change agreement (Kyoto Protocol). Nevertheless, its government has undertaken a 10-year demonstration project, "FutureGen," to create a coal-based zero-emission power plant.

6.4 Computational Methods

In support of experimental research programs, much work continues to be carried out in coal-related computational methods, including the following:

- Constitutive laws of multiphase flow
- Process simulation and modeling (e.g., black liquor gasification, circulating and spouted beds, spontaneous combustion, oxidative pyrolysis, coal–biomass co-firing, char gasification)
- Computational fluid dynamics in support of process design and optimization
- Three-dimensional modeling of subsurface conditions (e.g., simulation of coal bed for methane recovery)
- Engineering design models (e.g., hydroclone, circulating fluidized bed, transport reactors)
- Modeling for pollution control (e.g., NO_x formation)

Glossary

coal preparation A process that includes not only crushing and breaking methods (coal pretreatment) but also all the handling and treatment methods necessary to remove impurities and prepare coal for commercial use.
coal pretreatment A process consisting of breaking, crushing, and screening run-of-mine coal to produce coal with a predetermined top size.
coal screening A method to separate coal particles by passing them through a series of screens, of decreasing size.
coal sizing A process to separate raw coal into various particle sizes, either by screening or by other classification methods.
coal spontaneous combustion The process whereby coal ignites on its own, because the rate of heat generation by the oxidation reaction exceeds the rate of heat dissipation.
coal storage The storage process to accomplish various objectives: (1) to reclaim coal promptly and economically, (2) to carry-out blending/homogenization in order to achieve coal with uniform or desirable characteristics, and (3) to store various coals whose price and market demand vary seasonally, thus maximizing profits.
dead storage of coal The concept that coal is not immediately accessible because it is in a compacted pile to prevent weatherization and some means is needed to reclaim the coal.
live storage of coal The concept whereby stored coal is immediately accessible by the principal means of reclaiming in coal piles or by gravity flow in silos.
run-of-mine (ROM) coal A heterogeneous material that is often wet and contaminated with rock and/or clay and is unsuitable for commercial use without treatment.
unit train A railroad technique to efficiently transport coal on a predetermined schedule, by using a dedicated train and the associated equipment for loading and unloading.

This article deals with the coal management system that encompasses coal preparation, storage, and transportation. Coal must first be transported from the mines to the point of consumption, often an electric power plant. Railroads are the predominant form of transportation, sometimes in cost-effective "unit trains." Barges and ships are the other major mode of coal transportation, with trucks seeing limited use due to higher costs. At the preparation plants, the coal undergoes preparation processes that remove rocks, noncombustibles, and other impurities from run-of-mine coal and also crush and size the coal for its end use. After preparation, coal is usually stored. Since even prepared coal is not homogenous, various methods are employed to ensure that the coal properties remain fairly uniform when burned. Also, coal will weather and oxidize, changing its properties, and in certain cases, coal can self-ignite, unless precautions are taken.

1. COAL TRANSPORT

Coal has relatively low energy content per unit weight and competes on the market with other fuels as a low-cost boiler fuel. Consequently, a low-cost and efficient delivery system based on many alternatives is essential to maintain its competitiveness.

Based on statistics from Consol Energy, the modes of coal transportation in the United States are distributed as follows: 62% by rail, 12% by truck, 16% by barge and/or vessel, and 10% by conveyor belt or slurry pipeline; these numbers were presented at a coal and power training course in July 2000.

1.1 Rail Transport

Railroads are very well positioned to transport U.S. coals from the mines to end-use destinations, such as utility and industrial plants. Their dominance as the major carrier of coal is expected to continue. The U.S. railway system has 126,682 miles of Class 1 track, 47,214 miles of Class 2 and 3 track, and 1.2 million freight cars to carry all commodities, according to data from Consol Energy presented by Robert J. Schneid at the above-mentioned coal and power training course.

The trend in the industry is toward a consolidation through state ownership or a merger of privately owned systems. Dominant companies include the following: in the West, Union Pacific and Burlington Northern Santa Fe, and in the East, CSX and Norfork Southern. Table I gives an insight into the railroad consolidation of U.S. companies, with Stan Kaplan of PA Consulting Group as the source of information in year 2002.

Several strategies have been considered to improve railroad services and profitability: (1) cost cutting and productivity improvements; (2) merger; (3) differential pricing; (4) diversification; (5) new services; and (6) investment.

Strategies (1), (2), and (4) have exhausted their potential. Diversification is being abandoned. Cost cutting may be reaching a point of diminishing returns. Mergers have not proved to be a financial success. As a result, the focus of the railroad industry is on improved intermodal and other truck-competitive services, but not for coal as a high-priority service. The tension between demands for shipment at low rates with high-quality services and objectives to improve profitability will persist.

TABLE I

Consolidation of U.S. Railroad Companies

Old companies	New company
Seaboard Coast line	CSX
Chessie System	
Conrail	
Conrail	Norfolk Southern (NS)
Norfolk & Western	
Southern Railroad	
Missouri Kansas Texas	Union Pacific (UP)
Denver & Rio Grande Western	
Southern Pacific	
Union Pacific	
Missouri Pacific	
Chicago North Western	
Santa Fe	Burlington
Burlington Northern	Northern Santa Fe
Kansas City Southern	Kansas City Southern
Illinois Central Gulf	Canadian Pacific

Source. Adapted from Kaplan (2002).

In general, railroads have offered three major types of service to transport coal: (1) multiple-carload, (2) trainload, and (3) unit trains. Another less important type of service is single-carload rates for low volumes of smaller mines. Multiple-carload rates ranging from as few as 5 or 10 cars to as many as 100 cars are usually significantly lower than single-carload rates. Trainload rates are characterized by large minimum-volume or car requirements, since they move from origin to destination as one unit. Not meeting the annual volume requirements could lead to a higher penalty rate. Unit train rates usually have the lowest rates possible; the difference between them and trainload rates is that unit train rates use dedicated equipment and operate on a regular schedule.

The unit train (approximately 100 to 150 cars) came into existence in the early 1960s in response to other competitive alternatives in the transportation industry. Whereas most unit trains consist of 100 cars, they can also operate with as few as 20 cars. For a train unit of 100 to 150 cars, the payload would range from 10,000 to 15,000 tons and require four to six locomotives per train rated at 4000 to 5000 hp each. If lightweight aluminum cars are used, a unit train of 100 to 120 cars, carrying 121 tons (110 tonnes) each, could move more than 14,000 tons (12,700 tonnes) in total.

In terms of motive power for unit trains, five or six earlier diesel locomotive models (3000 hp) would be required to move a train of 100 to 125 cars. In the 1990s, distributed power became the most efficient method of transporting coal by rail. In this system, a remote-controlled engine is placed in the middle of the train. In the early 2000s, two or three modern diesel electric locomotives (6000 hp) based on microprocessor and alternating current motor technology could do the work of five earlier models. In addition, advances in control technology, called microwave centralized traffic control systems, have facilitated the safe movement of trains with minimal between-train clearance, therefore leading to significant increases in moving capacity.

1.1.1 Loading and Unloading Railcars

Typical coal railcars can carry 80 to 125 tons per car and the average load is 100 to 110 tons. Two types of

railcars are in service: the solid bottom gondola and the hopper car.

A rotary dump system can handle gondola and hopper cars, whereas the undertrack pit can handle only hopper cars with bottom-opening doors.

The selection of the unloading method requires an evaluation of several trade-offs, such as the following: (1) gondola cars are the least expensive, need minimal maintenance, and can be completely unloaded with minimum coal hang-up but do require an expensive rotary dumper with the capability to accurately position the cars; and (2) hoppers (or bottom-dump cars) are more expensive and require more maintenance than the gondolas, due to the gate mechanism, but they can be unloaded more quickly on a relatively inexpensive track hopper. In addition, hopper cars are more difficult to unload under freezing conditions.

In addition to loading and unloading the coal, the issue of windage losses is frequently overlooked. Windage losses, i.e., coal blown out by wind from open-top cars, cause economic loss and environmental concern. One solution is a lid system, such as a flip-top lid, to control windblown loss, reduce dust, and prevent additional moisture from penetrating the coal, thus reducing the potential for freezing. Frozen coal is a troublesome problem related to unloading coal because the exposed top surface, the size plates of the car, and the surfaces of the sloped hoppers could be frozen. Several methods to thaw the cars are available, ranging from bonfires and oil-burning pans to sophisticated sheds. Treating the car sides and bottoms of the cars with oil can minimize freezing and ease the coal unloading process.

In terms of loading systems, three types of trackage are commonly used for unit trains. These are (1) the loop or balloon track, (2) the single track that is situated above and below the loading station, and (3) the parallel tracks that allow loading on both tracks. The loading system consists of locomotive, car haul, tripper conveyor, and hydraulic ram. The locomotive moves the cars in one pass under the loading station. The car-haul system moves two strings of cars in opposite directions on parallel tracks under two loading stations. The tripper conveyor system moves two-way loading chutes over two stationary parallel strings of cars. The hydraulic ram system moves the cars into loading position, after the locomotive has been removed.

In terms of unloading systems, there are two major types: the rotary dump and the undertrack pit. The rotary dump system handles the rollover type of car (hopper or gondola design) and the undertrack pit handles bottom-up cars.

1.2 Transport by Barge and Ship—Water Transport

The U.S. Great Lakes and inland waterway systems are a very valuable asset for moving coal and other commodities, as shown in Table II. In addition, the U.S. river network is connected to the Gulf Intracoastal Waterway, allowing highly efficient barge and lake carrier services. The Great Lakes facilitate shipments to the export market but have seasonal limitations. The inland waterway system is characterized by open top barges and the size of the tow. The tow is a function of the width and depth of the respective river and the configurations of its locks and dams.

1.2.1 Barge Transportation—Loading and Unloading

Barge transportation offers a lower cost alternative to railways for the majority of power plants and coke ovens that are located on inland waterways. In this waterway system, 25,000 miles of navigable rivers, lakes, and coastlines and a system of 192 locks and dams are ideal means for moving coal over long distances. Consequently, barge transportation could be considered competitive because it requires less fuel, the infrastructure is already in place or needs only to be updated, and barges carry large loads. A jumbo barge can carry an amount of coal equivalent to 15 railcars or 58 truck loads.

In addition, barge transportation is a good example of an intermodal carrier. With mines near a navigable waterway, several combinations are possible: (1) for short distances, trucks or conveyors

TABLE II

U.S. Riverways

Characteristics
• River network with portion highly navigable (depth of 9 ft or more)
• Connects with the Gulf Intracoastal Waterway
• Spans the country from Pennsylvania and West Virginia to the east and Minnesota and Wisconsin to the north
• Alabama and Florida on the Gulf Coast to the southeast
• Louisiana and Texas on the Gulf coast to the southwest
• Great Lakes allows heavy freight distribution
— From Illinois, Wisconsin, and Minnesota to the west and to Ohio, Pennsylvania, and New York to the east
— Access for exports to Canada through the St. Lawrence Seaway to overseas customers (Europe and Mediterranean region)

Source. Adapted from Lema (1990).

are used to transport coal to a barge terminal (for instance, up to 10 miles for conveyors and 30 or more miles for trucks, away from the mine); and (2) for longer distances, railroads can be used to transport coal to the river terminal (for instance, over 100 miles away from the mine).

However, the economics of barge transportation is affected by the circuitry of the waterways, their nature, the weather, and market conditions. Barge size is subject to the size, number, and condition of the locks. Low water levels and frozen rivers can halt shipment. In shipment, coal competes with other commodities to be transported and backhaul is a good solution to reduce coal rates.

To increase productivity, barge size has increased from a standard 1000-ton capacity to the jumbo-sized barge (9 ft draft) capable of carrying 1400 to 1800 tons. Usually, the jumbo-sized barge would carry 1800 tons, which enables the tow to move approximately 72,000 tons of coal. This is comparable to the loading of five unit trains. Towboats have pushed up to 48 jumbo barges on the Lower Mississippi River where there are no locks, but 40 barges are more common. In other instances, 15 jumbo barges (as maximum) are more common for a single lock, such as the 1200 ft lock on the Ohio River.

In the United States, five categories of loading plants are used, depending on the loading requirements. These categories are as follows:

1. The simple dock, which is used only to a small extent, mostly by small operators and for temporary facilities. It depends on a relatively stable water level. The trucks dump directly into the barges or into a fixed chute.
2. The stationary-chute system has declined in popularity; it is relatively economical and has the same disadvantages as the simple dock system (sensitive to water level fluctuations).
3. The elevating-boom system is commonly used; it is very flexible and adjustable to variations in water levels. It can handle high capacities. The common features of this system found in most plants are the hinged boom, the pantograph trim chute, and the extensive dock area.
4. The spar-barge system is suitable for rivers with fluctuating levels. It has two essential components: the floating spar barge and the shuttle. The floating spar-barge (as floating dock) contains the loading boom and the barge-positioning equipment. The shuttle or retracting loading belt leads to the spar-barge.
5. The traveling-tripper system is the method used to stockpile coal at large power plants; it is applied to load barges. The barges are held stationary by a barge-mooring system. The traveling tripper (as a movable loading point), with a reversible traverse shuttle belt and telescoping chutes, discharges coal in the barges. This barge loading method can load eight barges at a time, four on each side.

Regarding barge unloading, coal operators usually receive barge sizes and types that will accommodate their barge unloading systems. Earlier, barge unloading was performed using whirler-type cranes with clamshell buckets. Most barge coal is still unloaded by clamshell buckets that are mounted on either stationary straight-line-type towers or on moving tower barge unloaders; in the latter case, the tower is mounted on rails, it straddles the dock belt, and the barges remain stationary.

1.2.2 Ocean Transport

The U.S. export coal market has primarily been exporting coking coal for use in steel production overseas, but the market for steam coal has developed at a fast rate. Consequently, modern vessels and modern or upgraded docking facilities (e.g., larger and faster processing capabilities) are needed.

In addition, several possible schemes to transport steam coal from the mine to overseas markets have been considered. These schemes are based on coupling ocean transport with pipeline or railroad transport and moving the coal in either dry or slurry form. The first scheme involves transportation from the mine to the preparation plant (size reduction, storage, and pumping), to the pipeline, and to the ship, and from the ship to the pump station/pipeline and to the dewatering plant/thermal drying and to the end-use. The second scheme is similar to the first scheme, except that the coal is dewaterized before being loaded into the ship and on the other shore the coal is turned into slurry again before being shipped through a pipeline. In the third scheme, the coal is reduced in size and washed before it is loaded on the railway. The railroad brings the coal to a maritime terminal, where on the other shore it is again transported by rail to a grinding plant and to the end-use destination.

Coal is exported from the United States through several major coal loading facilities located in Baltimore (Maryland), Philadelphia (Pennsylvania), Mobile (Alabama), Jersey City (New Jersey), Charleston (South Carolina), New Orleans (Louisiana), Newport News (Virginia), and Norfolk (Virginia).

The last two facilities have undergone extensive modernization and new construction to satisfy the increasing demands for export coal. Coal is now shipped in modern vessels, such as Panamax vessels (60,000 dwt [deadweight tonnage]) and Capesize carriers (200,000 dwt or greater).

1.3 Truck Transport

For short distances, trucks play an important role in transporting the coal (or coke to foundries) to a stop station before the coal is shipped to its final destination or to mine-mouth power plants. Due to routing flexibility and low capital investments, trucks can economically move coal approximately 100 miles (at most) one way in relatively small batches. Trucks are used predominantly for short-distance hauls of 50 miles or less. The size of the payload varies according to state gross vehicle weight limitations; for instance, the payload is 20 to 40 tons per truck east of the Mississippi River and 40 to 60 tons per truck west of the Mississippi River.

Basically, there are two types of off-highway trucks: the rear-dump truck and the bottom-dump truck. In a conventional rear-dump truck, the body is mounted on the chassis and lifted up by means of a hydraulic hoist system. The bottom-dump truck, as indicated by its name, dumps material through the bottom and is not well suited to hilly or rough-terrain operation.

Rear-dump trucks have been tested in sizes up to 350 tons; however, 200 tons is considered a large truck and 100 tons is viewed as a standard off-highway truck. Typically, rear-dump trucks carry approximately 25 to 50 tons. Bottom-dump trucks are normally in the range of 35 to 180 tons.

Trucks of up to 85 tons are usually equipped with diesel engines having power shift transmission and torque converters. In the range of 85 to 100 tons, the diesel engine of these trucks could transmit power to the drive wheels by either mechanical or electrical means. At 100 tons and over, the diesel engine drives a generator that produces electricity for electric traction motors that move the wheels.

1.4 Transport by Slurry Pipelines

Pipelines carrying solids such as coal, iron concentrate, and copper concentrate follow the same process: (1) the solids are ground to a fine size, (2) mixed with a liquid vehicle such as water, and (3) pumped through a buried steel pipeline.

Although advantages related to economics, the environment, and simplicity of operation for gas and liquid pipelines are applicable to solid-carrying pipelines, only a few coal pipelines have been built: two in the United States (108 and 272 miles long) and one in the former Soviet Union (38 miles long).

Few coal pipelines have been built because several barriers exist, including long distances, high volumes required, inadequate rail service, and long-term commitment (20 years).

Slurry pipe technology is not new:

1. There are conventional coal water slurries (CWS) and coal water fuels (CWF). In the CWS case, pipelines ship coal at a ratio of approximately 50:50 coal and water by weight in a turbulent flow. In addition to water, other types of fluids can be considered vehicle fluids, such as oil, liquid carbon dioxide, or methanol. The carbon dioxide can be used for enhanced oil recovery, after separation from coal. In the CWF case, fuels are a mixture of coal and water, flowing in a laminar regime, and dry coal weight varies from 60 to 75% depending on the coal type and on the stabilizing additives.
2. In the slurry preparation process, coal slurry suitable for transportation is produced by performing size reduction (crushing and grinding) and chemically treating (corrosion inhibition and thinning) it, if needed, to improve the final characteristics of the product. Two parameters are important for controlling the slurry: density and the product top size. The slurry concentration affects the friction loss of the pipeline and the critical velocity of the flow. The top size is directly related to potential pipeline plugs caused by large settling particles (safety screens are used as countermeasures).
3. To be suitable for transportation, a compromise is made between pumpability and dewatering requirements. If particle size is fine, pumpability is enhanced, but if particle size is too coarse, dewatering at the destination is affected because the slurry must be pumped at higher flow rates to maintain a suspension.
4. To inhibit corrosion in the pipeline, chemical agents, such as sodium dichromate, are added to form a film on the wall, or oxygen scavengers, such as sodium sulfite, are added to prevent attack by dissolved oxygen.
5. A test loop is normally included in the system as the final control. All slurry must pass through it before entering the pipeline. Any increase above the specified limits of pressure drop would indicate the formation of a bed of fast-settling particles in the test loop.
6. For dewatering slurries, continuous vacuum filters and centrifuges are used. For the first U.S.

pipeline, dewatering was performed by thickening, vacuum filtration, and thermal drying.

7. Although the water requirements for coal slurry pipelines are significant, they normally are at approximately 15% of the required power plant makeup water; therefore, the slurry water is commonly used as part of the makeup water in conventional practice.

8. Some advanced transport modes have been considered based on pneumatic and container concepts, e.g., capsules in pipelines. The capsules may be rigid (cylinders or spheres of the cast material), semirigid (flexible container with the material inside), or paste plugs (material mixed with a liquid not miscible with the carrier liquid). These concepts have not yet been developed for commercial application.

1.4.1 Commercial Projects of Coal Slurry Pipelines

Consolidation Coal Company built the first major U.S. coal slurry pipeline from Cadiz, Ohio, to Cleveland, Ohio. This 108-mile pipeline was successful but was mothballed in 1963 after 6 years of operation. The second successful U.S. pipeline is the 273-mile-long Black Mesa pipeline built in 1970 in Arizona. The pipeline has a 5 million ton/year capacity and transports pumped coal slurry (47% solids by weight) through an 18 in. pipe. The Black Mesa pipeline is available 99% of the time. After being "dewatered" by centrifuges, the coal cake from the pipeline is used as fuel in two 750 MW power plants in southern Nevada.

1.5 Economics of Coal Transport Alternatives

Cost comparisons of coal transport alternatives on identical bases are not available. Assuming the best conditions is not appropriate because transport costs are strongly influenced by several factors, such as terrain conditions, sunk cost elements (such as existing railway infrastructure), and inflation.

In the past, several studies have provided some trends:

1. A study performed by Ebasco has indicated that pipelines are most economical for long-distance and high-quantity applications. In this study, the different forms of transporting coal energy have been considered, e.g., by rail, pipeline, rail–barge combination, and extra high voltage power lines, the assumptions being transportation distances of 500–1500 miles and power plant sizes of 1600–9000 MW. If water transport is available, the combination of rail–water transport is competitive, assuming that existing tracks are utilized.

2. The U.S. Department of the Interior conducted a study comparing costs based on the premise that 25 million tons of coal slurry was transported for 1000 miles. It led to the following generalizations:

- Water transport is almost always the most inexpensive way to move coal; it usually involves coupling it with another transport mode depending on the distance between mine and riverway—rail, pipeline, and trucks are possible.
- Truck transport is not competitive with rail or pipeline for high tonnage and long distances (e.g., more than 50 miles and 1 million tons per year). Trucks are the preferable mode for short distances from mine mouth to a terminal (preparation plant or en route to a final destination).

3. A U.S. Department of Energy-sponsored study by Argonne National Laboratory, involving Williams Technologies Inc., identified the potential for U.S. coal exports to the Asian Pacific Basin. High inland transportation costs combined with a relatively low heating value of western coal had resulted in coal prices exceeding world market levels. In a portion of this study, Williams considered how to lower the transportation costs of western coal to the Pacific Basin. The first target is a price of less than $2.05 per MBtu and the second target is $2.9 to $3.25 per MBtu. Four U.S. coal regions/states considered as sources were Four Corners, Utah, Powder River Basin, and Alaska. For Four Corners and Utah, the coal water slurry systems and the coal water fuel systems would go to Stockton, California, and Los Angeles, California; for Powder River Basin, pipeline delivery will go to Puget Sound. For Alaska, two routes were evaluated: (1) from Nenana to Cook Inlet and (2) from Beluga to Tyonek Dock. The findings of the study indicated that Four Corners and Utah, being close to existing ports, provide opportunities for both conventional coal slurries and coal–water fuels, whereas Powder River Basin offers potential for coal–water fuels.

In summary, railroads and slurry pipelines are usually the choices for high tonnage and long distances. Normally, railroad distances are longer than pipeline distances; railroads outperform pipelines when no track must be built, but if new trackage is needed, pipelines are more economical. If inflation is considered, the percentage of transport tariffs subject to inflation is higher for railroad than for pipeline.

2. COAL PREPARATION

Coal preparation is defined as the process of removing the undesirable elements from run-of-mine (ROM) coal by employing separation processes to achieve a relatively pure, uniform product. These separation processes are based on the differences between the physical and surface properties of the coal and the impurities. Coal preparation would include not only sizing (crushing and breaking), but also all the handling and treating techniques necessary to prepare the coal for market. Table III gives a general overview of the characteristics of different coal types offered in the market.

ROM coal is usually a heterogeneous material with no size definition and can consist of pieces ranging from fine dust to lumps; it is often wet and contains rock and/or clay, making it unsuitable for commercial use, such as in combustion. The objective of coal preparation, in terms of combustibility, is to improve the quality of the coal by removing these extraneous noncombustible materials leading to:

1. Ash reduction (lower particulates, reduced ash handling at power stations)
2. Sulfur reduction (lower SO_x emission at power plants)
3. Carbon consumption and NO_x emission reduction (at power plants)
4. Reduced transportation costs per unit of heat
5. A guaranteed consistent heat value (improved plant efficiency) to meet customers' requirements
6. For optimum calorific value (heating value) consistent grindability, minimal moisture, and ash variability, such as in the area of power generation
7. Economical design and operation of steam-generating equipment

TABLE III

Characteristics of Coal Types

Coal type	Characteristics
Lignite	4500 to 7000 Btu/lb (2500 to 3890 kcal/kg) High moisture (25%) with ash
Low-grade bituminous	5000 to 9000 Btu/lb (2780 to 5000 kcal/kg) High ash (+20%) with moisture (10%)
Thermal bituminous	8000 to 12,000 Btu/lb (4450 to 6675 kcal/kg) Medium ash (10 to 12%) with moisture (9%)
High-grade bituminous	+12,000 Btu/lb (+7000 kcal/kg) Low ash (<7%) with low moisture (<8%)

Source. Adapted from Sharpe (2002).

2.1 Size Reduction

Pretreatment, or size reduction, is a common term used to include the processes of breaking, crushing, and screening ROM coal to provide a uniform coal feed with a certain predetermined top size. The number of stages in the size reduction process will depend on the end use of the coal. For instance, in power generation, the number of stages is more than the number needed for coking coal. In breaking the coal, four types of equipment are available: rotary breakers; roll crushers; hammer mills (ring mills), and impactors.

Before describing these four systems, the following terms frequently used in pretreatment should be defined:

1. The top size (or upper limit) of the crushed material is the smallest sieve opening that will retain a total of less than 5% of the sample (ASTM D431);
2. The nominal top size is the smallest sieve opening that will retain a total of 5 to 20% of the sample;
3. The reduction ratio is defined as the ratio between feed top size and product top size;
4. The Hardgrove grindability index is the index determined after passing 50 g of 16×30-mesh dried coal in a standardized ball-and-race mill and sieve this sample through a 200-mesh sieve (ASTM D409) to determine the amount of material going through it.

The four types of equipment for size reduction of run-of-mine coal ([2] and [3]) are described as follows:

1. The rotary breaker causes the coal to break by lifting it to a given height and dropping it against a hard surface. It is a cylindrical unit (operating at low speed) that subjects the coal particles on the liner to undergo centrifugal motion; the liners of the rotary breakers are screen plates that allow peripheral discharge of the properly sized material along the length of the rotary breaker.

2. The roll crusher is the workhorse of coal size reduction to shear and/or compress the material. It is compactly engineered in the form of a rotating roll and a stationary anvil (single roll crusher) or two equal-speed rolls (double roll crusher) rotating in opposite directions.

3. The hammer mill is the most commonly used coal pulverizer. In this device, feed coal is impacted

by rotating hammers and further by grid breaker plates. Usually a high portion of fines is produced. A ring-type hammer mill (rings instead of hammers) would minimize the amount of fines in the product.

4. The impactor impacts the coal, which is then projected against a hard surface or against other coal particles. The rotor-type impact mill uses rotors to reduce the size of the material; the shattered material rebounds in the rotor path repetitively until the product is discharged from the bottom.

The sizing process usually follows the crushing process. The three major reasons for sizing the coal are to separate coal into various sizes for marketing, to feed washing and dewatering units, and to recover the solids used to control the specific gravity in these washing devices. Sizing of the coal is performed by screening or classification.

The most common screening method includes bringing each particle against an opening or aperture where the particle will either pass through or be retained. Several screen configurations have been developed, such as the following: (1) the Dutch sieve bend is a fixed screen with no moving parts and is situated at a level lower than the feed, (2) the Vor-Siv, developed in Poland, and (3) the loose-rod deck, developed in the United States by Inland Steel Corp., which consists of steel rods set at a suitable pitch to create the screening aperture.

Although most sizing of coal is performed with screening devices, classifiers are also in use. Classification refers to achieving size separation by exploiting different flow rates through a fluid. It includes dry classification and wet classification. Dry classification uses air as the ambient fluid and involves higher fluid volumes and higher velocities than those found in wet classification.

2.2 Cleaning Methods

Coal preparation has been evolving for more than a century and the core of most of the process development work is in the area of separating the impurities from the coal, utilizing the physical difference in specific gravity between the coal and the rock impurities. An overview of the different coal cleaning systems is provided in Table IV.

2.3 Coal Dewatering and Drying Systems

After the cleaning process, the coal retains a significant amount of moisture, which can have negative effects on its transport and handling and its calorific value. Therefore, there is a need to reduce the moisture content by either dewatering or drying. Dewatering means mechanically separating water from the coal and drying means separation by thermally evaporating water.

Table V outlines the different technologies used in the dewatering process or in the drying process of coal.

2.4 Arrangement of a Coal Preparation Facility

Given all the above-mentioned techniques for preparing the coal, it is useful to elaborate on the flow of coal within a coal preparation facility through the following stages:

1. Size reduction of coal
2. Sizing of the coal to match the proper feed sizes with the various types of coal-washing equipment
3. Washing the coal
4. Dewatering the products
5. Recycling the process water (treatment/reuse)
6. Blending the product streams into storage
7. Loading out the marketable products

Table VI gives an example of the flow of coal through a coal preparation facility and the equipment involved in the subprocesses.

3. STOCKPILES

3.1 Stacking and Reclaiming of Stockpiles

Coal pile management, an integral and vital element in the coal chain, is carried out at coal mines, coal preparation plants, the transshipment sites for export/import of coal, and end-user sites; end users usually include power plants, iron and steel plants, coking plants, and cement plants. Since these "stockyards" tie up capital with no return on investment, the owners of these plants are interested in optimizing coal inventories to minimize this capital and addressing the issues of stockpiling of coals. The significant issues are stock size, stock pile turnover period, and availability of cheaper coals on the international market. All of these issues involve the best strategy for blending coals with the accuracy required by the customer and just-in-time delivery. Coal pile management includes examining why stockyards are used and how they are designed/erected and operated in compliance with environmental regulations.

TABLE IV

Coal Cleaning Systems

Beneficiation method		Systems
Jigs		• Predominant washing technique throughout the world, as pulse water separators • Two jigs known as Tacub jig (with uniform air distribution underneath the screen) and Batac jig (with improved air valves and control mechanism in addition)
Cyclones	Dense-medium cyclonic separator	• First patent in 1958[a] using metal chloride salts, as first dense-medium cyclone • Dense-medium cyclones effect sharper separation between coal and impurity over a wider specific gravity range than jigs • Several variations (Japanese Swirl cyclone, three Russian cyclone models, British Vorsyl cyclone, and the Dynawhirlpool cyclone)
	Water-only cyclones	Not regarded as dense-medium cyclone that has a much greater included angle in the cone—up to 120°—and a longer vortex finder • Constant velocity separators • Do not achieve a separation as sharp as dense-medium cyclones; nevertheless, provide clean coal products free of high-ash materials in all but the finest sizes • Simplicity/small space requirements/economical operation attributes lead to adoption of water-only cyclones as a rougher device for decreasing the load on downstream cleaning units
Concentrating tables		• One of the oldest most widely used cleaning devices for washing coals • Configurations of two-deck and four-deck systems • Potential to remove pyritic sulfur down to a certain size
Froth flotation (aeration) cells[a]	Flotation air	• Coal particles adhere to air bubbles and form a froth a top the pulp • Froth skimmed off and separated from the refuse that remains in the pulp
Oil agglomeration		• A process of removing fine particles from suspension by selective wetting and agglomeration with oil • Preferential wetting of the coal by the oil; if air admitted, bubbles attach to the oil–wet coal surfaces, leading to increased buoyancy and rapid separation of heavier, unoiled mineral particles
Sand suspension process	Chance process[a]	• Patented in 1917, first applied to bituminous coal in 1925 (specific gravity separations of 1.45 to 1.60 commonly used) • One of the most successful heavy-medium cleaning processes; involves a large inverted conical vessel with sand in suspension in an upward current of water; increasing or decreasing the amount of sand in suspension causes a change in density of the fluid
Magnetite process	Conklin process[a]	• Used powdered magnetite in 1922 • After modification, as Tromp process in 1938 for magnetic medium
Pneumatic process	Air process	• Use air as separating medium

Source. Adapted from Sharpe (2002) and from Deurbrouck and Hucko (1981).
[a] Studies on flotation reagents reported in 1973 and 1976.

With the mounting pressure imposed by economic constraints associated with using smaller stockyards, blending various coals to the accuracy demanded by the customers, and addressing the just-in-time concept, the main functions of the coal pile are very clearly defined: (1) to serve as a buffer capacity to accommodate the differences between supply and demand, thereby acting as a strategic stock against short- and long-term interruptions, and (2) to provide a uniform feedstock of the required quality by accurate blending of coals available on the market.

In the case of a power plant or a process industry, stockpiling involves two important types of storage, namely, live and dead storage. Live storage is defined as "coal within reach" that can be retrieved by using available equipment or by gravity flow. In contrast, dead storage would require using

TABLE V

Technologies for Dewatering of Drying Coal

Method	Technology	Characteristics of technology
Dewatering	Screens	• Dutch State Mines sieve bend is a stationary wedge bar screen with the bars oriented at right angles and across the flow stream; advantageous feature is that the screen generally does not blind • Polish Vor-Siv is a stationary device to handle high volumes of solid in-water slurry; it combines certain characteristics of cyclones, sieve bends, and cross-flow screens • Conventional screens handle less flow volume than Vor-Siv per unit surface area
	Cyclones	• Normally processes a pulp with a low percentage of solids (5 to 20%) and produces a relatively thick suspension by removing a portion of water; solids discharged at the bottom, and water and slimes exit at the top of the unit
	Centrifuges	• Two main types available: solid bowl centrifuges and screen bowl centrifuges; there are many variations of these two types
	Filters	• Most often used is the vacuum disk filter; for best performance, solids in the feed should be coarse • Occasionally used is the drum-type filter; able to operate under varying load resulting from changes in feed rate • Also done is heating the feed slurry (steam filtration) by covering a conventional vacuum filter with a hood and applying steam under the hood to facilitate additional water drainage from the filter cake
	Emerging techniques	• Shoe rotary press developed by Centre de Recherche Industrielle du Quebec • Electro-acoustic apparatus developed by Battelle Columbus Laboratories • Tube filter press developed by English China Clays Ltd. • Membrane pressure filter developed by National Coal Board (England)
Thermal drying	Direct drying	• Before 1958, screen, vertical tray cascade, multilouvers, and suspension dryers dominated the market of thermal drying • After 1958, fluidized bed dryers gained rapid favor over the previous dryer techniques • After 1967, there was a decline in the use of fluidized bed dryer due to increased costs because of stricter emission regulations
	Indirect drying	• Eliminates the potential problem of excessive fines carryover of direct drying systems • Based on contacting the coal with a heated surface; two designs: Torus (or Thermal Disk) and Joy Holo-Flite (variation of a helicoid screw) with oil as heating medium • Another concept (Bearce Dryer) is to heat metallic balls and mix the balls with the wet coal as it travels down a sloping/rotating cylinder

Source. Adapted from Deurbrouck and Hucko (1981) and from Parek and Matoney (1991).

a secondary or an auxiliary means to reclaim this coal. When a coal arrives at a power plant, a decision is made either to add it to live storage or send it to long-term storage in the reserve stockpile; reserve stockpiles ensure against disruptions of deliveries or are opportunities for taking advantage of low prices on the spot market. Buffer stockpiles are sometimes available at power plants and act as a buffer between live and reserve stockpiles. Coals of a similar type can be stacked in the pile, but different coal types/grades are normally stored separately.

3.1.1 Features of Coal Stockpiles

Live and dead storage of large quantities of coal is usually carried out by storing the coal in open stockpiles on the ground, unless stringent environmental considerations require a roof over the stockpile, or enclosures. In this case, silos and bunkers are the alternatives to open piles, but these methods would be more expensive and capacity-limited due to the feasible size of the bunkers or silos.

For an efficient management of the stockpiles, the stockyard layout would satisfy the following requirements:

1. Optimize the land use (tons/acre) consistent with storage and environment constraints;
2. Maintain easy access to stored coal;
3. Maximize the load distance efficiency factor;
4. Position coal such that stacking and reclaiming rates can be achieved with the least effort;

TABLE VI

An Example of a Coal Preparation Plant

Coal preparation facility		
Step	**Interim products**	**Equipment involved**
Run-of-mine storage		• Ground piles • Bunkers • Raw coal blending
Size reduction		• Crushers and rotary breakers
Sizing/dedusting/desliming		• Cylindrical screens • Grizzlies • Vibrating screens
Cleaning method for various types of coal	Option (1) Pneumatic cleaning	• Refuse stream • Product as dry product
	Option (2) Coarse coal washers (+ 1/4 inch)	• Heavy media vessels • Jigs • Refuse stream
	Option (3) Fine coal washers (1/4 inch × 28 mesh)	• Heavy media cyclones • Fine coal jigs • Tables • Water-only cyclones • Refuse stream
	Option (4) Ultrafine coal washers (−28 mesh)	• Water-only cyclones • Flotation cells • Cleaned with coarse coal • Oil agglomeration
Dewatering	Option 2	• Vibrating screens • Centrifuges • Stream going to water clarification • Magnetite recovery circuit (with dryers)
	Option 3	• Sieve bends • Vibrating screens centrifuges, vibrating basket-solid screen bowls • Magnetite recovery circuit (with dryers)
	Option 4	• Raped sieve bend • High-speed screens • Filters • Solid bowl centrifuge
Water clarification (return to circuit use)	Options 2 and 4	• Thickeners and cyclones for option 4 • Refuse dewatering for option 4 with filters, solid bowl centrifuges, filter presses, and ponds
Thermal drying	Options 3 and 4	• Fluid bed dryer • Fine coal dryer
Dry product		• From Option 1
Product load-out		Coming from all the options

Note. See Fig. 6.1. of Speight (1994), for further details.

5. Attain the desired level of remote control of the equipment and the desired degree of automation of the plant;
6. Meet the homogenization and blending requirements if accuracy is requested;
7. Maintain/improve the uniformity, integrity, and quality of the stored coal;
8. Maximize equipment capability and reliability and minimize manpower requirements;
9. Provide a safe and dependable system consistent with environmental regulations, such as potential stock fires, dust emission, noise levels, and water drainage;

10. Minimize the overall costs (dollars per ton of coal handled) in terms of operation and capital costs.

Characteristics of the land location (in terms of size, shape, and load-bearing capacity) play an important role in defining the choice for the overall storage system of an open pile. These will determine the pile and height of the coal that can be stored.

Several measures must be considered in preparing the ground for a new coal pile:

1. The topsoil must be removed and a stabilizing layer of crushed rock or similar material be laid down;
2. Adequate site drainage must be in place;
3. Utility pipes and conduits should not be run under the pipes;
4. Long stockpiles should have their narrow side facing the prevailing winds to reduce dusting and oxidation.

In addition to the kidney-shaped stockpiles, the most commonly found shapes are the following:

1. Longitudinal beds (or linear beds): the beds are located either side-by-side or end-on. For instance, in the case of two beds, one pile is stacked and the other is reclaimed.
2. Circular beds: they are used for environmental reasons, requiring covering of the stockpiles; many small circular piles are preferred over a single large one for reducing the risk of a breakdown of the reclaimer system and for convenience of maintenance.

In today's business climate, the end user has no plausible reason to invest in excessive coal piles. The drawback of a circular bed is that it has only a limited storage capacity and cannot be increased once built. However, the circular beds eliminate the nonstandard end cones that are formed in the linear beds; these end cones are not representative of all layers in the stockpile; not reclaiming these end cones could cause short-term grade variations when these ends are processed. But the linear beds can store more coal, provided that space is available. The circular beds, which have limited pile capacity and short layer length, will have relatively smaller input lot size but will have many different lots. Capital operating and maintenance costs of circular beds are less than those of linear beds, but the costs for civil engineering work are higher for circular beds.

3.1.2 Methods of Stacking and Reclaiming Coal Piles

3.1.2.1 Stacking Coal During stacking, a stockpile is built with layers of coal, creating a pile with a triangular cross section; the layers may come from the same coal type or from different coal types. In this stacking process, several issues need to be addressed adequately, such as the following:

1. Minimize coal size segregation; the segregation could lead to spontaneous combustion and could contribute to flowslides;
2. Avoid dropping coal from excessive heights, thereby lessening the formation of dust;
3. Take into consideration coals that are more friable, that is, could lead to more formation of fines that, when wet, could cause pluggage of chutes.

Taking these issues into consideration, there are several main methods for stacking coal based on different components and arrangements. These methods are further based on the capability of the different types of stackers. The stacker runs on rails laid along the total length of the bed. The capability of the stacker will partly determine the ability to switch from one stacking method to another. The stacking equipment for longitudinal stockpiles is designed to reflect the different amounts of flexibility, the varying ability to blend/process the coal types, and the range of investments. To address these features, there are several types of stackers: (1) stacker with rigid boom; (2) stacker with luffing boom; (3) stacker with rigid and retractable boom; (4) stacker with luffing, rigid, and retractable boom; (5) stacker with slewing boom; (6) stacker with luffing and slewing boom.

In the cone shell method, a pile is formed by stacking coal in a single cone from a fixed position. When this cone is full, the stacking system moves to a new position to form a new cone against the shell of the previous cone. This method is not efficient for blending coals and is used in cases where homogenization is not required. The strata method stacks the coal in horizontal layers and will create alternating layers when two or more coals are to be blended; each layer will extend from one end of the bed to the other end and the whole bed should be completed before reclaiming is performed from the end of the pile. The skewed chevron is the strata method with the difference that the layers are inclined and reclaiming is carried out from the side of the bed.

The chevron, windrow, and chevron–windrow systems are all intended to have coal reclaiming carried out from one end of the bed and they can achieve a high blending efficiency. The chevron system is the simplest system since it requires only a stacker with one discharge point: the stacker moving along the central axis of the pile. The drawback is that segregation of material will lead to fine particles depositing in the central part of the pile and coarse particles depositing on the surface and at the bottom of the pile. The windrow and chevron–windrow methods will require more expensive stackers with a slewable boom allowing multiple discharge points; both of these methods minimize particle segregation. The Chevcon method (continuous chevron) is a combination of the cone shell and chevron methods and utilizes a circular rather than a linear bed. This circular bed has a round base with a ring-shaped pile where coal is stacked at one end and reclaimed from the other end.

3.1.2.2 Coal Reclaiming The technology of equipment for reclaiming coal has evolved from a discontinuous process originally to a continuous process, with the emergence of bucket-wheel, bridge-type, and portal scraper reclaimers.

In North America, the first bucket-wheel stacker reclaimer was installed in the Potomac Electric Power Plant at Chalk Point (Maryland) in 1963. Prior to this reclaiming method, coal stockpiles at large power plants relied on gravity systems that moved coal on a belt conveyor in a tunnel beneath the pile. The bucket-wheel stacker reclaimer that operates in the United States has two additional features not available in the early European version: (1) a movable counterweight instead of a fixed one (safety hazard eliminated) and (2) complete automation (labor-saving feature).

These reclaimers have become popular and make up approximately 90% of the total coal applications. The ability to perform homogenization/blending efficiently varies from one type to another. They reclaim different coal types stored in separate beds in a sequence as defined by the blending process required to meet a customer's expectations. This key feature is helpful at transshipment facilities tasked with blending imported coals.

A description of the types of reclaimers in light of their key features and functionality is given below:

1. The bucket-wheel recalimer is designed with a bucket wheel to reclaim the coal and operates from the side of the bed. This type of reclaimer is suitable only for operation in the open (due to the counterweight); it is deployed in stockyards with high throughput. Its homogenization/blending efficiency is not good. The bucket wheel is often combined with a stacker.
2. The gantry-type reclaimer may have multiple bucket wheels to improve the homogenization/blending efficiency.
3. The drum-type reclaimer uses buckets attached to a long rotating drum to reclaim the coal across the entire width of the pile, resulting in an improvement of the homogenization/blending efficiency.
4. The bridge-type scraper is designed with a scraper chain to reclaim coal across the front face of the longitudinal pile. This reclaimer has a very good blending/homogenization efficiency, but it cannot jump over stockpiles (whereas side-face reclaimers can).
5. The portal, semiportal, and cantilever scraper systems reclaim coal from the side of the bed. As side-face reclaimers, they are suitable for removing coal with signs of imminent spontaneous combustion.
6. The portal bridge scraper combines the advantages of the side- and front-face scraper reclaimers. A special version has been developed to reclaim circular beds; this special version is based on a bridge-type scraper and a cantilever scraper reclaimer, both mounted on a central column.
7. Front-end loaders and bulldozers are used for smaller stockpiles to stack and reclaim coals.
8. The gravity reclaim is utilized in some stockpiles. This system uses hoppers (located in a tunnel below the stockpile) and feeders (to control the discharge into the conveyors) to reclaim coal. Vibratory stockpile reclaimers would improve the reclaiming process. The use of multiple hopper systems (allowing intersection of flow channels) would improve the reclaiming performance. Blending efficiency within the stockpile is poor.

In addition to the reclaimers, some other types of mobile handling equipment play a role in stacking/reclaiming coal at a smaller volume than the above-mentioned reclaimers do. Front-end loaders and bulldozers are used to compact the coal and to move coal from reserve pile to live pile.

3.1.3 Bins and Silos

Coal can be stored in silos or bunkers as an alternative to open piles on the ground or in areas with enclosures. However, this method of storing coal in silos or bunkers is more expensive and constrained by the feasible size of the units.

Silos and bunkers are either steel or concrete, usually have round cross sections, and can have single or multiple outlet cones. An internal lining of stainless steel is a big advantage when storing high-sulfur coals to prevent corrosion. Regarding structural integrity of the foundations, loads should not be offset on the foundations when eccentrically charging or eccentrically withdrawing coal from these units.

A silo with a large diameter and a flat bottom will have multiple outlets. Bunkers with a height-to-diameter ratio of 2:1 to 3:1, designed to be self-cleaning, will have a cone bottom (with a suitable angle, e.g., a suitable flow factor) and a single outlet.

These coal storage devices do offer unique benefits such as: (1) controlling the dust and moisture content of the coal, (2) controlling runoff from rainwater, and (3) providing blending capacities by having several units feeding a single reclaim conveyor.

3.1.4 Trends in Management of Coal Piles

Traditionally, the coal stockyard for U.S. power plants contained approximately one-fourth of the plant's annual burn, such as the 90- to 120-day storage level at several American Electric Power plants, but that level in the United States has declined to much lower coal inventories. In the United States, stockpile levels have decreased to a level of approximately 50 days since mid-1993.

In comparison, some power plants have even kept 7- to 10-day coal inventories when their plants were located in the vicinity of their mines, such as the case of the South African Kendal mine-mouth power plant.

With a just-in-time delivery system, some power plants have coal stockpiles of only 5–8 days, such as those in the Netherlands or in U.S. centralized plants. Relative to just-in-time delivery, the decision to buy is driven more by demand than lower on-the-spot coal prices. As such, the decision could be subject to increases in coal prices due to regional coal shortages. These shortages could affect several utilities drawing on the same pool of mines. Consequently, before reducing its coal inventory, a power plant would need to carefully consider many factors such as: (1) transport options (rail, barge, truck, and ROM conveyor) in terms of reliability; (2) number of supply sources; (3) backup sources, such as other power plants; (4) reduced burn rate; and (5) delivery time for coal from supplier to the power plant (in terms of days).

Another trend in management of coal stockpiles is outsourcing; this concept is suitable for mine-mouth plants or power plants served by a single supplier.

3.2 Sampling, Analysis, and Auditing

With larger, more expensive shipments of various compositions, coal must be sampled and analyzed before storage for the following reasons:

1. Sampling is performed during loading operations at terminals or at power plants to ensure that the coal meets the contract specification (penalty and bonus clauses related to coal properties).
2. Sampling leads to knowledge about the coal consignment; this information allows the coal operators to store coal in different piles—coals of similar grade are stockpiled together and blending of different types of coal can be performed based on this knowledge.
3. Sampling during the reclamation process helps evaluate changes in properties during the storage period.

Given the above-mentioned reasons, a good sampling technique is critical for obtaining a truly representative sample of the coal consignment and of paramount importance for the analysis of the coal. The usual procedure is to divide the sample into three parts—one for the supplier, one for the customer, and one for independent analysis in case of a contract dispute.

3.2.1 International Standards for Coal Sampling Techniques

Coal is one of the most difficult materials to sample because it has the tendency to segregate by size and mass. The ideal objective of a sampling would be to have every particle size represented—ash content and heating value may be different for each particle size.

Other factors in the sampling process are the use of analytical results, the availability of sampling equipment, the quantity of the sample, and the required degree of precision according to standards (ASTM D2234).

Since biased results can be introduced into the sampling procedure, certain precautions to reduce the sources of bias are used, such as: (1) selecting the most suitable location for sampling purposes; (2) using sampling equipment that conforms to necessary specifications; and (3) taking special precautions when performing specific sampling procedures, such as sampling for total moisture content or size.

Table VII gives an overview of the international standards on sampling and sampling procedures. These standards are applicable only for sampling coal from moving streams.

In general, the standards specify the number and weight of the increments to be taken for each sampling unit. The increment is defined as a small portion of the coal lot collected in a single operation of the sampling device; the higher the number of increments, the greater the accuracy. A greater number of increments is recommended when sampling blended coal. The individual increments can be evenly spaced in time or in position, or randomly spaced, and taken out of the entire lot. The increments are then combined in a gross sample; the gross sample is then crushed and divided, according to standard procedures, into samples for the analysis. In the analysis part, standards differ in detail and often do not take into account the characteristics of the coal being sampled. These coal characteristics would include particle size distribution, density, particle shape of the coal, and the distribution of the parameter of interest. Consequently, sampling models have been developed to supplement these standards.

3.2.2 Sampling Systems and Bias Testing

Sampling in a stockpile *in situ* presents an enormous challenge in terms of obtaining a representative sample given the following:

1. Since the coal is subject to weather/oxidation and to size segregation, its quality is always different at the various locations of the pile (top, sides, or in the middle).
2. With many additions of different coals to the pile, the pile may contain coal zones that vary markedly.
3. Because sampling coal in the middle of the pile is difficult, sampling from a moving stream during the stacking or reclaiming process is preferable; however, if sampling of stockpiles *in situ* is necessary, the sample should be taken by drilling or augering into the pile.
4. Drill sampling and auger sampling have limited applications. The drill sampling method is used to penetrate the full depth of the pile at each point sampled and extract the whole column of coal. However, this technique does not collect all of the fine material at the bottom of the pile, because of the drill or auger design. Because this technique can

TABLE VII

International Standards on Sampling Coal from Moving Streams

Organizations	Standards
American Society for Testing and Materials (ASTM)	• D2013 Preparation of samples for analysis • D2234 Collection of a gross sample • D4702 Inspection of coal-sampling systems for conformance with current ASTM standards • D4916 Mechanical auger sampling
Standards Australia (AS)	• AS 4264.1 Coal and coke—Sampling; with Part 1 of sampliing procedures for higher rank coal • AS 4264.3 Coal and coke—Sampling; with Part 3 of sampling procedures for lower rank coal • AS 4264.4 Coal and coke—Sampling; with Part 4 of determination of precision and bias
British Standards Institution (BSI)	• BS 1017: Part 1 as sampling of coal and coke; methods for sampling of coal revised to adopt ISO/DIS 13909
International Organization for Standardization (ISO)	• ISO 1988 Hard coal—Sampling • ISO 5069/1 Brown coals and lignite—Principles of sampling; Part 1 of sampling for determination of moisture content and general analysis • ISO 9411-1 Solid mineral fuels—Mechanical sampling from moving streams; Part 1: Coal • ISO/DIS 13909-1 Hard Coal and coke—Mechanical sampling; Part 1: General Introduction • ISO/DIS 13909-2 Hard coal and coke—Mechanical sampling; Part 2 of coal—Mechanical sampling from moving streams • ISO/DIS 13909-3 Hard coal and coke—Mechanical sampling; Part 3 of coal—Mechanical sampling from stationary lots • ISO/DIS 13909-4 Hard coal and coke—Mechanical sampling; Part 4 of coal—preparation of test samples • ISO/DIS 13909-7 Hard coal and coke—Mechanical sampling; Part 7 of methods for determining the precision of sampling • ISO/DIS 13909-8 Hard coal and coke—Mechanical sampling; Part 8 of methods of testing for bias

Source. Adapted from Carpenter (1999).

break the particles, it is not recommended when collecting samples for size analysis and bulk density determination.

As mentioned above, standards specify the method and the number of increments to be collected. The method of collection is particularly important in terms of sampling location and tool. Standard scoop tools allow every coal particle size to have an equal chance of being sampled; spades are inappropriate and give a sample that is mainly fines. Regarding sampling location, coal can be collected while it is transported on the belt conveyors or to and from the stockpile.

The most accurate sampling method is the stopped-belt or reference method (a full cross section of the flow would be obtained). If stopping the belt is impractical or uneconomical, sampling could be done manually either from the moving belt or from a falling column of coal at a certain point. For high tonnage rates, sampling should be done by mechanical samplers. Some standards, such as BS 1017 and ISO 1988, stipulate that manual sampling should not be exercised in cases where the nominal coal top size is above 63 mm or when the coal flow rate is greater than 100 tons per hour.

Mechanical samplers provide a representative sample that is difficult to attain with manual sampling. The advantage of mechanical samplers is that statistics of precision and bias are applicable. However, these mechanical samplers cannot be applied to all situations, such as sampling within a stockpile or at facilities with small tonnages. The common characteristics of the mechanical samplers are as follows: (1) they provide a full cross-sectional representation instead of a partial cross-sectional sample, (2) their design and operation are covered in various standards, (3) their functionality is to avoid separation of the various coal densities and/or sizes by minimizing disturbances of the coal, (4) they require sufficient capacity of coal to perform sampling without any loss or spillage, (5) they require material to flow freely through all stages of the sampling system without clogging or losing material, and finally (6) the standards specify the design and the number of increments to be collected and the size of the cutter opening (typically three times the coal top size) and its speed.

In terms of categories, these mechanical samplers are divided into two types:

1. Cross-belt samplers (sweep arm or hammer samplers) sweep a cross section of the coal on the moving conveyor (or belt) into the hopper. For the sake of accuracy, these devices need to be adjusted so that no coal fines are left on the belt.
2. Cross-stream (or falling-stream or cross-cut) cutter samplers collect a cross section of a freely falling stream of coal. The location of this sample collection is typically a gap at a transfer point, such as between two conveyor belts.

All sampling systems should be checked for bias, because systematic errors may be introduced. These systematic errors generally are caused by a loss or gain in the mass of increments during collection or by cyclical variations of coal quality at time intervals coinciding with systematic sampling time. Bias testing is discussed in certain standards, such as ISO/DIS 13909 Part 8 for bias testing of mechanical samplers and in ASTM D4702 with guidelines for inspecting cross-cut, sweep arm, and auger mechanical sampling systems.

3.2.3 On-line Analyzers

Obtaining representative samples of coal from large stockpiles is burdensome and time-consuming when laboratory analysis of these samples based on standards is applied. The results do not reflect the variations in coal quality. Real-time information about these variations would help stockyard operators manage their assets much more efficiently. In response to this problem, on-line analyzers have been developed to continuously determine the coal quality and in real time.

Advantages of on-line analyzers over conventional analyzers are obvious when it comes to the following: (1) determination of coal quality in real time, thereby allowing the performance of trend and variability analyses; (2) simplification of sampling requirements in the context of large coal quantities to be analyzed; and (3) determination of coal quality in tons per hour instead of grams per day.

On the downside, on-line analyzers are expensive because they are too site-specific and application-specific. Their performance is related strongly to the initial installation, calibration, maintenance, and application environment. Analysis of coals beyond the initial calibration will not produce the same accuracy. Calibration drifts over time result in the need for recalibration of the analyzer.

International standards (such as ISO CD 15239, ASTM, and AS 1038.24) do not provide particular test methods because of the multitude of on-line analyzers and their interaction with sampling/analysis systems. On-line analyzers have gradually reached

the level of precision and reliability to be used in several commercial applications:

1. Monitoring the incoming coal to determine whether it meets specified requirements, as is done at the Herdrina plant in South Africa;
2. Sorting and segregating coal into different stockpiles (as is done at the Rotowaro coal handling facility in New Zealand);
3. Blending coal from different stockpiles to meet customer requirements (the Rotowaro coal handling facility);
4. Monitoring coal during reclamation to check for the desired specifications.

On-line analyzers available on the market have been developed based on various technologies, such as: (1) electromagnetic principles, (2) X-ray fluorescence, and (3) capacitance/conductance methods. Table VIII lists the application areas for these on-line analyzers based on the principle of operation.

All of these on-line coal analysis techniques are capable of meeting ASTM measurement standards for a predetermined range of coals. Table IX gives an overview of the four main on-line measurement techniques that are in use.

3.2.4 Stockpile Audits

Coal pile management also involves coal stock audits; the intent is to adjust the book inventory. In this task, the stockpile tonnage (calculated by measurements of volume and density), as the measured inventory, is to be reconciled with the book inventory.

In the book inventory, recorded weights of coal going in and out of the stockpile are documented.

Consequently, accurate weighting systems are important to gain better control over the stockpile and eliminate overpayment; it is recommended that the systems are properly situated, installed, maintained, and regularly calibrated. By knowing more precisely how many tons of coal are in the stockpile, one can write off coal used more quickly and/or can reduce inventories that are too large and thereby achieve significant savings.

Both the book inventory and the measured inventory are subject to measurement errors. Whereas inventory is subject to errors coming from volume and density measurements, several sources of errors are associated with the book inventory: (1) weight errors associated with the stockpile; (2) unaccounted changes in coal moisture in the stockpile; (3) losses due to spontaneous combustion; (4) losses due to runoff and wind erosion; and (5) losses due to contamination of the coal at the base of the pile in contact with the underlying strata.

Because stockpiles have various shapes and sizes, measurements must be used to determine volume. Both ground and aerial surveys are used to determine volume.

In an aerial survey using a photogrammetry method, two independent photogrammetrists using the same photograph on stockpiles between 50,000 and 500,000 tons can obtain accuracies of $\pm 5\%$.

For ground surveys, an electro-optical distance ranging system has been developed. It uses a theodolite (based on a laser) for distance measurement. The theodolite applies numerous point measurements to provide three-dimensional information about the surface of the pile. Using density contour information, specialized computer software computes the mass of the stockpile.

For density determination, the methods used would include volume displacement procedures and nuclear surface and depth density determination. Among these methods, a nuclear depth density gauge is probably the most dominant method, although the procedures have not yet been standardized. The gauges take horizontal and vertical density measurements at different locations and depths within the pile. However, these gauges require calibration for

TABLE VIII

Applications Areas for On-line Analyzers

Principle of operation	Suitable for measuring	Energy source
Prompt gamma neutron activation analysis	S, Btu, Ash, H, C, Si, Fe, N, Cl, Al, Ti, Ca	Californium-252
Gamma-energy transmission	Ash	Barium-133, cesium-137, americium-241
Gamma-energy backscatter	Ash	Americium-241
Microwave energy attenuation	Moisture	Microwave generator

TABLE IX

Overview of Four Main On-line Measurement Techniques

On-line analyzer technique	Characteristics
Natural gamma systems	• Requires no radioactive source • Measures the gamma emission from the conveyed coal • Combines this measurement with a measurement of the weight of the load to calculate the ash content • Not the most accurate system but the least expensive
Dual-energy gamma-ray transmission systems	• Combines measurements of the intensity of two narrow beams of high-and low-intensity gamma rays passing vertically on the conveyor belt to determine the ash content; coal must be mixed well • Instrumentation to split the beam and with multiple detectors has been developed to determine ash content across the full belt width • Varying chemical composition, especially iron content, can cause inaccuracies; accuracy is better for low-ash coals • Triple-energy gamma transmission systems developed for improving accuracy
Prompt gamma neutron activation analysis (PGNAA)	• Provides an elemental analysis of coal through measurement of the gamma radiation emitted when coal is exposed to a neutron source (such as californium-252) • Extra radiation shielding required for safety precaution and sophisticated signal-processing equipment needed to interpret the gamma-energy signals • Energy of the gamma ray is characteristic of the emitting element; gamma rays detected and collected in a spectrum and later correlated to coal composition • Interpretation of the spectrum is a complicated process; each manufacturer has a corresponding deconvolution process • Carbon, hydrogen, sulfur, nitrogen, and chlorine are measured directly • Ash content measured indirectly by its elements (mainly silicon, iron, calcium, aluminum potassium, and titanium) • Calculation of heating value possible if moisture analyzer is present • Instrumentation with multiple sodium iodide detectors developed to deal with coals from multiple sources • PGNAA is the most accurate analyzer but is also significantly more expensive than gamma analyzers
Microwave moisture meters	• Determine moisture content by measurement of energy attenuation and phase shift of microwaves through coal—Moisture of coal absorbs energy by a "back and forth" rotation of the water molecules in tune with the microwave frequency • Often incorporated in dual-energy gamma-ray transmission or on PGNAA analyzers to enable calculation of heating value • Measurement of coal density or inference of coal density required, usually provided by a high-energy source similar to that in gamma-energy attenuation ash analyzers • Not applicable for measuring frozen coal because ice and coal matter have similar energy-absorbing properties

Source. Adapted from Carpenter (1999) and from Connor (1987).

each type of coal and therefore encounter problems when measuring a stockpile with different types of coals. In addition, their accuracy depends on penetrating the coal without disturbing the *in situ* density and they are expensive to acquire.

3.3 Coal Deterioration

During storage in open stockpiles, most coals are subject to weathering and atmospheric oxidation; these processes alter the properties and structure of the stored coal and could render the coal less valuable for its intended use. Assessing the effects of weathering and atmospheric oxidation of the stored coal would mean examining the following key factors: (1) heating value losses, (2) handling related to coal moisture content, (3) coal cleaning (coal flotation), (4) combustion behavior, and (5) coking behavior.

3.3.1 Heating Value Losses

Oxidation can reduce the heating value of coal. Coal is affected by several factors, such as the characteristics (composition, rank, and particle size) of the

stored coal, the storage conditions (temperature and moisture content in the stockpile, storage time, location in the depth of the pile, and ventilation pattern through the pile), and the climatic conditions. The oxidation rate is coal-type-dependent. Low-rank coals are more susceptible to weathering and atmospheric oxidation than high-rank coals. Smaller particles, given their increased surface area, tend to oxidize more rapidly than larger particles. The heating value of the coal decreases with an increase in ash content. Also, the temperature and moisture content in the stockpile affect the rate of coal oxidation and hence the heating value. In a stockpile, the heating value losses decrease with depth; these losses are highest at the surface of the pile where coal comes in intimate contact with the atmosphere. Local hot spots can lower the heating value, due to the airflow through the pile. Compacted coal piles have less heating value losses than uncompacted piles.

Climatic conditions cause coal to lose or gain moisture. Climatic factors, such as solar intensity and rainfall frequency, cause heating value losses. Coal with ice formation on the surface can reduce the oxidation rate.

3.3.2 Coal Handling—Coal Moisture Content

The performance of the coal handling equipment is strongly affected by the moisture content of the coal. In open stockpiles, weather conditions (heavy rainfall or freezing) can increase the coal moisture content or freeze the coal so that equipment failures occur in belt conveyors, chutes, and bins. In hot and dry climates, through moisture loss by evaporation, the stored coal becomes more friable and dustiness increases. A high percentage of fines in combination with high moisture content can lead to a high potential for pluggage. In all these cases, weathering and oxidation increase the friability of the coals and the production of more fines.

Several practices at the stockyard should be avoided. Others are beneficial to control the coal moisture content of the pile. The practices that lead to increased moisture content and that should be avoided are the following: (1) creating large stock piles with little, if any, runoff; (2) allowing "ponding" on the surface of the pile; (3) moving coal through low areas with standing water during the reclaiming process; and (4) having pile levels lower than groundwater levels.

The practices that are beneficial to controlling the coal moisture content include the following: (1) stacking the pile with a maximum height over the smallest area, consistent with stable side slopes; (2) avoiding flat tops for the piles; (3) compacting the surface and the side slopes of the stockpile to enhance runoff; (4) developing a good strategy for efficient drainage; and (5) reducing the moisture content of the incoming coal to the maximum level practical at coal preparation plants.

Other practices include adjusting the equipment to handle wet coal by inserting plastic liners in the chutes and by using intermittent air blasts and vibrators. Chemicals should not be added since they rarely can be applied in sufficient quantities and mixed well enough to be effective. In addition, these chemical treatments affect the end-use behavior of the coal.

3.3.3 Coal Cleaning—Flotation

Coal cleaning processes, such as flotation, are negatively impacted by weatherized or oxidized coal. No method for efficiently cleaning the coal has been found.

Acidic oxidation products on the surface of the coal have dissolved in the process water and lowered the pH. Consequently, this has led to a reduction in flotation recovery and equipment wear. In response, wear-resistant material has been used for surfaces exposed to these adverse elements and magnesium hydroxide is added to raise the pH of the process water. Blending the oxidized coal (up to 20%) with fresh coal to dilute these adverse effects has been practiced.

Another adverse effect of the oxidation process is that oxidation causes a change in the wettability of coal that consequently affects the surface-based separation processes (flotation and oil agglomeration).

The performance of these separation processes decreases with the storage time. As remedies to improve the performance of these coals, several measures have been carried out:

1. neutralizing these adverse acidic oxidation products with alkalis;
2. using surface conditioners (or collectors);
3. using cationic collectors (amines);
4. using low-concentration electrolytes (iron chlorides);
5. grinding the stored coal to −28-mesh (standard flotation size) before subjecting it to flotation;
6. washing the stored coal with water to remove the dissolved metal ions prior to the flotation process.

3.3.4 Impact on Combustion Behavior

Coal stockpiles stored in the open for a long period of time undergo changes that affect their combustion

behavior and consequently affect boiler operations. The NO_x emission levels, carbon burnout, and slagging behavior could be impacted by changes in swelling index, maceral composition, and chlorine. Moisture increase in the stored coal would have significant consequences in the boiler plant in terms of the ability to handle the coal, mill capacity, and boiler efficiency.

In addition to lowering the heating value of the stored coal, atmospheric oxidation of the coal causes a delay in devolatization, leading to a change in coal reactivity. Stored coals with high free swelling index (FSI) have shown a significant loss in the FSI value and hence a loss in reactivity. A decrease in FSI and reactivity also means the appearance of oxidized vitrine, which is found to produce compact char structures requiring long combustion times.

The loss-on-ignition (LOI) directly related to char burnout increases significantly when weathered coals are fired. Any increase of unburned carbon in the fly ash, as the consequence of LOI, would affect the sale of the fly ash. To ensure a satisfactory burnout of the char, a longer residence time in the furnace burning zone is needed.

In general, to minimize the above-mentioned negative effects on the performance of the boiler (power plant), several measures have been put into practice: (1) modifying the plant operating parameters; (2) blending the oxidized coals with unoxidized coals; and (3) minimizing the storage time of sensitive coals.

3.3.5 Coking of Coal

Weathering and oxidation have several negative effects on the coking of coal: (1) reduction in coke stability; (2) issues of coal bulk density (related to particle size distribution and moisture content); (3) reduced coke production; (4) overheated charges; (5) carbon deposits; (6) oven damage, such as to coke oven walls; (7) generation of fines; (8) increased coke reactivity; and; (9) decreased coking rate.

Bulk density decreases with decreases in particle size distribution and increases with additional moisture over 8%. To produce a good metallurgical coke, two properties are important: good thermoplastic and caking properties. Deterioration of these properties due to weathering/oxidation of the coal in open stockpiles would affect coke production. Alvarez *et al.* presented the influence of natural weathering on coal in two papers in 1995 and 1996. The study was performed on a typical blend of 13 different coals in a 100-ton open stockpile in Spain during a 1-year period. Four of the component coals (in piles of 50–60 tons) were stored without grinding (unlike the blend) and were exposed to weathering for a period of 5 to 6 months. With mild weathering conditions, results based on the test parameters of the free swelling index, Gieseler maximum fluidity, and Audibert-Arnu dilation demonstrate that there was no significant change in free swelling index for the blend for each of the four coals, except for one coal after 138 days, and the Gieseler maximum fluidity factor (as the most sensitive indicator for loss of thermoplastic properties and oxidation) decreases over time for the blend and the four coals.

Another result of the study was that weathering/oxidation does not necessary lead to deterioration of coke quality. Mild weathering and oxidation can help produce a coke of improved quality in high-volatility and high-fluidity coals and in some medium-volatility coals.

Other studies indicated that the free swelling index generally is not sensitive to slight-to-moderate weathering, although there are exceptions. Studies also suggest that moderate caking coals (FSI between 3 and 5) are more prone to lose their caking properties than coals with higher FSIs.

With the increased trend to use pulverized coal injection into the tuyeres of steel blast furnaces and to blend coals, coke use has declined. Because coke strength and reactivity are especially important, steel works are very interested in having the right coke blend.

3.4 Spontaneous Coal Combustion

Spontaneous coal combustion is an important concern due to its effect on safety, the environment, economics, and coal handling. Economic losses occur because of fires in the coal pile and subsequent unsuitability of the coal for its intended use. Even if spontaneous combustion does not happen in coal piles, fires can occur later in confined spaces, such as on ships or in railroad cars. Ship fires, such as those reported on coal shipments from New Orleans, Louisiana, to the Far East in 1993, have led to the practice of not loading coal at temperatures greater than 104°F (40°C).

Although coal producers cannot always control the factors that govern spontaneous combustion, they can control management of the coal piles.

The tendency of coal to heat spontaneously in storage is related to its tendency to oxidize. This oxidation process is closely related to the rank of the coal (the higher the rank, the less potential for oxidization), the size of the coal in the pile, the

stacking method, the temperature at which the coal is stored, the external heat additions, the amount/size of pyrite present in the coal, the moisture content, and the storage conditions (in terms of oxidation heat release and heat dissipation by ventilation).

In lower rank coals, the amount of carbon is low and the amount of oxygen is high. In the higher rank coals, the reverse is true. Hydrogen remains relatively constant. Sulfur in the coal is present in the form of iron-free sulfur, organic sulfur, pyrite, and sulfate in various percentages, ranging from less than 0.5 to 8%.

Spontaneous combustion is the result of oxidation of the coal when heat generated by complex chemical reactions exceeds the rate of heat dissipation. Of the coal types, subbituminous coals and lignite require special handling to prevent spontaneous combustion. The lower the rank of the coal, the more easily it can absorb oxygen. In addition, the low-rank coals are higher in moisture, oxygen content, and volatile matter, all of which contribute to rapid oxidation. Also, coal can gain or lose moisture during storage. When dried or partially dried coal absorbs moisture, heat is generated (heat of wetting) and the temperature of the coal can increase significantly if this heat is not removed. Consequently, spraying water to extinguish fires in coal piles is not the solution, but instead chemical dust suppressants could be used.

Other factors that can contribute to coal oxidation are coal porosity, particle size, segregation during stockpile construction, and mineral content and composition. A more porous coal is more susceptible to oxidation because of the larger number of exposed areas. The effects of particle size are linked to coal porosity; a decrease in the particle size provides a greater surface, and hence a higher oxidation effect.

Regarding particle size segregation, differently sized coals should not be stacked. During construction of the pile, size segregation can occur in conical piles when there is a range of particle sizes; the outer area of the pile contains large-size particles and the middle of the pile has fine particles. This will lead to a so-called "chimney effect," whereby air passes up freely from the outer to the inner areas of the pile, creating the potential for heat production. In terms of mineral content and composition of the coal, some mineral elements can accelerate the spontaneous heating process. Pyrite, sodium, and potassium (in the form of organic salts) can act as catalysts for spontaneous combustion.

3.4.1 The Five Stages of Spontaneous Combustion

Although opinion differs on the exact mechanism of oxidation, the process of oxidation occurs in five steps:

1. Coal starts to oxidize slowly until a temperature of approximately 120°F is reached.
2. The coal–oxygen reaction rate increases at an increasing rate and the coal temperature increases until the temperature reaches 212 to 280°F.
3. At approximately 280°F, carbon dioxide and most of the water are given off.
4. The liberated carbon dioxide increases rapidly until a temperature of 450°F is attained; at this stage, spontaneous combustion may occur.
5. At 660°F, the coal ignites and burns vigorously.

For pyrite, the chemical reaction of FeS_2 with water and oxygen leads to the formation of iron sulfate ($FeSO_4$) and sulfuric acid (H_2SO_4) and is an exothermic reaction. In an open pile, pyrite, through its transformation to bulkier materials, is sometimes responsible for causing slacking and forming fines. Consequently, coal operators are reluctant to store high-sulfur coals for extended periods of time, but coals with low sulfur content are no guarantee for safe storage either.

3.4.2 Safe Storage of Coal through Prevention

Coal producers and users must know the self-heating propensity of stored coals. Practices for long-term storage include the following:

1. The storage area should be dry and on solid ground or sloped to allow good drainage of any pockets of water.
2. The area should be cleared of any debris and combustible materials with low-ignition temperatures, such as wood, oil-soaked rags, paper, and chemicals.
3. The area should be void of any buried steam lines, sewer lines, hot water lines, and other heat sources—stockpiles should not be added to on hot, sunny days.
4. The formation of conical piles should be avoided because larger pieces tend to roll away, creating a chimney effect for the fines situated at the center; for conical piles, removal should occur according to the principle of "first-in, first-out."
5. The windrow method is preferred over the chevron method for stacking coals that are prone to spontaneous combustion.

6. Air must be able to circulate freely in the pile or the pile must be packed in 1 ft layers or less to ensure the absence of air circulation (either restrict the entry of oxygen into the pile or provide adequate ventilation to remove the generated heat).
7. Upright structural supports in or adjacent to the storage piles could create chimney effects.
8. Particle-size segregation should be avoided.
9. Stoker-sized coals may be treated with oil before storage to slow the absorption of oxygen and moisture. Road tar, asphalt, coal tar, and various surfactant dust-control binders have been used as a seal; among these, asphalt is unsatisfactory in some applications.
10. Seals of compacted fine coal may be used to minimize the undesirable formation of fines if the coal has a tendency to slack. Chemical inhibitors have been used to reduce the reactivity of coal; these inhibitors include phenol, aniline, ammonium chloride, sodium nitrate, sodium chloride, calcium carbonates, and borates.
11. Good access should be available around the perimeter of the pile to allow the removal of hot spots.

3.4.3 Detection and Control

Early detection of conditions that cause spontaneous combustion is critical for safe storage of the coal and elimination of conditions, such as subsurface voids, that can endanger operators. The cost and effort to monitor stockpiles are generally small compared to the value of the coal piles. Spontaneous combustion is often detected visually by smoke or steam coming out of the pile or by the melting of ice or snow at certain locations in the pile. In hot weather, a hot area is identified by the lighter color of dry coal surfaces due to the escaping heat, a situation that requires immediate action. To detect/monitor the coal self-heating process, two means are available: (1) temperature measurements, through metal rods, thermocouples, and infrared detectors; and (2) gas analysis, such as monitoring the carbon dioxide, hydrocarbon, and hydrogen concentrations emitted.

Once self-heating is under way, two basic control options are available:

1. Removing the hot coal and using it immediately; if it is too hot for the transport equipment, it should be cooled first.
2. Removing the hot coal, cooling it by spreading into thin layers, and repiling and recompacting it; the coal can be left overnight to cool or can be sprayed with water. However, wet coal is difficult to handle.

Water is generally not recommended for extinguishing fires in coal piles. Dry ice (solid carbon dioxide) has been used successfully to control spontaneous coal combustion in an enclosed or covered area. However, dry ice is not recommended in an open area because wind would disperse it.

3.5 Dust Emissions

Fugitive dust emissions are considered monetary losses and pose environmental problems in the areas surrounding a stockyard. Coal dust poses health risks and damages equipment. Environment regulations are becoming more stringent regarding emissions of particulates such as PM_{10} and $PM_{2.5}$.

Dust emissions can be caused by wind erosion in a coal pile and stacking and reclaiming operations of coal piles.

The magnitude of these coal dust emissions depends on the following: (1) the coal characteristics (moisture content, particle shape, and particle size distribution); (2) the stockpile arrangement (layout and construction); and (3) the local climatic conditions (wind velocity, sun, and rainfall).

From these above-mentioned factors, the moisture content of the coal plays an important role in defining the level of dust generated. This dust emission potential is viewed as severe when the surface moisture of the coal lies between 0 and 4%, mild if it is between 4 and 8%, and low at 8% or above. In addition to this moisture factor, the volume of fines is another factor affecting dust emission. Small-size coal piles with a high volume of fines will produce higher dust emission levels than coal piles with larger particles; coal particles greater than 1 mm in size are not likely to become airborne. The next factor affecting wind-borne dust emission is the particle size distribution (which is related to the friability of the coal). Low-rank coals are generally more friable and consequently more prone to generate dust. Very high rank coals are also susceptible to dust emission.

Regarding the stockpile arrangement and its layout, an appropriate selection of the stacking and the reclaiming method, when combined with a series of control measures, can help lower dust emissions.

3.5.1 Methods for Dust Emission Control and Monitoring

Several methods are available to address dust suppression: (1) wind control (stockpile layout and construction with fences/berms); (2) wet suppression systems (water, chemical wetting agents, and foams);

(3) chemicals binders and agglomerating agents; (4) sealants (chemicals or vegetation); and (5) stockpile enclosure (complete or partial).

Table X gives an overview of the applicability of these dust control methods.

These dust control methods are applied during stacking and reclaiming of coal and applicable to active and inactive (long-term) storage piles. In the stacking process, controlling the size and the particle distribution of the stock piles is important. Conical piles are subject to particle segregation; minimizing the drop height by fitting appropriate stacking chutes can decrease particle fragmentation and consequently reduce dust emissions. Among reclaiming systems, gravity reclamation (through bottom reclaimers underneath the pile) typically generates the least dust, but safety precautions must be exercised due to fire and explosion hazards related to dust generation.

The orientation of the stockpiles can help minimize the dust emission level. This orientation can include presenting the smallest surface area (narrowest side) of the piles to the prevailing wind (wind direction according to climatic conditions), taking advantage of any natural shelters, or setting berms and fences. In addition to acting as wind breaks, berms (earth embankments) would also reduce noise pollution and diminish the visual adverse impact of the piles on the landscape. Fences, if erected upwind, can reduce the wind speed and turbulence; if placed downwind, they can prevent dust transport but can also create dead zones where dust can be deposited before being redispersed.

3.5.2 Dust Suppressants

Several dust control and suppressing agents are available for use on coal piles, including water, wetting agents, foams, binders, agglomerating agents, and chemicals. These agents are as follows:

1. Water is the simplest, cheapest method in the short-tem, but not always the most effective. Water cannons are used to wet the coal. There are many drawbacks, such as short-lived effect, reduced heating value of the coal with excessive water content (compromising contract moisture specification), and accelerated surface weathering of the coal (the coal breaks down). Also, as a consequence, handling of wet coal and water runoff must be taken into consideration.

2. Wetting agents are added to reduce the amount of water used; they reduce the surface tension of water to enable fine water droplets and to enable the ability of water to wet the coal. The concentration of wetting agents ranges from 0.05 to 2% in spray water. A substantial number of wetting agents is offered on the market, but the appropriateness of the wetting agent to a certain type of coal must be established in laboratory or field tests and needs to satisfy environmental requirements (biodegradability and aqueous toxicity).

3. Foams are produced from water, air, and a foaming agent. If properly applied, they are better at controlling the moisture content of coal than water or a wetting agent.

4. Agglomerating agents (also called binders) bind the particles to one another or to larger particles; they include oils, oil products (such as asphalt), lignins, resins and polymer-based products. Oil and oil products are suitable when freezing problems are encountered. Safety (fire) and environmental issues (groundwater) need to be considered; polysulfides may be toxic to aquatic organisms. The binders that claim to be nontoxic are Dustcoat series and Coalgard (oil emulsion).

5. Sealants, as crusting or coating agents, are sprayed over the stockpile with a water cannon to form a water-insoluble crust. This method is suitable only for long-term stockpiles and requires regular inspection; reapplication of the crusting agent is necessary once the surface of the pile is broken for reclaiming. The crusting agents include polymer-based products (polyvinyl acetates, acrylics, and latex), resins, lignosulfonates, lignins, waste oils,

TABLE X

Applicability of Dust Control Methods

	Wind control	Wet suppression	Agglomerating agents	Sealants	Enclosures
Stacking		X	X		
Reclaiming		X	X		
Active piles	X	X	X		X
Long-term piles			X	X	

Source. Adapted from Carpenter (1999).

and bitumens. Lignins and waste oil have drawbacks in terms of water solubility and heavy metal contamination. Other novel approaches as sealant solutions are applications of grass or fly ash to the pile.

6. A complete or partial enclosure of piles is a solution to limit dust formation. Circular stockpiles are cheaper to cover than longitudinal piles. Safety measures would include ventilation to inhibit fire and explosion (dusts and methane). In addition, provision of ample openings to allow access for moveable handling equipment should be considered.

Monitoring of dust levels around a stockyard not only helps determine the effectiveness of dust control practices, but also helps to confirm that ambient air quality standards have been satisfied.

A successful monitoring of coal dust would require adequate measurement points (taking into consideration the direction of the prevailing wind), knowledge of the meteorological conditions (wind speed, temperature, humidity, and rainfall), and coal-handling operations. Although instrumentation to measure dust concentration or dust deposition is available, particulate measurements are generally known to be difficult to standardize.

3.6 Runoff and Flowslides

3.6.1 Coal Pile Runoff

In light of more stringent environmental regulations, rising costs of water management, and disposal of waste products, stockyard operators are encouraged to incorporate systems that will address runoff and flowslide of coal piles.

Coal pile runoff occurs when water seeps through the pile or runs off the ground surface. Several elements could generate this runoff: rain, snow, piles left to drain to meet moisture content requirements, and underground streams beneath the pile.

The amount of rainfall has the greatest impact on the amount of runoff; soil permeability under the pile also has an impact but to a lesser extent. Factors influencing the coal pile runoff include the following: the composition and size distribution of the coal; the drainage patterns in terms of contact time between coal and infiltrating water; and the amount of water seeping through the pile.

In general, runoff is characterized by high levels of solids in suspension, a variable pH, and heavy metal content. The composition of this effluent can vary widely. Acidic leachates show high levels of many metals. The pH of these leachates also depends on the presence of the neutralizing elements in the coal. Thus, bituminous coals produce runoff that is acidic; subbituminous coals produce neutral to alkaline runoff.

3.6.2 Runoff Collection

Site evaluation and site preparation are necessary steps to limit soil contamination caused by runoff. The potential site is evaluated in terms of its soil characteristics, bedrock structure, drainage patterns, and climatic conditions (precipitation records and potential flooding). Site preparation would involve compacting the soil, layout, and the construction of drainage ditches around the perimeter of the piles; the ground of the piles would be slightly sloped toward the drainage ditches and sloped away from the reclaiming area. The drainage system is designed to collect the runoff, collect rainwater from the entire stockyard, and handle the storm water. Several ways to prevent runoff and groundwater contamination include the installation of an impenetrable layer under the stockpile by using the following: (1) a plastic liner with compacted sand as the protected layer (Ashdod coal terminal, Israel); (2) a reinforced polypropylene membrane layer with fly ash/bottom ash mixed with an activator as the protective layer (Morgantown, West Virginia, Generating Station); and (3) an impermeable membrane protected by a cement-treated base overlain by rejected waste coal as the protective barrier (Los Angeles, California, Export Terminal).

3.6.3 Runoff Treatment

For recovery of the coal fines, coal pile runoff is directed to settling ponds located close to the corners of the stockyard and away from the stacking and reclaiming areas. Another alternative would be to install presettling ponds ahead of the settling ponds so that the bulk of the fines would be recovered in the primary ponds. This would reduce the amount of fines collected in the settling ponds, leading to a less frequent cleanup of these ponds. Different types of coal produce different types of runoff. In certain effluents (runoff), additives are used to remove the suspended solids and to modify the pH. Examples of these additives are alum (added to the runoff of the Powder River Basin [PRB] subbituminous coal at the U.S. St. Clair Power Plant) and cationic polymer flocculant (added to the runoff at Bolsover Works, United Kingdom). In addition, filter presses, other mechanical equipment, and chemical processes for wastewater treatment may be involved. Bioremedia-

tion techniques can be applied to produce biodegradable by-products and recover metals.

3.6.4 Coal Pile Flowslides

Instability in coal piles results from two types of slope failure: shallow slipping and deep-seated sliding, which is the type that causes flowslides.

In the first case, wetting of the surface layer can lead to erosion gullies and to shallow slipping with small flows depositing saturated coal at the toe of the slope. In the second case, deep-seated sliding causes a major flowslide within a short time. The stockpile shows a flat final slope and a temporary steep scarp that subsequently slumps back to the angle of repose. This slope failure results in economic loss associated with cleanup costs, loss of production, damage to equipment, and danger to personnel. Significant conditions that could lead to flowslides include the following:

1. Saturation of the stockpile base due to the infiltration of heavy rainfall, leading to the potential of a deep-seated slip;
2. Redistribution of moisture within the coal at placement (there is a threshold moisture content below which no saturated zone develops);
3. Loosely stacked coal (prone to structural instability);
4. Particle size distribution (migration of fine coal particles under the influence of water flow causes local water saturation and reduction in shear strength).

Failures can happen with relatively fresh coal (placed within the previous 2 weeks), and a significant coal pile height increases the risk of collapse.

Ideally, strategies to prevent and control flowslides would mean modifying the stacking method and the overall stockpile installation, but in reality operational and other factors may preclude major modifications to the existing operations. Consequently, a more practical approach is to adopt safety precautions and adjust the height of the stockpiles as prevention measures:

1. Excluding pedestrians and mobile equipment from stockpiles thought to be prone to flowslides or from coal piles with modified characteristics, particularly in the week after heavy rain or placement of wet coal.
2. Minimizing stockpile height during the rainy season; in case of busy shipping schedules and heavy rain, access roads should be closed to personnel; if a coal slide occurs, it should be cleaned up and restacked.
3. Reclaiming the coal from the toe of the pile by front-end loaders should be avoided because of the hazard; as coal dries out and adhesion between particles becomes weaker, the unstable sides of the pile may collapse.

To control flowslides, experience has shown that:

1. Controlling the moisture content of the pile can decrease the risk of flowsliding.
2. Compacting the entire coal pile, or selected areas of it, can reduce the tendency for the saturated coal to suddenly lose strength and to flow.
3. Building drainage slopes can facilitate surface runoff.
4. Constructing the pile with an appropriate profile and top facilitates runoff (with convex longitudinal profile and no flat-topped center, or slightly concave cross-sectional profile, or slightly crowned top for compacted piles).
5. Sealing the coal pile is useful in heavy rain areas but is not practical for working piles.
6. Enclosing the pile keeps the coal dry but is an expensive option and not applicable at coal blending terminals.
7. Draining the stockpile toe is beneficial for preventing minor instabilities that could lead to an overall failure.

4. HANDLING COAL AT THE END-USE SITE

4.1 Pneumatic Transport of Solids

Pneumatic transport of particles occurs in almost all industrial applications that involve powder and granular materials. The purpose of pneumatic transport is to protect the products from the environment and protect the environment from the products. Although this is not an energy-efficient method of transport because it requires power to provide the motive air or gas, it is easy and convenient to put into operation.

Five components are included in a pneumatic system: conveying line, air/gas mover, feeder, collector, and controls.

Pneumatic systems are broken down into three classifications: pressure system, vacuum system, and pressure/vacuum system. Their modes of transport are categorized as dilute, strand (two-phase), or

dense phase and take into account the characteristics of the particles in terms of the following:

1. Material size and size distribution;
2. Particle shape;
3. Overall force balance of the particle/gas system, taking into account the acceleration, the drag forces, the gravity, and the electrostatic forces; terminal velocity is usually the characterizing term for particles—the higher the terminal velocity value, the greater the size and/or density of the particle;
4. The pressure drop and the energy loss for operational costs; the pressure loss calculations would take into account the voidage, the particle velocity, and the friction factors;
5. Acceleration of the flow at several locations of the pneumatic system (bend or connection, outlet or inlet);
6. Saltation (deposition of particles at the bottom surface of the pipe);
7. Pickup velocity, defined as the feed point of the solids and the velocity required to pick up particles from the bottom of the pipe;
8. Compressibility, which is of paramount importance for long distances and high-pressure systems;
9. Bends, creating significant pressure loss for systems with several bends and a relatively short length (<300 ft);
10. A dense phase that includes all types of flow, except dilute-phase flow (a lightly loaded flow); and
11. Choking conditions (in a vertical direction).

4.2 Pneumatic Transport of Coal

Three different types of air movers are commonly used for pneumatic transport: fans, blowers, and compressors. The fans are the most inexpensive movers, the blowers are the workhorse of pneumatic transport, and the compressors are used for pressure ratios over 2:1.

When any of these movers are used in coal-fired steam power plants, primary air fans are used to supply air to the mills. There are many varieties of feeders, such as rotary feeders with different design variations (rotor, blades, and casing), gate lock feeders in pressurized systems, and screw feeders. In addition, filters and cyclones are available for separating, dividing, or redirecting the flow.

4.3 Transport Properties of Slurries or Wet Solids

Understanding and accurately predicting the flow behavior of solid–liquid mixtures through the slurry fuel-handling system is key to the successful operation of these handling systems. Slurries are solid–liquid mixtures. By definition, slurries should contain sufficient liquid to wet the surface of every particle, small and large. Therefore, particle size and the relative density between solids and liquids are important and highlight four types of slurry flow regimes: homogenous; heterogeneous; saltation; and moving bed.

These flow regimes are investigated in laboratory-scale and pilot-scale rheological tests to elucidate slurry behavior, e.g., its viscosity under certain flow conditions. In these tests, various geometries and instruments can be used to measure the rheological properties of the slurry. These properties are expressed in terms of shear stress (force/area), shear rate, or strain rate (velocity/distance). Equations or charts are developed to distinguish between Newtonian and non-Newtonian fluids. Virtually all slurries display non-Newtonian behavior and are represented commonly by shear stress characteristics, such as velocity gradient curves (pseudo-plastic, plastic, Newtonian, and dilatant curves). The Bingham plastic is the most common curve; it is actually characterized by a straight line with an intercept on the shear stress axis. This helps in designing the handling systems and the operating parameter ranges. For heterogeneous slurries, the design of this type of transport is based almost entirely on correlations developed from experience.

Pipelines are used to transport slurries over long distances and these slurries must be stable enough to withstand the demands of transport, readily separable after reaching their destination, and cost-competitive with other forms of transport.

For pipelines, operating at lower velocities would result in less pressure loss per length of pipe (smaller pumps) and greater pipeline lifetime (less erosion). The minimum operating velocity is the lowest velocity at which all the particles stay in suspension.

As expected, for a given particle size distribution, the greater the solids loading, the more difficult it is to pump the slurry. However, adding wood pulp fibers to the slurry has considerably reduced the drag because of changes in the turbulent flow regimes. For instance, in aqueous slurries of 20% coal with and without wood pulp fibers flowing at 15 and 60 ft/s, the drag has been reduced up to 30% over this range of velocities by the addition of 0.8% fibers.

In addition to the type of drag-reducing additives that help increase the solid loading in the slurry (to 70% solids with additives, compared to 55% solids without additives), there are other additives that will help to retard particle settling. These can increase the

shelf-life of the slurry from a few days to several months.

4.4 Slurry Transport of Coal

A particle size must be created to transport coal slurry, requiring a balance between pumping and dewatering characteristics. If the slurry is too fine, the pumpability is good but the process of separating water from solids could be difficult. If the slurry is too coarse, it is not homogenous and higher pumping power is needed. In short, two parameters need to be controlled: the density of the slurry and the top particle size. The first parameter, in terms of slurry concentration, has an important impact on friction loss and the critical velocity of the slurry. The second parameter prevents pluggage of pipelines by controlling the coal particles. In addition, corrosion inhibitors, such as sodium dichromate, will protect the pipe wall, and other additives, such as sodium sulfite, will act as oxygen scavengers.

In commercial pipelines, a so-called critical concentration range exists where the slurry provides maximum support for the particles without an untenably high critical velocity (for the pumping stations). At the destination, the objective is to remove the water and recover the solids with minimum moisture content by using centrifuges or filters.

Coal slurries find applications in power generation. The IEA Coal Research report of 1993 gives an insight into the impact of the coal on the power station performance. In conventional steam power plants, coal slurry technology has been commercialized. One example is the 273-mile Black Mesa coal pipeline that provides all the fuel requirements (approximately 5 million tons/year) to two 750 MW generating units in southern Nevada.

In pressurized fluidized bed combustion, coal and sorbent (usually lime or limestone) are injected into a fluidized bed as a water-mixed paste using concrete pumps or pneumatically as a dry suspension via lock hoppers. In the first case, the coal could be crushed by roll crushers to a certain size distribution, such as a top size of 6 mm, and the sorbent could be crushed through hammer mills to a certain top size, such as 3 mm. After that, the coal and sorbent are mixed to form a pumpable slurry. Optimizing the paste moisture content at 20–30% is an acceptable compromise relative to boiler efficiency. At the Tidd Plant in Brilliant, Ohio, for example, the coal paste had a nominal value of 25% weight water.

Regarding atmospheric circulating fluidized bed combustion, coal slurry represents a preferable solution when using low-grade coals and coal wastes. Three options are available: a dilute slurry ($>40\%$ water), a dense slurry ($<40\%$ water), or a nominally dry material ($\approx 12\%$ water). Coal slurry has also been used in integrated gasification combined cycles, such as at the Wabash power station and at the Tampa Electric Company's Polk power station.

TABLE XI

Example of Coal Storage Requirements at a Coal-Fired Power Plant

	Coal			
	Lignite	**Subbituminous**	**Midwestern bituminous**	**Eastern bituminous**
Heat to turbine	4591×10^6 kJ/h	4591×10^6 kJ/h	4591×10^6 kJ/h	4591×10^6 kJ/h
Boiler efficiency	83.5%	86.2%	88.5%	90.5%
Coal heat input	5499×10^6 kJ/h	5326×10^6 kJ/h	5185×10^6 kJ/h	5073×10^6 kJ/h
Coal HHV	14.135 MJ/kg	19.771 MJ/kg	26.284 MJ/kg	33.285 MJ/kg
Coal flow rate	429 tons/h	297 tons/h	217 tons/h	168 tons/h
	Design storage requirements, tons			
Bunker (12 h)	5148	3564	2604	2016
Live (10 days)	102,960	71,280	52,080	40,320
Dead (90 days)	926,640	641,520	468,720	362,880
	Storage time for eastern bituminous plant design[a]			
Bunker	4.7 h	6.8 h	9.3 h	12.0 h
Live	3.9 days	5.7 days	7.7 days	10.0 days
Dead	35 days	51 days	69 days	902 days

5. STORING COAL AT THE END-USE SITE

5.1 Safe Storage of Crushed Coal

Crushed coal storage can be divided into two types: live storage (e.g., active storage with a short residence time) and dead storage (e.g., reserve storage). A common practice is to directly transfer part of a shipment to live storage and divert the remainder to reserve storage.

Usually, the storage components are sized to a certain capacity equivalent to a fixed period of firing at full load. The length of time for each storage type is as follows: 12 h for in-plant storage in bunkers, 10 days for live storage, and more than 90 days for reserve storage. These time periods are usually set by the operating procedures of the plant (power station capacity, heat rate, and coal heating value) and by other constraints (e.g., stocking strategies). If the actual heating value of the coal changes and if the steam generator is expected to operate at a certain fixed heat input, the storage capacity and the quantities delivered to the plant must increase. As a result, silos or bunkers represent an important link to provide an interrupted coal flow to the pulverizers. Typically at coal-fired power plants, a number of round silos with conical bottoms are stationed on each side of the boiler (steam generator).

Silos and bunkers are constructed of either concrete or steel and are generally round. Loading and unloading of coal from the silo are carefully controlled to prevent dangerous offset loading on the foundations. The coal is supplied to the mills and pulverized continuously and a mixture of pulverized coal/air is pneumatically transported to the burners. A single mill can supply several burners (tangentially fired systems and wall-fired systems). Table XI gives an example of coal storage requirements at a coal-fired power plant in the 1980s.

TABLE XII

Preferred Range of Coal Properties for Mills

Properties	Mill type		
	Low speed	Medium speed	High speed
Maximum capacity	100 tons/h	100 tons/h	30 tons/h
Turndown	4 : 1	4 : 1	5 : 1
Coal feed top size	25 mm	35 mm	32 mm
Coal moisture	0–10%	0–20%	0–15%
Coal mineral matter	1–50%	1–30%	1–15%
Coal quartz content	0–10%	0–3%	0–1%
Coal fibre content	0–1%	0–10%	0–15%
Hardgrove grindability index	30–50, 80	40–60	60–100
Coal reactivity	Low	Medium	Medium

Source. Adapted from Sligar (1985).

5.2 Milling of Pulverized Coal

At the mill, fine grinding of coal involves producing coal particle sizes such that 70% or more are finer than 75 μm (200-mesh) to ensure complete

TABLE XIII

Impact of Coal Properties on Mill Performance

Mill performance	Low-speed and medium-speed mills
Drying	• Moisture affects primary air requirements and power consumption of mills • Volatile matter affects the susceptibility to mill fires • Total moisture causes a −3% throughput for a 1% moisture increase for low-speed mill; a −1.5% throughput for 1% moisture increase above 12% moisture for medium-speed mill
Mill throughput	• Total moisture (see above) • −1% throughput for 1-unit reduction in HGI[a] for both mill types (caution when using HGI for coal blend behavior) • Raw coal top size: −3% throughput for 5 mm increase in top size for low-speed mill; no loss in throughput below 60 mm top size for medium-speed mill • Pulverized fuel size distribution: reduction of fraction going through <75 μm mesh screen by 0.35% for a 1% increase in throughput for low-speed mill; reduction by 0.9% for a 1% increase in throughput for medium-speed mill
Wear	• Mineral matter and size distribution influence the operation and maintenance of both types of mills

Glossary

absorption chiller An absorption chiller transfers thermal energy from the heat source to the heat sink through an absorbent fluid and a refrigerant. The absorption chiller accomplishes its refrigerative effect by absorbing and then releasing water vapor into and out of a lithium bromide solution.

cogeneration The simultaneous production of electric and thermal energy in on-site, distributed energy systems; typically, waste heat from a prime mover is recovered and used to heat/cool/dehumidify building space. Technically, if cooling is an end result, the process is called trigeneration.

combined heat and power Synonymous with cogeneration, combined heat and power (CHP) is more commonly used in the United States than in Europe or China, where cogeneration is more common. The term CHP applies more to the industrial sector, in which "waste heat" may be used in applications other than heating or cooling building space.

desiccant A solid or liquid material with an affinity for absorbing water molecules.

desiccant dehumidifier Desiccant dehumidifiers use recovered heat from the prime mover to dry building space using a desiccant material. The two general types are based on the desiccant used: solid (dry desiccant) and liquid (liquid desiccant).

distributed generation In contrast to centralized utility electricity generation, distributed generation involves small-scale prime movers that can be located at or near the building or facility where the energy is used to provide greater power reliability and reduced emissions.

district energy District energy systems produce steam, hot water, or chilled water at a central plant and then pipe that energy out to buildings in the district for space heating, domestic hot water heating, and air-conditioning. A district energy system can obviate the need for individual buildings to have their own boilers or furnaces, chillers, or air conditioners. A district energy system can serves many customers from one location; use a variety of conventional fuels, such as coal, oil, and natural gas; and transition to use renewable fuels, such as biomass, geothermal, and combined heat and power.

"first-generation" packaged cooling, heating, and power systems On August 8, 2001, Energy Secretary Abraham announced awards to seven industry teams for research, development, and testing of first-generation packaged cooling, heating, and power systems. In doing so, the U.S. Department of Energy is helping manufacturers work together to integrate their individual cogeneration components into easier to use packages and to make "plug-and-play" packages more readily available in the commercial and industrial marketplace; objectives include reduction of engineering time/cost at the installation site.

fuel cell Device for producing electricity using a chemical process that combines hydrogen and oxygen rather than conventional combustion processes with electric generators.

prime mover The electric and thermal energy generator; typically an on-site distributed generator. For cogeneration purposes, microturbines, reciprocating engines, and industrial turbines are most commonly used; other prime movers include fuel cells, concentrating solar power systems, and Sterling engines.

Public Utilities Regulatory Policy Act (PURPA) Congress passed PURPA in 1978. The nation had recently survived several energy crises resulting from the escalation of crude oil prices coupled with curtailments of production. Policymakers belatedly realized that fuel was dependent on the forces of international interests and beyond the control of governmental officials and industries in the United States. Public utility regulators and Congress determined that steps to avoid future energy crises should include both focused conservation programs and the development of alternative sources for producing electricity. PURPA was a major response to these crises and started the power industry on the road to competition by ending promotional rate

 © 2004 Elsevier Inc. All rights reserved.

structures, establishing unconventional qualifying facilities, and encouraging conservation. Unintentionally, PURPA started the competitive process because it enabled nonutility generators to produce power for use by customers attached to a utility's grid. PURPA broke the stranglehold on power companies' previous monopoly in the generation function because now any unregulated cogenerator or renewable energy producer could sell electricity into the power grid, and regulated utilities were unable to dictate terms. Of particular note regarding the cogeneration industry, PURPA promoted cogeneration as an energy-efficient technology.

thermally activated technologies Thermally activated technologies (TATs) represent a diverse portfolio of equipment that transforms heat for a useful purpose, such as energy recovery, heating, cooling, humidity control, thermal storage, or bottoming cycles. TATs are the essential building blocks for cogeneration systems.

trigeneration The simultaneous production of electric and thermal energy in on-site distributed energy systems; typically, waste heat from a prime mover is recovered and used to heat and cool/dehumidify building space. Technically, if cooling is an end result, the process is called trigeneration.

waste heat The portion of the energy input to a mechanical process that is rejected to the environment.

The efficiency of central electricity generation has not improved much in the past 40 years, with the exception of an increase in natural gas utilization and the use of combined cycle plants by central plants. Currently, power plants are approximately 33% efficient, meaning that only one-third of the energy is used to generate new power. The remaining two-thirds is lost, vented as "waste heat" to the environment that, along with carbon/nitrogen/sulfur-based emissions from coal or oil, causes significant ecosystem degradation. Cogeneration, or combined heat and power, is a clear alternative to central electricity generation: Using smaller scale generation technologies that primarily use natural gas at or near a building, campus, or industrial facility, cogeneration systems take advantage of waste heat by using it to heat, cool, or dehumidify building space, with overall system efficiencies in the 70–90% range. (Technically, an energy system that makes heat, power, and cooling is considered trigeneration. In this article, cogeneration includes trigeneration.) This doubling or tripling of efficiency from cogeneration or trigeneration has far-reaching implications for the possibility of a more sustainable energy paradigm in commercial and industrial sectors in industrialized countries.

1. TIME LINE

1.1 Historical

Cogeneration is not new. It first appeared in the late 1880s in Europe and in the early 20th century in the United States, when most industrial plants generated their own electricity using coal-fired boilers and steam-turbine generators. Many of these plants used the exhaust steam for industrial processes. According to COGEN Europe, an advocacy group based in Belgium, cogeneration produced as much as 58% of the total power from on-site industrial power plants in the United States in the early 1900s.

As a result of improvements in the cost and reliability of electricity generated by the separate electric power industry as well as increasing regulation, the electric generation capacity at most cogeneration facilities was abandoned in favor of more convenient purchased electricity. A few industries, such as pulp and paper and petroleum refining, continued to operate their cogeneration facilities, in part driven by high steam loads and the availability of by-product fuels.

In the mid-1900s, the pendulum began to swing in the opposite direction with the advent of central electric power plants and reliable utility grids, which allowed industrial plants to begin purchasing lower cost electricity. As a result, on-site industrial cogeneration declined significantly to only 15% of total U.S. electrical generation capacity by 1950, and it then declined to approximately 4% by 1974.

The first dramatic rise in fuel costs and uncertainty in the fuel supply in the 1970s triggered an upswing in cogeneration, particularly in large industrial applications that required vast quantities of steam. In recent years, smaller cogeneration systems have begun to make inroads in the food, pharmaceutical, and light manufacturing industries, commercial buildings, and on university campuses.

In the late 1970s interest in cogeneration in the United States was renewed in response to the Public Utilities Regulatory Policy Act of 1978 (PURPA), which included measures to promote cogeneration as an energy-efficient technology. With the passage of PURPA, multiple megawatt projects at large pulp and paper, steel, chemical, and refining plants were undertaken. Although PURPA created an enormous incentive for these large-scale projects that helped increase cogeneration capacity significantly, the act may have caused utilities to discourage beneficial projects because of the regulatory mandate. However, these attitudes are changing: Forward-thinking

utilities are actively pursuing new cogeneration projects as part of their business strategy. PURPA has played a critical role in moving cogeneration into the marketplace by addressing many barriers that were present in the early 1980s.

During the 1990s, approximately 9500 miles of new high-voltage transmission lines were constructed (an approximately 7% increase)—short of the need—which represented a new opportunity for efficient distributed generation (DG) and cogeneration use. The U.S. Department of Energy (DOE) estimates that more than 390 GW of new generating capacity will be needed by 2020 to meet growing U.S. energy demand and offset power lost from retired power plants. However, obtaining approval for construction of new transmission lines and acquiring right-of-ways is very difficult.

According to Tom Casten, founder of Trigen and currently chairman and CEO of Private Power, "The public simply detests new transmission lines, and no one wants them in their back yard. Most recent U.S. power problems were caused by lack of adequate transmission and distribution (T&D), and nobody close to the industry believes enough new transmission can be built." Distributed cogeneration systems require no new construction of T&D lines. Tom Casten cites industry forecasts that estimate that the United States will need 137,000 MW of new capacity by 2010. According to Casten, meeting this demand will require $84 billion for new power plants and $220 billion for new T&D, for a total of $304 billion. Meeting the same demand with DG will require $168 billion for new plants but $0 for T&D. Casten notes, "A distributed energy future would save $136 billion of capital investment and reduce the cost of new power by about 3¢/kW."

1.2 Present

The Energy Information Administration (EIA) reports that as of 2000, cogeneration accounted for approximately 7.5% of electricity generation capacity and almost 9% of electricity generated in the United States. Private Power studied data from an unpublished EIA survey and other EIA data and determined that total DG was 10.7% of U.S. totals in 2000.

In stark contrast, in The Netherlands, more than 40% of electricity is obtained from combined heat and power (CHP) systems, and in Denmark, approximately 60% is obtained from these systems. In the United Kingdom, cogeneration's share of electric power production has doubled in the past decade, with additional growth targeted by the government.

2. TECHNICAL CHARACTERIZATION

2.1 Efficiency Gains

According to the U.S. Combined Heat and Power Association, cogeneration technologies produce both electricity and steam from a single fuel at a facility located near the consumer. These efficient systems recover heat that normally would be wasted in an electricity generator, and they save the fuel that would otherwise be used to produce heat or steam in a separate unit.

Cogeneration offers dramatic advantages in efficiency and much lower air pollution than conventional technologies (Fig. 1). A wide variety of cogeneration technologies generate electricity and meet thermal energy needs (direct heat, hot water, steam, and process heating and/or cooling) simultaneously at the point of use. Cogeneration can result in system efficiencies of 70–90%, compared with the national average of 30% efficiency for conventional electricity plants and perhaps 50% for conventional thermal applications.

The environmental benefits of cogeneration are apparent. Cogeneration systems in the United States:

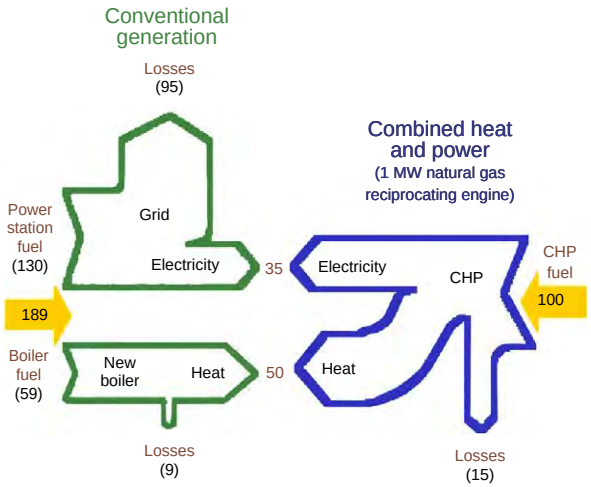

FIGURE 1 This diagram compares the typical fuel input needed to produce 35 units of electricity and 50 units of heat using conventional separate heat and power. For typical electric and thermal efficiencies, cogeneration is nearly twice as efficient.

- Decrease energy use by approximately 1.3 trillion Btus/year.
- Reduce NO_x emissions by 0.4 million tons/year.
- Reduce sulfur dioxide (SO_2) emissions by more than 0.9 million tons/year.
- Prevent the release of more than 35 million metric tons of carbon equivalent into the atmosphere.

2.2 Technology Advances

Nearly all U.S. buildings and industries use thermal energy from boilers for space heating, hot water, steam systems, and direct process heating applications. Most cogeneration systems installed in the United States are used for industrial applications, but there is increasing usage by U.S. commercial and institutional building owners and district energy systems worldwide. Newer thermally activated technology applications include recycling waste heat for cooling and humidity control, which has significant energy and economic potential.

Recent advances in technology have resulted in the development of a range of efficient and versatile systems for industrial and other applications. Improvements in electricity generation technologies, particularly advanced combustion turbines and engines, have allowed for new configurations that reduce size but increase output. Distributed, on-site power generation technologies, such as microturbines, reciprocating engines, industrial turbines, and fuel cells, are becoming more effective at generating electricity and producing recoverable thermal energy.

Recovered heat from these generation technologies can be used to power thermally activated technologies, control humidity with desiccant dehumidifiers, and heat buildings with steam or hot water in cogeneration systems.

2.3 Prime Movers

Prime movers generate electricity and heat, or electric and thermal energy. They include several technologies. First, microturbine generator units are composed of a compressor, combustor, turbine, alternator, recuperator, and generator. In a simple cycle turbine (without a recuperator), compressed air is mixed with fuel and burned under constant pressure conditions. The resulting hot gas is allowed to expand through a turbine to perform work.

Recuperated units use a heat exchanger (recuperator or regenerator) that recovers some of the heat from the turbine exhaust and transfers it to the incoming air stream for combustion in the turbine. By using recuperators that capture and return waste exhaust heat, existing microturbine systems can reach 25–30% cycle efficiency. The incorporation of advanced materials, such as ceramics and thermal barrier coatings, could further improve their efficiency by enabling a significant increase in engine operating temperature.

Microturbines offer many advantages over other technologies for small-scale power generation, including the ability to provide reliable backup power, power for remote locations, and "peak shave." Other advantages include less maintenance and longer lifetimes because of a small number of moving parts, compact size, lighter weight, greater efficiency, lower emissions, and quicker starting. Microturbines also offer opportunities to use waste fuels such as landfill gas.

Second, gas-fired reciprocating engines are the fastest selling, least expensive distributed generation technology in the world. Commercially available natural gas versions of the engine produce power from 0.5 kW to 10 MW, have efficiencies between 37 and 40%, and can operate down to NO_x levels of 1 g per horsepower-hour. When properly treated, these rugged engines can run on fuel generated by waste treatment (methane) and other biofuels. By using recuperators that capture and return waste exhaust heat, reciprocating engines can also be used in cogeneration systems in buildings to achieve energy-efficiency levels approaching 80%.

Gas-fired reciprocating engines offer many advantages over other technologies for small-scale power generation, including the ability to provide highly reliable, inexpensive backup power; provide power for remote locations; and generate on-site power during peak periods when utility charges are highest.

Reciprocating engines require fuel, air, compression, and a combustion source to function. Depending on the ignition source, they generally are classified into two categories: spark-ignited engines, typically fueled by gasoline or natural gas, and compression-ignited engines, typically fueled by diesel oil.

Third, tremendous efficiency strides with regard to industrial gas turbines have been made in recent years. Combustion turbines are a class of electricity-generation devices that produce high-temperature, high-pressure gas to induce shaft rotation by impingement of the gas on a series of specially designed blades. Industrial gas turbines are used in many industrial and commercial applications ranging from 1 to 20 MW.

Because gas turbines are compact, lightweight, quick starting, and simple to operate, they are used widely in industry, universities and colleges, hospitals, and commercial buildings to produce electricity, heat, or steam. In such cases, simple cycle gas turbines convert a portion of input energy from the fuel to electricity and use the remaining energy, normally rejected to the atmosphere, to produce heat. This waste heat may be used to power a separate turbine by creating steam. The attached steam turbine may generate electricity or power a mechanical load. This is referred to as a combined cycle combustion turbine since two separate processes or cycles are derived from one fuel input to the primary turbine.

These reliable distributed generation technologies are becoming the mainstay of peak shaving equipment. When needed, this equipment can be started immediately and can quickly generate full capacity.

The waste heat generated by the turbine can be used to generate steam in a heat recovery steam generator (HRSG), which can power a steam turbine, heat living space, or generate cooling using steam-driven chillers. The advantages of these types of systems are inexpensive electrical power and better reliability since the user may be independent from the grid. These systems can be started even if the grid has failed.

Advanced materials, such as ceramics, composites, and thermal barrier coatings, are some of the key enabling technologies under development to improve the efficiency of distributed generation technologies. Efficiency gains can be achieved with materials such as ceramics, which allow a significant increase in engine operating temperature. The increased operating temperature also lowers greenhouse gas and NO_x emissions.

Two successful applications of HRSG systems are at Princeton University and the Massachusetts Institute of Technology (MIT). Each school deploys a gas turbine for electrical generation to meet the majority of the campus's needs. The exhaust heat from these turbines drives an HRSG. The steam from the HRSG provides heating for campus living spaces and cooling through steam-driven chillers. Frequently, summer peak-time operation of electrical chillers is expensive. Producing steam on-site enables the use of steam-driven chillers. Operating steam-driven chillers acts to peak shave the user's high demand operations, thus saving money. The electricity generated by the gas turbine may also be used to operate conventional electric chillers. Since the user generates this electricity, the price may be lower than that of the local utility and does not have a peak or demand charge associated with it.

Fourth, fuel cells were discovered in 1839 when scientist William Grove accidentally let a hydrolysis experiment run backwards. He was surprised to learn that electron flows were created when hydrogen and oxygen combined. NASA made this technology well-known with its use in space shuttles.

Fuel cells consist of two electrodes (cathode and anode) around an electrolyte. The generation process involves introducing hydrogen to one side of the fuel cell (the anode), where it breaks apart into protons and electrons. The electrode conducts protons but not electrons. The protons then flow through while the electrons travel through the external circuit and provide electrical power. The electrons and protons are reunited at the other end of the fuel cell (the cathode). When combined with oxygen from the air, fuel cells produce water and heat in a process that is practically silent, nearly emission free, and involves no moving parts.

Fuel cells are categorized by the kind of electrolyte they use. Electrolyte types used in the building sector include phosphoric acid, molten carbonate, solid oxide, and proton exchange membrane. High-temperature molten carbonate and solid oxide fuel cells are undergoing full-scale demonstration with some existing applications. Manufacturers are actively pursuing this technology for widespread, general use in commercial buildings, homes, and transportation.

Although price and performance data on reciprocating engines and turbines are fairly well established, data for fuel cells are based on a limited number of demonstration projects. As a result, comparisons of price and performance should be interpreted with caution.

The price and performance of engines, turbines, and fuel cells are summarized in Table I.

Finally, concentrating solar electric generators concentrate solar power during the high solar radiation periods onto tubes of water (or oil) to make usable steam, which can then be used to make electricity in a steam generator or to power a chiller. Some concentrating solar electric generators use a hybrid renewable/fossil fuel system to diversify their energy source.

California's Mojave Desert is home to the world's largest concentrating solar power facility. The Solar Electric Generating System plants have a combined capacity of 354 MW and are configured as hybrids. The nine hybrid plants generate more than 75% of the total power output from the sun, with natural gas providing the balance.

TABLE I

Cost and Performance of Distributed Generation Technologies for Cogeneration Systems[a]

Technology	Reciprocating engine	Turbine and microturbine	Fuel cell
Size	30 kW–8 MW	30 kW–20 + MW	100–3000 kW
Installed cost ($/kW)[b]	300–1500	350–1500	2000–5000
Electricity efficiency (LHV)	28–42%	14–40%	40–57%
Overall efficiency[c]	~80–85%	~85–90%	~80–85%
Variable O&M ($/kWh)	0.0075–0.02	0.004–0.01	0.002–0.05
Footprint (ft^2/kW)	0.22–0.31	0.15–0.35	0.9
Emissions (lb/kWh unless otherwise noted)			
Diesel			
NO_x	0.22–0.025	3–50 ppm	<0.00005
CO	0.001–0.002	3–50 ppm	<0.00002
Natural gas			
NO_x	0.0015–0.037		
CO	0.004–0.006		
Fuels	Diesel, natural gas, gasoline, digester gas, biomass and landfill gas; larger units can use dual-fuel (natural gas-diesel) or heavy fuels	Natural gas, diesel, kerosene, naphtha, methanol, ethanol, alcohol, flare gas, digester gas, biomass and landfill gas	Natural gas, propane, digester gas, biomass and landfill gas (potentially)

[b] Cost varies significantly based on siting and interconnection requirements as well as unit size and configuration.
[c] Assuming cogeneration.

2.4 Thermally Activated Technologies

Thermally activated technologies (TATs) take advantage of the waste heat from prime movers. There are several types of TATs.

First, absorption chillers provide cooling to buildings by using heat. This seemingly paradoxical but highly efficient technology is most cost-effective in large facilities with significant heat loads. Absorption chillers not only use less energy than conventional equipment but also cool buildings without the use of ozone-depleting chlorofluorocarbons.

Unlike conventional electric chillers, which use mechanical energy in a vapor compression process to provide refrigeration, absorption chillers primarily use heat energy with limited mechanical energy for pumping. These chillers can be powered by natural gas, steam, or waste heat.

An absorption chiller transfers thermal energy from the heat source to the heat sink through an absorbent fluid and a refrigerant. The absorption chiller accomplishes its refrigerative effect by absorbing and then releasing water vapor into and out of a lithium bromide solution. The process begins as heat is applied at the generator and water vapor is driven off to a condenser. The cooled water vapor then passes through an expansion valve, where the pressure reduces. The low-pressure water vapor then enters an evaporator, where ambient heat is added from a load and the actual cooling takes place. The heated, low-pressure vapor returns to the absorber, where it recombines with the lithium bromide and becomes a low-pressure liquid. This low-pressure solution is pumped to a higher pressure and into the generator to repeat the process.

Absorption chiller systems are classified by single-, double-, or triple-stage effects, which indicate the number of generators in the given system. The greater the number of stages, the higher the overall efficiency. Double-effect absorption chillers typically have a higher initial cost, but a significantly lower energy cost, than single-effect chillers, resulting in a lower net present worth. Triple-effect systems are underdevelopment.

Chillers employ cogeneration thermal output during cooling periods when heating uses are limited to domestic hot water loads or zonal heating, which may be small in many building types. These units involve a complex cycle of absorbing heat from the cogeneration system to create chilled water. The

waste heat from the cogeneration system is used to boil a solution of refrigerant/absorbent. Most systems use water and lithium bromide for the working solution. The absorption chiller then captures the refrigerant vapor from the boiling process and uses the energy in this fluid to chill water after a series of condensing, evaporating, and absorbing steps are performed. This process is essentially a thermal compressor, which replaces the electrical compressor in a conventional electric chiller. In so doing, the electrical requirements are significantly reduced, requiring electricity only to drive the pumps that circulate the solution by single-effect chillers (Table II).

Second, engine-driven chillers (EDCs) are essentially conventional chillers driven by an engine instead of an electric motor. They employ the same thermodynamic cycle and compressor technology as electric chillers but use a gas-fired reciprocating engine to drive the compressor. As a result, EDCs can provide cooling economically where gas rates are relatively low and electric rates are high. EDCs also offer better variable-speed performance, which yields improved partial load efficiencies (Table III).

Third, desiccant dehumidifiers use thermal energy to dehumidify and to some extent control the indoor air quality of building space. With the recent push toward building humidity control, manufacturers of desiccant dehumidification systems have developed new packages designed to treat building ventilating air efficiently. A desiccant dehumidifier uses a drying agent to remove water from the air being used to condition building space. Desiccants can work in concert with chillers or conventional air-conditioning systems to significantly increase energy system efficiency by allowing chillers to cool low-moisture air. Desiccants can run off the waste heat from distributed generation technologies, with system efficiency approaching 80% in cogeneration mode.

The desiccant process involves exposing the desiccant material (e.g., silica gel, activated alumina, lithium chloride salt, and molecular sieves) to a high relative humidity air stream—allowing it to attract and retain some of the water vapor—and then to a lower relative humidity air stream, which draws the retained moisture from the desiccant. In some applications, desiccants can reduce cooling loads and peak demand by as much as 50%, with significant cost savings.

In stand-alone operations, a solid (dry) desiccant removes moisture from the air; a heat exchanger and evaporative cooler then chill the air. A desiccant dehumidifier wheel, composed of lightweight honeycomb or corrugated matrix material, dries the air as the wheel rotates through the supply air before reaching the building. Once the desiccant material reaches its saturation point, heat must be added or the material must be replaced to regenerate the moisture-absorbing capability. Natural gas, waste heat, or solar energy can be used to dry moisture that

TABLE II

Cost and Performance of Single-Effect, Indirect-Fired Absorption Chillers[a]

Tons	Cost ($/ton)	Electric use (kW/ton)	Thermal input (Mbtu/ton)	Maintenance cost ($/ton annual)
10–100	700–1200	0.02–0.04	17–19	30–80
100–500	400–700	0.02–0.04	17–18	20–50
500–2000	300–500	0.02–0.05	17–18	10–30

TABLE III

Cost and Performance of Engine-Driven Chillers[a]

Tons	Cost ($/ton)	Electric use (kW/ton)	Thermal input (Mbtu/ton)	Maintenance cost ($/ton annual)
10–100	800–1050	0.05–0.07	9–12	45–100
100–500	650–950	0.01–0.05	8–11	35–75
500–2000	450–750	0.003–0.01	7–8	25–60

[a] *Source*. Resource Dynamics Corporation (2002).

is either absorbed or collected on the surface to regenerate the material.

Liquid absorption dehumidifiers spray the air with a desiccant solution that has a lower vapor pressure than that of the entering air stream. The liquid has a vapor pressure lower than water at the same temperature, and the air passing over the solution approaches this reduced vapor pressure. The conditioner can be adjusted so that it delivers air at the desired relative humidity. Liquid desiccant materials include lithium chloride, lithium bromide, calcium, chloride, and triethylene glycol solutions (Table IV).

Finally, hybrid power systems combine different power generation devices or two or more fuels for the same device. When integrated, these systems overcome limitations inherent in either one. Hybrid power systems may feature lower fossil fuel emissions as well as continuous power generation when intermittent renewable resources, such as wind and solar, are unavailable.

Solar concentrators/chiller systems use sunlight, which is plentiful in many regions of the country and is a load follower for afternoon cooling demand, to power an absorption cooling in low- to medium-temperature-driven systems, with either nontracking or tracking solar energy collectors and a two-stage absorption chiller. The resultant hybrid systems can produce an average cooling season solar fraction of at least 60% (40% of the cooling load supplied by natural gas) so that the net primary source fuel COP for the fossil fuel used is 3.0. Therefore, solar/gas absorption cooling systems will consume one-third the average primary source energy used for electric air-conditioning in the United States.

The widespread use of solar/thermal systems would have a significant impact on reducing the demand for electric power and for extending natural gas reserves. Every 1000 tons of installed solar/natural gas absorption air-conditioning equipment relieves the electric power grid of an average of 1 MW of demand.

3. APPLICATIONS AND MARKETS

New cogeneration project growth throughout the United States has been curtailed because of natural gas and oil prices and price volatility, making spark spread an unreliable cogeneration potential indicator. Natural gas price volatility and historic high prices have dampened new cogeneration natural gas-fueled projects in general. Market factors causing these price excursions are complex and not fully understood. Concurrently, there has been a similar increase in oil prices.

Because of the uncertainty in fuel prices and availability, spark spread is a difficult dimension to quantify or qualify, and industry growth should take precedence over other standard measures of cogeneration economic feasibility such as spark spread—the cost differential between electricity generated from central plants vs distributed generation—according to the American Council for an Energy-Efficient Economy (ACEEE).

Cogeneration systems can be especially useful in areas of the country in which development is constrained due to poor air quality. This is particularly significant in older, industrial cities such as Chicago. In air emission zones in California, the Northeast, and the Midwest, new development can create the need for emissions offsets. Cogeneration systems can meet this requirement, especially when using output-based emission standards that capture these system's high fuel efficiencies.

3.1 Utilities

Grid reliability could be a strong driver for cogeneration growth; for example, New York City's power system needs an additional 7100 MW to enhance reliability, according to the Center for Business Intelligence. With utility restructuring, access to downtown generation capacity from a cogeneration

TABLE IV

Cost and Performance of Desiccant Dehumidification Systems[a]

SCFM	Cost ($/SCFM)	Thermal input (hourly Btu/SCFM)	Maximum latent removal (hourly Btu/SCFM)
1500–5000	8–18	30–100	30–60
5000–10,000	6–11	30–100	30–60
10,000 +	6–9	30–100	30–60

[a] *Source*. Resource Dynamics Corporation (2002).

facility may be more attractive and less problematic to the local electric utility in terms of projected load loss.

Addressing the need for distributed energy systems to interconnect to the electric utility grid, and to obtain supplemental and backup power, is critical to the success of cogeneration projects throughout the United States. Including multiple, dispersed generating and cogeneration units throughout the grid is a relatively new concept—one that has to be incorporated into the existing technical, regulatory, and institutional framework.

Some utilities are considering investing in the cogeneration value proposition to not only help them meet air quality objectives in their service territories but also to respond to customer service demands. Some utilities understand that cogeneration systems can significantly lower power plant, offer affordable incremental power costs, help optimize natural gas resources, hold gas costs down, and may open the door to new thermal energy business.

Also, if regulators do not permit, or if utilities disincent, cogeneration competition on an interconnected basis, end users will be forced to install the on-site systems on an "islanded" basis, leaving electric utilities out of the energy business. Now is an opportune time for utilities to embrace cogeneration as part of a national energy security campaign and as part of their own strategic business plans.

3.2 Industrial

Cogeneration has been most successful in large industrial applications that require large amounts of steam, but it is also well suited to use in hospitals, laundries, and health clubs. Since 1980, approximately 50,000 MW of cogeneration capacity has been built in the United States.

Cogeneration in the large to medium industrial market is typically found in the process industries, such as petroleum refining, pulp and paper, and chemicals. These systems have installed electricity capacities >25 MW (often hundreds of megawatts) and steam generation rates measured in hundreds of thousands of pounds of steam per hour. This sector represents the largest share of the current installed cogeneration capacity in the United States and is the segment with the greatest potential for short-term growth. Some facilities of this type are merchant power plants using combined cycle configurations. They are owned by an independent power producer that seeks an industrial customer for its waste stream and sells excess electricity on the wholesale market.

Thousands of boilers provide process steam to a broad range of small industrial U.S. manufacturing plants. These boilers offer a large potential for adding new electricity generation between 50 kW and 25 MW by either modifying boiler systems to add electricity generation (e.g., repowering existing boilers with a combustion turbine) or replacing the existing boiler with a new cogeneration system. Small manufacturers represent an important growth segment during the next decade.

Various industrial markets, including petrochemical, food products, bioproducts, and biotech, rank as the highest priority markets for future industry growth. The petrochemical market is the largest cogeneration market sector nationally, representing approximately 40% of existing cogeneration capacity. Bulk chemicals are in economic decline domestically. Some sectors of the chemicals industry are continuing to experience significant growth, including pharmaceuticals, specialty chemicals, and bioproducts including ethanol and biofeedstocks.

Food products manufacturing is a fast growing and stable market with demonstrated opportunity for cogeneration. The ACEEE has identified food products as one of the most geographically dispersed industry groups, with a significant presence in almost all states. In contrast to wood products and bulk chemicals industries, which are in economic decline domestically, the food products industry is among the fastest growing industry groups.

The growing biotech industry has overtaken the computer and semiconductor industry as a leader in projected economic growth. Both sectors have similar power reliability and thermal management needs. The biotech market has not experienced the same slowdown that has been seen in the computer-related markets.

3.3 District Energy

District energy systems are a growing market for cogeneration because these systems significantly expand the amount of thermal loads potentially served by cogeneration. District energy also has a major added benefit of reducing the requirement for size and capital investment in production equipment due to the diversity of consumer loads. These systems also tend to use larger and more efficient equipment and can take advantage of such things as thermal energy storage that are not economically effective on a small scale. Additionally, district energy systems aggregate thermal loads, enabling more cost-effective cogeneration. District energy systems may be installed

at large, multibuilding sites, such as universities, hospitals, and government complexes. District energy systems can also serve as merchant thermal systems providing heating (and often cooling) to multiple buildings in urban areas.

According to the International District Energy Association (IDEA), there are three primary markets for district energy: colleges and universities, downtowns, and airports. The college and university market seems to be the most promising due to several factors. Colleges and universities are installing cogeneration in response to campus load growth, asset replacement of aging boiler capacity, and the favorable economics from fuel efficiency improvements with cogeneration.

Frequently, large campuses centralize heating and cooling and have large electrical loads. Many options are available for satisfying this electrical, heating, and cooling demand. A common way is to size a boiler for the entire campus's heating load. Large facilities may be able to negotiate attractive fuel contracts that lower heating costs and may choose to oversize the boiler, enabling the use of excess steam to power a steam turbine for electrical generation or a steam-driven chiller. This cheap, on-site secondary power source (steam) may make the generation of electricity or cooling less expensive than conventional methods such as purchasing from the grid and using conventional electric chillers.

The University of North Carolina at Chapel Hill, the University of Texas at Austin, and Cornell University represent examples of this situation. In each case, the universities have large boilers making steam for a variety of uses. Each campus ties the boilers to a steam turbine and the campus's heating system. The steam turbine generates electricity for campus use, reducing the dependency on the local grid and saving operating dollars for the campus. This cheap electricity may also be used to operate electric chillers for cooling, further reducing cooling costs. The remainder of the steam is used for heating of domestic water and all the campus's office, classroom, and dormitory spaces. Steam generated by the boilers may also be used by steam-driven chillers for cooling campus living space.

IDEA reports that college and university markets have significant pressures for "greening the campus," especially in the Northeast. Princeton, MIT, Rutgers, and the New Jersey Higher Education Partnership for Sustainability are exemplary, but there are other promising college and university examples throughout the country.

IDEA also notes that many colleges and universities conduct critical research and therefore need reliable power to avoid losing months or years of research and to assure students and the community that test animals are being properly cared for. Cogeneration could provide both power reliability and space conditioning.

Major urban centers are also a very promising market for adding cogeneration to existing district energy systems. Many district energy steam plants were originally cogeneration facilities that generated both power and steam when owned by the local electric utility. There is a growing need for local grid support in light of utility divestiture of generating capacity coupled with solid market growth in downtown district energy systems.

Airports represent another promising opportunity; these facilities are often in NO_x nonattainment areas and face significant emissions pressure from both regulators and the community. With large space conditioning and electrical load with long hours of operation, airports are often well suited to add cogeneration to their district energy systems.

3.4 Federal Government

The federal government is the largest energy consumer in the United States, with new mandates to meet increased demand, reduce peak operating costs, enhance energy security, and improve the reliability of electric power generation through DG and cogeneration. The Federal Energy Management Program was created to reduce government costs by advancing energy efficiency, water conservation, and the use of solar and other renewable energies. Executive Order 13123, "Greening the Government through Efficient Energy Management,: specifies that federal facilities shall use combined cooling, heat, and power systems when lifecycle costs indicate that energy reduction goals will be achieved. This market sector resembles the district energy sector, although the two sectors have different drivers and budgetary pressures.

According to the ACEEE, the largest cogeneration potential at federal facilities has been identified at military facilities, many of which are managed by various agencies within the Department of Defense.

3.5 Commercial/Institutional

The United States consumed more than 94 quadrillion Btus of energy in 2000. Of this total,

commercial buildings accounted for more than 16 quadrillion Btus—equivalent to the amount of energy of gasoline consumed in the United States in 1 year. The growth of the economy, as well as the nation's increasing population, is leading to greater numbers of larger and more energy-intensive homes and commercial buildings, resulting in increased energy consumption in this sector.

Several reports indicate CHP potential and interest in the large commercial office buildings, hospital/health care, supermarket, hotel/motel, restaurant, and large retail markets. Some markets appear to have strong drivers to adopt CHP; for example, grocery stores have significant dehumidification loads to keep water from condensing on freezer displays, and hospitals and health care facilities have significant reliability needs. Schools appear to be a prime market for desiccant dehumidifiers, which control humidity and therefore reduce the likelihood of mold and bacteria growth.

In 2002, the Federal Communications Commission (FCC) adopted a plan that will give consumers access to digital programming over television by requiring off-air digital television (DTV) tuners on nearly all new TV sets by 2007. By enacting a 5-year rollout schedule that starts with larger, more expensive TV sets, the FCC is minimizing the costs for equipment manufacturers and consumers but creating new demands on power reliability for TV stations.

Commercial brownfield sites, or "real property, the expansion, redevelopment, or reuse of which may be complicated by the presence or potential presence of a hazardous substance, pollutant, or contaminant," are an appealing market for cogeneration. Redeveloping contaminated brownfield sites removes serious environmental hazards. Cogeneration can play an important role in the effort. Suzanne Watson of the Northeast-Midwest Institute notes that "with the right new technology fixes, there is the potential to create developments that improve the natural environment. Cogeneration is one of these technology solutions."

The DOE is helping manufacturers work together to integrate their individual CHP components into easier to use packages and to make "plug-and-play" packages more readily available in the commercial marketplace. On August 8, 2001, Energy Secretary Abraham announced awards to seven industry teams for research, development, and testing of "first-generation packaged cooling, heating, and power systems.

3.6 Residential

The DOE and the U.S. Department of Housing and Urban Development (HUD) are currently encouraging residential cogeneration units for individual or aggregated loads, which could be achieved in the multifamily markets under HUD jurisdiction.

There is significant potential for cogeneration in the privately owned assisted and public housing multifamily markets, where electric and thermal loads are already aggregated. According to HUD, the assisted housing market has a greater number of properties with less than 50 units, as opposed to the public housing market (20 units was used as a reasonable cogeneration entry point for both markets). In the assisted housing market, there are approximately 109,000 HUD properties with 20–49 units and 53,000 properties with more than 50 units. In the public housing market, there are approximately 4535 HUD properties with 20–49 units and 7154 properties with more than 50 units.

4. REGULATORY AND RATE STRUCTURE ISSUES

4.1 Standardizing Interconnect

Addressing the need for distributed energy systems to interconnect to the electric utility grid, and to obtain supplemental and backup power, is critical to the success of cogeneration projects. Until recently, the U.S. electric system was based on central station generation, tied to customers through the use of transmission lines. Including multiple, dispersed generating, and cogeneration units throughout the grid is a relatively new concept—one that has to be incorporated into the existing technical, regulatory, and institutional framework.

The DOE has been working for several years with industry through the Institute of Electrical and Electronics Engineers (IEEE) to develop a uniform national standard for interconnection. The IEEE P1547, "Standard for Distributed Resources Interconnected with Electric Power Systems," will provide interconnection guidelines for performance, operation, testing, safety, and maintenance. It is hoped that many utilities and state utility regulators will adopt it, giving their customers more power generation choices.

The Federal Energy Regulatory Commission has a rule making under way to establish standards and practices for interconnection of DG systems. The comment period for the proposed rule closed in early 2002.

In some cases, cogeneration projects would be able to proceed if the interconnection procedures for generators were standardized through a process of law making or rule making with the state simplifying, or at least setting, a recognized standard for the process. Both Texas and California have developed state-level interconnection standards (CEC 2001 and Texas 2000). These standards represent a compromise between utilities and generators. Although the guidelines differ in some specifics and main motivation, both create a relatively rapid and standard procedure for all generators seeking to connect to the grid.

The Texas Public Utility Regulatory Act of 1999 granted all utility customers access to DG. On February 4, 1999, the Texas Public Utility Commission (PUCT) adopted interconnection standards (PUCT 1999). PUCT continued to investigate DG and in May 2002 published a guidebook to interconnection in the state.

California's decision to expedite the streamlining of interconnection procedures resulted from their well-publicized energy problems in 2000 and 2001. Although there are many reasons why California had to resort to rolling blackouts, increasing DG is a way to remove pressure from the grid and reduce the likelihood that the event will be repeated.

The California Energy Commission (CEC) completed a state DG plan (CEC 2002), which included a plan for creating standardized guidelines for interconnection to the grid. In 2002, the CEC's Rule 21 Interconnection Working Group completed this guideline. Soon thereafter, the California Public Utilities Commission adopted the standards. Individual utility versions of the interconnection standards can be found at www.energy.ca.gov.

4.2 Output-Based Standards

Implementation of output-based standards, pollution allowances per kilowatt-hour, or useful electrical and thermal energy recognizes that cogeneration systems achieve significant reductions in environmental emissions due to their much higher efficiencies of fuel conversion relative to conventional separate heat and power systems. These standards would measure environmental emissions, or the rate at which emissions are discharged by the technology to the environment per unit of total usable energy produced by the technology as opposed to emissions per unit of fuel consumed. These standards should value electric and nonelectric output equally and be independent of fuel source. They should not discriminate against different ownership situations.

A promising development that the U.S. Environmental Protection Agency (EPA) is sponsoring is "demand response" run by regional transmission organizations. End users can bid back to the grid pool to reduce their electricity use by using on-site power or energy efficiency at set rates.

4.3 Time-of-Use Pricing

Time-of-use pricing is a rate structure intended to encourage customers to shift their energy use away from peak hours when wholesale electricity prices are highest. Real-time pricing can be readily used in large commercial and industrial facilities to manage thermal loads, making cogeneration more cost-effective. Chilled water and ice thermal energy storage, for example, are effective means to shift load to off-peak periods.

5. U.S. FEDERAL GOVERNMENT SUPPORT

The U.S. federal government is supporting cogeneration at the highest administration levels as well as through various agency programs and association support.

5.1 Administration

Released in May 2001, the Bush administration's National Energy Plan recognized the important role that cogeneration can play in meeting national energy objectives and maintaining comfort and safety of commercial and office buildings. Section 3–5 states:

> *A family of technologies known as combined heat and power (CHP) can achieve efficiencies of 80% or more. In addition to environmental benefits, CHP projects offer efficiency and cost savings in a variety of settings, including industrial boilers, energy systems, and small, building scale applications. At industrial facilities alone, there is potential for an additional 124,000 MW of efficient power from gas-fired CHP, which could result in annual emissions reductions of 614,000 tons of NO_x emissions and 44 million tons of carbon equivalent. CHP is also one of a group of clean, highly reliable distributed energy technologies that reduce the amount of electricity lost in transmission while eliminating the need to construct expensive power lines to transmit power from large central power plants.*

5.2 U.S. Environmental Protection Agency

Currently, power plants are responsible for two-thirds of the nation's annual SO_2 emissions, one-fourth of

the NO_x emissions, one-third of the mercury emissions, and one-third of the CO_2 emissions, a leading greenhouse gas. These emissions contribute to serious environmental problems, including global climate change, acid rain, haze, acidification of waterways, and eutrophication of critical estuaries. They also contribute to numerous health problems, such as chronic bronchitis and aggravation of asthma, particularly in children.

The EPA understands that resolving these problems must start with pollution prevention, which equates to using fewer energy resources to produce goods and services. The National Energy Plan includes four specific recommendations to promote efficient cogeneration, three of which were directed to the EPA for action:

1. Promote cogeneration through flexible environmental permitting.
2. Issue guidance to encourage development of highly efficient and low-emitting cogeneration through shortened lead times and greater certainty.
3. Promote the use of cogeneration at abandoned industrial or commercial sites known as brownfields.

As a follow-up to these recommendations, the EPA joined with 18 *Fortune* 500 companies, city and state governments, and nonprofits in February 2002 in Washington, DC, to announce the EPA Combined Heat and Power Partnership. Cogeneration advances cogeneration as a more efficient, clean, and reliable alternative to conventional electricity generation.

As another follow-up to the National Energy Plan, the EPA is continuing work on a guidance document that clarifies how source determinations should be made for district energy and cogeneration projects under the New Source Review and Title V permitting regulations. The EPA intends for this guidance to help permitting officials and project developers streamline the development and permitting of these projects nationwide.

Through multiple programs, the DOE and its network of national laboratories have been working with manufacturers, end users, and other government offices to support increased use of cogeneration technologies.

5.3 U.S. Department of Energy

The DOE's Office of Distributed Energy Resources coordinates the CHP Initiative to raise awareness of the energy, economic, and environmental benefits of cogeneration and highlight barriers that limit its increased implementation. The initiative supports a range of activities, including regional, national, and international meetings; industry dialogues; and development of educational materials.

The DOE is also helping manufacturers work together to integrate their individual cogeneration components into easier to use packages and to make plug-and-play packages more readily available in the commercial and industrial marketplace. On August 8, 2001, Energy Secretary Abraham announced awards to seven industry teams for research, development, and testing of first-generation packaged cooling, heating, and power systems.

Integrated energy systems (IES) is a new approach to integrating all types of energy technologies into a building's energy system, including DG, cogeneration, HVAC, doors, windows, distribution systems, controls, insulation, building materials, lighting, and other building equipment. The link between building design and energy use is key to IES. As a DOE National User Facility, Oak Ridge National Laboratory (ORNL) provides manufacturers access to the user facility to help them evaluate and optimize the performance of IES and develop IES certification protocols.

The IES test center at the University of Maryland is designed to show building owners and managers how to save energy without sacrificing comfort in their buildings. The center is testing various cogeneration systems in an office building on campus. Phil Fairchild, program manager for Cooling, Heating, and Power for ORNL, explains,

> *What we're trying to do at the test center is to put together different pieces of equipment, use recoverable energy, and in doing so, understand the science of integration so that we can assist or better advise manufacturers about how to integrate the equipment in the future. If we reach our goals, manufacturers will have a better incentive, in terms of efficiency gains, to offer packaged or modular systems to the commercial building sector.*

The DOE is supporting a series of regional CHP application centers to provide application assistance, technology information, and education to architects and engineering companies, energy services companies, and building owners in eight states. The Midwest CHP application center was the first, established in March 2001 as a partnership between the DOE, the University of Illinois at Chicago's Energy Resources Center, the Gas Technology Institute, and ORNL. The center's educational material includes a Web site, accredited training classes, engineering tool kits, case studies, and application screening tools.

The DOE's Industrial Technologies Program (ITP) coordinates a combustion program with the industrial combustion community. The program promotes research and development of combustion systems used to generate steam and heat for vital manufacturing processes, heat-processing materials from metals to chemical feedstocks, and change the mechanical and chemical properties of materials and products.

The Steam Challenge is a public–private initiative sponsored by ITP. The goal of Steam Challenge is to help industrial customers retrofit, maintain, and operate their steam systems more efficiently and profitably. Steam Challenge provides steam plant operators with tools and technical assistance while promoting greater awareness of the energy and environmental benefits of efficient steam systems.

Glossary

adiabatic flame temperature The highest flame temperature that is achievable under the condition of no external heat transfer.
combustion The burning of fuel and oxidant to produce heat and/or work.
computational fluid dynamics (CFD) Computer program for calculating fluid dynamics properties of a flow.
diffusive flame Separate fuel and oxidant inlets before burning takes place.
flammability Combustion reaction criteria.
gasification Incomplete fuel-rich combustion that produces CO and/or H_2.
ignition Initial conditions for sustained combustion.

Much solar energy is stored in hydrocarbons. Early humans, seeking protection and comfort, learned to convert hydrocarbon energy to fire to survive. Combustion, the most important form of energy conversion, is a chemical reaction between a hydrocarbon fuel and an oxidant. Combustion generates significant amounts of light, heat, and/or mechanical work. Furnaces and combustors have been developed to generate electricity and manufacture tools and equipment. Combustion engines have enabled transportation in every region of Earth and even into space. In recent years, concerns over energy availability and the environmental impacts of combustion processes have attracted more and more attention. To use energy resources efficiently and responsibly has become a main goal of many societies. To achieve this goal, knowledge of combustion science has to be learned and applied.

1. INTRODUCTION

Combustion includes thermal, hydrodynamic, and chemical processes. Combustion starts with the mixing of fuel and oxidant, and sometimes in the presence of additional compounds or catalysts. The fuel/oxidant mixture can be ignited with a heat source; chemical reactions between fuel and oxidant then take place and the heat released from the reactions makes the process self-sustaining. Instability may occur, inhibiting or strengthening combustion. Combustion products include heat, light, chemical species, pollutants, mechanical work, and plasma. Sometimes, a low-grade fuel, e.g., coal, biomass, and coke, can be partially burned to produce a higher grade fuel, e.g., methane. The partial burning process is called gasification. Various combustion systems, e.g., furnaces, combustors, boilers, reactors, and engines, have been developed to utilize combustion heat, chemical species, and

work. Figure 1 shows a flow diagram of typical combustion processes.

Advanced measurement/control devices have been traditionally used as tools for analysis of combustion systems. The analysis can lead to lower energy use and lower pollutant emissions by a system. In recent years, the computational analyses, including computer models of kinetics and fluid dynamics, have been used as an added tool for combustion analysis. The focus here is to assess the overall process of analyzing a combustion system.

A computational combustion analysis starts with the identification of the participating elements and their thermochemical properties and relations. This is followed by derivation of the governing equations and development of the required phenomenological models, including turbulent mixing, droplet evaporation, particle devolatization, radiation heat transfer, and interfacial interactions. Then, the governing equations are solved numerically on a computer. The results are validated with experimental data. Thus, the validated computer code can be used to evaluate the combustion system and to control combustion products.

2. COMBUSTION ELEMENTS

The elements (or species) involved in a combustion process include reactants, inert and intermediate species, products, and catalysts. Reactants generally include a fuel and an oxidant. Fuel can be in solid, liquid, or gas phase. Solid fuels include coal and biomass. Liquid fuels include hydrogen, gasoline, diesel, kerosene, and jet fuels. Gas fuels include natural gas, methane, and propane. The oxidant is mostly oxygen but may include F_2O, F_2O_2, NF_3, ClF_3, ClF_3, ClO_3F, O_3, and N_2F_4 in some rocket applications. The fuel and the oxidant can also be formed as a monopropellant in rocket applications. Catalysts are sometimes used to enhance combustion.

Inert species are not directly involved in the combustion process, but at high temperatures these species can be dissociated or ionized. These species include the nitrogen in the air and the ash in coal. Major combustion products include CO_2 and H_2O. Because these species can emit and absolve radiation energy, they are regarded as greenhouse gases that are related to the global warming issue. Many intermediate species, such as OH, CO, CH, are present during combustion. Combustion products also include some minor species, i.e., NO_x, SO_x, unburnt hydrocarbons (UHCs), and soot. These species are regarded as pollutants. NO_x and SO_x are believed to cause acid rain, UHCs play a role in smog, and soot chemicals, including polynuclear aromatics, may be carcinogenic.

In a combustion reaction, there can be so many combustion elements that it is impossible to analyze them all. Therefore, many combustion elements are lumped into one category for the convenience of analysis. For example, coal consists of thousands of hydrocarbons, but in most coal combustion analyses, the hydrocarbons are grouped into four categories: moisture, volatiles, char, and ash. The moisture is water, the volatiles represent all of the hydrocarbons that can be vaporized during combustion, the char includes all hydrocarbons that cannot be vaporized, and the ash is inert material, mostly metals.

3. THERMOCHEMISTRY

Assume that Reaction (1) represents a combustion reaction of I lumped reactants and J lumped products:

$$\sum_{i=1}^{I} n_i \text{ Reactants} \rightarrow \sum_{j=1}^{J} n_j \text{ Products.} \qquad (1)$$

In the reaction, the n_i values on the reactant side and n_j values on the product side are called the stoichiometric coefficients. The coefficients can be on a molar or a mass basis. On a molar basis, the unit is moles; on a mass basis, the unit is kilograms.

A computational combustion analysis calculates the heat, work, and/or species generated from a combustion process, which includes the combustion reaction, fluid dynamics, and heat transfer. Thermodynamic and chemical (thermochemical) properties of the combustion elements are needed to calculate the heat, work, and species. The thermochemical properties most often used in a combustion analysis include temperature, pressure, density, enthalpy, specific heat, viscosity, diffusivity, thermal conductivity, Gibbs free energy, molecular weight, species concentration, heat of combustion, latent heat, and equilibrium constant.

3.1 Equations of State

The thermochemical properties of a combustion species can be obtained by direct measurements or theoretical calculation. These properties are not all independent. Thermodynamic properties of a combustion species are generally functions of temperature and pressure. In most practical applications, these properties can be expressed in terms of temperature only. Sometimes, even constant property values are used. Most properties of a combustion species have been determined and tabulated in tables and other references produced by the joint interagency (Army, Navy, NASA, and Air Force) committee, JANNAF (formerly JANAF, before NASA was included). Properties of a mixture are determined by adding the properties of its components according to their concentrations. The partial pressure of a component is defined as the total pressure times its molar concentration.

Other than direct measurement, the thermochemical properties of members of a grouped ("lumped") combustion element (or species) can be obtained by adding the properties of its major constituents according to their proportion. For example, a fuel composed of 90% methane (CH_4) and 10% ethane (C_2H_6) becomes a lumped species $C_{1.1}H_{4.2}$. Its molecular weight is 17.1 kg/mol, calculated by adding 90% of 16 kg/mol (molecular mass of methane) and 10% of 30 kg/mol (molecular mass of ethane). Similarly, other properties of the lumped species can be obtained from those of the chemical species.

3.2 Chemical Equilibrium

At constant temperature and pressure, a combustion reaction such as Reaction (1) will reach an equilibrium state. The equilibrium constant K_p is defined as

$$K_p = \prod_{j=p} P_j^{n_j} / \prod_{i=r} P_i^{n_{ij}} \qquad (2)$$

in which the P_i values are partial pressures of the reactants (r) and products (p). The equilibrium constants of many combustion reactions have been determined and are tabulated in most combustion textbooks.

A combustion process generally consists of many reactions. The equilibrium species concentrations can be calculated from the equilibrium constants and the initial species concentrations. Bittker and Scullin developed a general chemical kinetics computer (GCKP) program to perform equilibrium calculations of hydrogen/air combustion and many other combustion processes.

3.3 Adiabatic Flame Temperature

Combustion of a fuel produces heat. When all of the heat is used to heat the products, without heat transfer from external sources, the final temperature is called the adiabatic flame temperature. The temperature can be determined by balancing the heat of combustion, the heat of dissociation, and the total enthalpy of the combustion products. At a combustion temperature higher than 2000 K, a small portion of the combustion products CO_2 and H_2O dissociates into intermediate species, such as CO, O, and OH, and the dissociation uses up a significant amount of the heat of combustion. Thus, the energy balance equation needs to be solved in conjunction with the equilibrium calculation to obtain an adiabatic flame temperature. Assuming the initial temperature and pressure are under standard conditions, the adiabatic flame temperature of a methane/air mixture is about 2200 K. Chang and Rhee developed a set of empirical formulations that can be used to estimate adiabatic flame temperature of lean fuel/air mixtures. The adiabatic flame temperature is an important thermochemical property in a

combustion analysis because it is the upper bound of the temperature.

4. HYDRODYNAMICS AND MIXING

A fuel and an oxidant must mix to react. The mixing process is a part of flow dynamics. Gas phase mixing is mainly due to turbulence; liquid injection in droplet sprays is commonly used to enhance the mixing between liquid droplets and gas, and some solid fuels are pulverized to increase the mixing between the particles and gas.

4.1 Governing Equations

Combustion generates heat, work, and product species. In a computational combustion analysis, heat is calculated from the temperature and velocity; work is calculated from pressure and density; and the species are calculated from concentrations and velocities. The governing equations of these properties are derived from fundamental thermodynamic, hydrodynamic, and chemistry principles. The derivation can be on a fixed mass basis or a control volume basis. In the following discussion, a control volume approach is used.

The principles of mass, species, and momentum conservation are used to determine pressure, concentration, and velocity. The first law of thermodynamics (or conservation of energy) is used to determine temperature. The equation of state is used to determine density. In deriving the governing equations, many derived properties are created. For example, enthalpy is used in the energy equation and specific heat is used in the caloric equations of state. Equation (3) is a typical energy equation derived on a Cartesian coordinate system:

$$\sum_{i=1}^{3} \frac{\partial}{\partial x_i}\left(\rho u_i h + \frac{\mu_e}{\sigma_h}\frac{\partial h}{\partial x_i}\right) = S_{\text{comb}} + S_{\text{rad}} + S_{\text{int}}, \quad (3)$$

in which x_i is a coordinate, ρ is density, u_i is velocity components, h is enthalpy, μ_e is effective viscosity, σ_h is a turbulent scale factor for the enthalpy, S_{comb} is the combustion heat release rate, S_{rad} is net radiation heat flux, and S_{int} is heat transfer from the liquid or solid phase. Effective diffusivity is used in the momentum, energy, and species equations. It is the sum of both laminar and turbulent diffusivities. The source terms of the governing equations need to be determined from various models. In the energy equation (3), there are three source terms. The combustion heat release rate needs to be calculated from combustion kinetics, radiation heat flux needs to be solved from a radiative transport equation, and the last term needs to be determined from an interfacial interactions model.

4.2 Turbulent Mixing

Diffusive flames, commonly used in a furnace or a combustor, are mostly turbulent. Turbulence is understood to be the small eddies that enhance mixing and combustion, but understanding the physics of the turbulence is still far from complete. An enclosure type of the $k-\varepsilon$ turbulence model is commonly used for combustion analysis. The model expresses the turbulent viscosity μ_t in terms of two turbulent parameters, kinetic energy k and dissipation rate ε,

$$\mu_e = \mu + \mu_t = \mu + C_\mu \rho k^2/\varepsilon,$$

in which C_μ is an empirical constant.

Lauder and Spalding proposed two additional transport equations to solve for these two turbulent parameters. Turbulent diffusivities for the enthalpy and species equations are also expressed in terms of the turbulent viscosity with a scaling factor. In a multiphase flow, solid particles or liquid droplets tend to inhibit eddy motion and reduce turbulent diffusion and the adjustment of the turbulent viscosity is needed. In addition, statistical turbulence models are used to describe the turbulence mixing effects. In this approach, probability density functions are chosen to represent the fluctuation of the flow properties. Large eddy and direct numerical simulations have been introduced with the hope of improving the description of turbulent flow.

4.3 Liquid Spray and Droplet Vaporization

Liquid fuel can be burned in pools or sprays. The burning processes start with the vaporization of the liquid fuel. Next, the fuel vapor is mixed with oxygen. Finally, the combustion reaction takes place. The pool burning is mostly fire. Because of limited contact area, the mixing of fuel vapor and oxygen is poor. Therefore, combustion is mostly fuel rich and a lot of smoke is produced. A fuel injector breaks up the liquid into tiny droplets and the high pressure makes droplets penetrate deep into the gas flow. Empirical models have been developed to describe the droplet size and number distributions off the tip of an injector. The penetration enhances the mixing of the fuel and the oxygen and the high ratio of surface area to volume speeds up the evaporation process.

Liquid fuel vaporizes in two modes. At low temperature, vaporization occurs due to the diffusion of mass. At a temperature higher than the boiling point, the liquid boils and the vaporization rate is controlled by the heat transfer rate from the surroundings to the liquid. In most combustion systems, the heat transfer is convective. Empirical correlations have been developed to calculate the interfacial heat transfer rate from other flow properties, such as, velocity, conductivity, and viscosity.

Liquid droplets are generally treated in a Lagrangian or an Eulerian approach. The Lagrangian approach takes one droplet at a time. It traces the motion of a single droplet in the flow and takes the average effect of all the droplets. Zhou and Yao also included the group effects on the spray dynamics. The Eulerian approach treats a group of droplets as a continuum. Governing equations are derived for each droplet group for solving the flow field.

4.4 Devolatization of Solid Fuel

Pulverized coal is used in many utility boilers. Due to the small particle size, pulverized coal can be transported pneumatically. Coal particles contain four major components: moisture, volatiles, char, and ash. When heated, the moisture is dried and the volatiles are devolatized. The volatile vapor mixes with oxygen and the mixture burns. The char left on the particles is burned with oxygen when contacted. The drying and devolatilization processes are controlled by the heat transfer from the gas to the particles. Similar to the liquid vaporization, the heat transfer is convective. Empirical correlations are used to determine the interfacial heat transfer rate. Similar Lagrangian and Eulerian approaches can be applied for particles.

5. CHEMICAL REACTIONS

The mixture of fuel and oxidant is burned in chemical reactions. A combustion reaction is the effective collisions of reactants (and catalyst), breaking the chemical bonds of the reactants, forming the products, and releasing heat. Three types of reactions are significant in a combustion analysis: ignition, heat release, and pollutant formation.

5.1 Ignition and Flammability

Fuel and oxidant can be self-ignited (autoignition) or by an external heat source. For example, diesel engine combustion is autoignition and gasoline engine combustion is ignited by a spark. At an ignition temperature, the combustion reactions generate heat and the heat is lost to the surroundings by conduction, convection, and radiation heat transfer. If the heat generation is larger than the heat loss, the combustion reactions are sustained.

There are mixture ratios of fuel and oxidant that the combustion will not sustain after the ignition source is removed. For premixed laminar flame, there exist flammability limits that are frequently defined as percentage fuel by volume in the mixture. The lower limit is the leanest mixture that will allow steady flame, and the upper limit represents the richest mixture. Flammability limits in both air and oxygen are found in the literature. For example, the lower flammability limit of methane is about 5% by volume.

5.2 Combustion Reactions

Assume that fuel is a hydrocarbon C_mH_{4n}. The combustion of the fuel and oxygen is shown in Eq. (4):

$$C_mH_{4n} + (m+n)O_2 \xrightarrow{k} mCO_2 + 2nH_2O. \quad (4)$$

The extent of reaction, ξ, is defined as the molar concentration of the consumed fuel. For each mole of ξ consumed, the sum $(m+n)$ moles of oxygen is consumed and m moles of CO_2 and $2n$ moles of H_2O are produced. The reaction rate $d\xi/dt$ of the combustion reaction can be expressed in an Arrhenius formulation:

$$\frac{d\xi}{dt} = -\frac{d}{dt}[C_mH_{4n}] = -\frac{1}{m+n}\frac{d}{dt}[O_2] = \frac{1}{m}\frac{d}{dt}[CO_2] = \frac{1}{2n}\frac{d}{dt}[H_2O], \quad (5a)$$

$$\frac{d\xi}{dt} = k_{30}\exp(-E/RT)[C_mH_{4n}][O_2]^{(m+n)}, \quad (5b)$$

in which [ ] represents molar concentration of a species, t is reaction time, k_0 is a preexponential constant, E is an activation energy, and R is the universal gas constant. The preexponential constant and the activation energy are empirical constants extracted from experimental data. Thus, the species consumption/generation rates can be obtained from Eqs. (5a) and (5b) and the heat release rate becomes

$$dq_{comb}/dt = (d\xi/dt)H_o, \quad (6)$$

in which H_o is the heat of combustion.

5.2.1 Gasification Reactions

Gasification is an incomplete combustion of the fuel. In a fuel-rich combustion, the intermediate species such as CO becomes a major product species. If water is added to the reaction, hydrogen is also produced. Because both CO and H_2 can be burnt later with oxygen and can release heat, the gasification has been used to convert low-grade fuels, such as, coal and biomass, to a higher grade gaseous fuel, CO and H_2. The gasification process is now also used to convert diesel or gasoline fuel to hydrogen for fuel-cell applications.

5.2.2 Heterogeneous Reactions

Heterogeneous reactions include char burning with oxygen and gaseous reactions on catalyst surfaces. Char burning is regarded as similar to a combustion reaction. Empirical constants are extracted from experimental data. The catalytic reaction is generally treated as a third-body reaction and an Arrhenius formula is used for analysis.

5.3 Pollution Reactions

In addition to the major heat release reaction, many intermediate species are produced in numerous combustion reactions. Pitz and Wesbrook have compiled hundreds of combustion reactions and the list is still growing. Some of the intermediate species attract more public attention because they are pollutants. Pollution is defined as the contamination of the environment. All matter emitted from combustion chambers that alters or disturbs the natural equilibrium of the environment must be considered as a pollutant. Pollutants of concern include particular matter, the sulfur oxides, unburned and partially burned hydrocarbons, nitrogen oxides, carbon monoxide, and carbon dioxide.

5.3.1 Soot Kinetics

Soot is formed in the fuel-rich region of a combustion flow. Because soot is a strong contributor to the radiation heat transfer, a soot model is needed to calculate soot concentration for the radiation heat transfer calculation. The following simplified soot model assumes that soot (st) is generated in the fuel-rich flame by the cracking of the fuel and is burnt up by oxygen. The soot formation/oxidation rate is expressed as

$$df_{\mathrm{st}}/dt = A_{\mathrm{O2}} f_{\mathrm{fu}} \exp(-E_2/RT) - A_{\mathrm{O3}} f_{\mathrm{st}} f_{\mathrm{ox}} T^{1/2} \exp(-E_3/RT). \quad (7)$$

5.3.2 NO_x Kinetics

NO_x is formed by combustion in the presence of nitrogen. There are three types of NO_x formation: thermal, prompt, and fuel. Thermal NO_x is formed in high-temperature reactions, prompt NO_x comes from reactions with intermediate species, and fuel NO_x comes from the nitrogen in the fuel, e.g., coal. The Gas Research Institute (GRI) has compiled a long list (over 300) of reactions related to NO_x formation. However, lumped reduce mechanisms with many less reactions are used in practice.

5.3.3 SO_x Formation

Many coals contain significant amount of sulfur. The sulfur reacts with oxygen during combustion and produces SO_x. Sulfur is also contained in many lubricants. In diesel combustion, SO is formed and becomes a major source of soot particle nucleation.

6. RADIATION HEAT TRANSFER

At combustion temperature, radiation is an important if not dominating mode of heat transfer. In a combustion process, radiatively participating species include soot and gaseous species such as CO_2 and H_2O. Heat is emitted, absorbed, and scattered in waves of various wavelengths. Assuming the scattering effect in the combustion flow is negligible, the radiative heat transfer becomes the balance of emissive and absorption powers. For each wavelength, local net radiation heat power is obtained by integrating the absorption of the incoming radiation from all other locations and subtracting the emitted power. A radiative transport equation is obtained by integrating the net radiation heat power over all wavelengths, Eq. (8):

$$q_r(x, y, z) = \int_0^\infty \left[\oint \kappa'_\lambda e'_{b\lambda}(T') e^{-\int \kappa'' dl''} d\nu' - \kappa_\lambda e_{b\lambda}(T) \right] d\lambda, \quad (8)$$

in which λ is wavelength, κ is volume absorptivity, l is optical length, ν is a control volume, and $e_{b\lambda}(T)$ is the blackbody radiation function. The spectral volumetric absorptivities of these media must be determined from gas and soot radiation models.

6.1 Gas Radiation Model

The H_2O species has five strong radiation bands, centered at wavelengths of 1.38, 1.87, 2.7, 6.3, and

20 μm, and the CO_2 species has six bands, at 2.0, 2.7, 4.3, 9.4, 10.4, and 15 μm. A wideband model was introduced to calculate total band absorptance of these species. For each band, species concentrations, pressure, and temperature are used to determine a set of semiempirical parameters: the integrated band intensity, the bandwidth parameter, and the line width parameter. A semiempirical correlation is then used to calculate the total band absorptance from these parameters.

6.2 Soot Radiation Model

If the scattering is negligible, the Rayleigh-limit expression of the soot volume absorptance $\kappa_{s\lambda}$ can be used:

$$\kappa_{s\lambda} = \frac{36n^2k(\pi/\lambda)f_v}{[n^2(1+k^2)+2]^2 + 4n^4k^2}. \qquad (9)$$

Soot volume absorptance is proportional to the soot volume fraction f_v and inversely proportional to the wavelength. The optical refraction indices, n and k, are weak functions of wavelength that can be derived from classical electromagnetic theory.

7. TOOLS FOR COMBUSTION ANALYSIS

Measurement and testing have long been the ways to analyze and evaluate combustion systems. However, computational software has now become an additional tool for combustion analysis.

7.1 Computational Fluid Dynamics

Combustion flow calculations adopt a control volume approach to convert the governing equations to algebraic equations on a staggered, discretized grid system. The algebraic equations are solved iteratively with proper boundary conditions. Exit flow conditions have a strong impact on the convergence of the calculation. Because most flows are not fully developed, the exit flow conditions that satisfy global mass balance appear to improve numerical convergence the most.

The major species flow calculation uses Patankar's SIMPLER computational scheme to solve the pressure-linked momentum equations. A major species flow calculation is considered to have converged if the local and global mass balances are smaller than a set of predetermined criteria. The subspecies flow is solved using the flow properties calculated from the major species flow calculation. Free from the interactions of the pressure and velocity fluctuations, the calculation of the partially decoupled subspecies transport equations becomes very stable numerically.

Chang and colleagues developed an advanced methodology to solve the radiative transfer equation (RTE) in a Cartesian coordinate system. The methodology guarantees the integrity of the energy balance between emitting and absorbing powers. The RTE solution routine divides the radiation heat flux into many bands of wavelength. The blackbody radiation function can be discretized in the wavelength domain by using a closed form solution. For each wavelength band, a calculation is performed to balance the emitted and absorbed energy. For each node in the computational fluid dynamics (CFD) grid system, energy emitted is calculated. This emitted energy is then traced along the optical paths of all angles. The energy absorbed in every node (including the wall surface node) is calculated and added to the absorption energy of the initial node.

7.2 Kinetics Calculations

Many schemes have been proposed for the number of equations and reaction rates that may be used to simulate combustion reactions. One of examples is the GCKP program developed at the National Aeronautics and Space Administration (NASA). Another example is the CHEMKIN program, a widely used general-purpose package for solving chemical kinetics problems. CHEMKIN was developed at Sandia National Labs and provides a flexible and powerful tool for incorporating complex chemical kinetics into simulations of fluid dynamics. The latest version includes capabilities for treating multifluid plasma systems that are not in thermal equilibrium. These features allow researchers to describe chemistry systems that are characterized by more than one temperature, in which reactions may depend on temperatures associated with different species; i.e., reactions may be driven by collisions with electrons, ions, or charge-neutral species.

Both thermodynamic and kinetic databases are needed for the kinetics calculations. The GRI-Mech combustion model is a widely used database of detailed chemical kinetic data. The latest version is an optimized mechanism designed to model natural gas combustion, including NO formation and reburn chemistry, containing 325 reactions and 53 species. It provides sound basic kinetics and also furnishes the best combined modeling predictability of basic combustion properties.

7.3 Measurements

Measurements of flame properties can be made by the insertion of probes into a flame, by optical methods applied to emissions from the flames, or by laser probing. The techniques for probing in flames include temperature measurement by thermocouples, velocity measurement by pressure impact probes and particle-tracking photography, and species concentration measurements using suction probes followed by gas analysis.

The optical methods for making measurements in flames include interferometry, schlieren, and photographic methods. All of the probing methods may cause some form of disturbance to the fluid flow, heat transfer, and species concentrations. Optical methods provide information that is integrated over the optical length of the measurement and the spatial resolution is poor. Lasers provide noninvasive probing of flames and high spatial resolution of measurements. The measurement of temperature and species concentration in flames can be carried out by laser spectroscopy. Laser anemometers are widely used to measure velocity components, turbulent characteristics, and particle size in flames. Various advanced combustion sensors have been developed with the potential to enable direct measurement of key combustion parameters for improved combustion control.

8. POLLUTION CONTROL TECHNIQUES

Control of pollutant emissions is a major factor in the design of modern combustion systems. Pollution control techniques can be mainly classified as two types. One involves process modification to prevent or reduce the formation of pollutant emissions. The other is postcombustion treatment to remove or destroy pollutants from combustion before being emitted into the ambient air.

8.1 Process Modification

The techniques to modify combustion for reducing pollutant emissions include fuel changes and combustion modifications. Switching vehicles from gasoline to compressed natural gas, propane, or ethanol can reduce vehicular air pollutant emissions. Adding oxygenated compounds to motor fuels can change the combustion reaction to lower CO emissions significantly. Using low-sulfur fuels can reduce sulfur dioxides emissions.

The principle of combustion modification is widely used in NO_x emission control. Modifying burner configuration or operation conditions can change distributions of temperature, oxygen, and nitrogen to reduce the formation of NO_x. Such techniques include using low excess air, staged combustion, low NO_x burners, water injection, oxyfuel combustion, exhaust gas recirculation (EGR), and reburn. These techniques can be economical and effective. However, in some applications, combustion system modification alone is unable to reduce pollutant emission levels below legislated standards, and postcombustion treatment may be required.

To reduce SO_2 emissions, fluidized bed combustion, in which limestone particles are used as bed materials, is an alternative way to burn coal. Another combustion modification alternative for SO_2 reduction that is in the demonstration stage is the combined-cycle power plant.

8.2 Postcombustion Treatment

Postcombustion treatment involves installation of pollution control devices downstream of the combustor. For example, selective noncatalytic reduction (SNCR) and selective catalytic reduction (SCR) processes are widely used for NO_x reduction. These techniques involve a nitrogen-containing additive, either ammonia, urea, or cyanuric acid, that is injected and mixed with flue gases to effect chemical reduction of NO to N_2, without or with the aid of a catalyst. Other postcombustion treatment techniques utilize wet or dry limestone scrubbers and spray dryers to reduce SO_2 emissions; cyclones, electrostatic precipitators (ESPs), filters, and scrubbers for particle removal; or three-way catalytic converters for the control of NO_x, CO, and hydrocarbon (HC) emissions from automobiles.

To stabilize and ultimately reduce concentrations of the greenhouse gas CO_2, carbon sequestration (carbon capture, separation, and storage or reuse) is a major potential effective tool for reducing carbon emissions from fossil fuel combustion.

9. CONCLUDING REMARKS

This article is intended to guide a reader through the overall process of analyzing a combustion system, especially using the newly added computational tools, and to advocate the good use of combustion

analyses to convert combustion processes for cleaner and more efficient energy production.

Glossary

annual total energy The sum of all energy used from all sources in a year.
British thermal unit (Btu) Generically, the amount of energy or heat required to raise the temperature of 1 lb of water (about 0.5 quart or 0.5 liter) 1 degree Fahrenheit (equals about 1055 joules).
commercial sector The portion of buildings in a nation or the world including all buildings that are not residential, industrial, or agricultural.
electricity losses Energy lost in generation, transmission, and distribution of electricity.
empirical Obtained through physical measurement or observation.
energy intensity Annual total energy divided by some normalizing factor, usually gross floor area of a building.
energy performance An empirical value indicating the energy efficiency of one commercial building compared to other, usually similar, commercial buildings.
Energy Star rating system Energy performance rating systems developed by the United States Environmental Protection Agency for specific U.S. commercial building types, which as of June 2003 included offices, hospitals, primary and secondary schools, grocery stores, and hotels and motels, with adjustment capabilities for special spaces such as computer centers and parking garages.
exajoule (EJ) 10^{18} joules.
joule Watt-second, the energy to maintain 1 W for 1 sec.
kBtu 1000 British thermal units.
microdata Detailed survey data arranged in an electronic file for computer analysis.
normalization A method to adjust a quantity, in this case energy use, to account for allowable differences in operational or other factors, such as worker density, hours of operation, and personal computer density.
quads A quadrillion British thermal units; 1 quadrillion is 10 raised to the fifteenth power.
rating scale A numerical scale matched to a range of values of interest, such as normalized annual energy use.
regression An analysis method for statistically determining functional relationships between quantities that are correlated, often using empirical data.
standards Authoritative or legally fixed bases for comparison, valuation, or compliance.
subsectors Subsets of a sector; office buildings, for example, represent a subsector of the commercial sector.

Energy use in commercial buildings is complicated to understand, due to the wide range of building uses and ownership, variations in the size and complexity of energy systems, differences in energy system operation, and other factors. Due to this complexity, as national economies grow toward more specialized services and enterprise management, the share of national energy use held by the commercial sector also tends to grow relative to other sectors. Increased understanding of commercial building energy performance, probably through performance ratings and certifications, is needed to help reduce commercial sector energy growth relative to other sectors in advancing economies.

1. DEFINITION AND EXTENT OF COMMERCIAL SECTOR

The commercial sector is defined typically in terms of including everything else that other sectors do not

 © 2004 Elsevier Inc. All rights reserved.

include. The energy use breakout of national economies related to buildings typically covers residential and commercial buildings; where commercial buildings are typically all buildings that are not residential, industrial, or agricultural. Sometimes this broader grouping of commercial buildings is separated further into institutional and commercial, or governmental and commercial. Thus the commercial sector consists of buildings used by businesses or other organizations to provide workspace or gathering space or offer services. The sector includes service businesses, such as shops and stores, hotels and motels, restaurants, and hospitals, as well as a wide range of facilities that would not be considered commercial in a traditional economic sense, such as public schools, specialized governmental facilities, and religious organizations. Many other types of buildings are also included.

The wide range of building uses is one factor contributing to the complexity of the commercial sector. In the United States, a major national survey of commercial buildings, examining an extensive set of their characteristics and their energy use, is conducted every 4 years. The latest available survey, for 1999, includes in the detailed microdata over 40 different types of building uses that can categorize commercial buildings (Table I). Commercial buildings in the United States, where perhaps the most specialized services and enterprise management exist, are estimated to number 4–5 million, with a total gross floor area of over 6 billion m^2 (over 65 billion ft^2). The approximate breakout of commercial buildings (Table I), showing the range of building uses, the number of buildings, and total floor area estimates, provides an informative starting point for understanding the commercial sector in the United States and elsewhere. Although comparison of these estimates with other, more detailed estimates for subsectors, such as schools, would show some discrepancy in estimates, the scope and size of the commercial sector are well illustrated. For even the least developed countries, the same general range of facilities that comprise the commercial sector will exist, although the aggregate size relative to other sectors typically is smaller.

2. MAGNITUDE AND SIGNIFICANCE OF COMMERCIAL ENERGY USE

The amount of energy consumed in the commercial sector often must be estimated as a fraction of energy use in the combined residential and commercial sectors; national energy use in buildings is often tracked within the major sectors, categorized as industrial, transportation, and "other," with residential and commercial buildings aggregated and accounting for most of the energy use in this "other" sector. Thus some quick checks on world total energy consumption are useful. The units used to sum world energy use are not easily comprehended by most people, so the important knowledge to retain is the relative values. Total world energy consumption in the year 2000 was about 395 quads (1×10^{15} Btu), or about 420 EJ (exajoules). Fuel processing, nonenergy use of fuels, and other losses reduce the total final energy consumption in the major energy-using sectors to about 270 quads (280 EJ).

Because the importance of energy use in the industrial and building sectors can be misunderstood if losses associated with generation and distribution of electricity are not included, comparisons that show both totals are useful. The estimated sectoral breakouts (Table II), without accounting for electricity losses, are 87 quads for industry, 71 quads for transport, and 109 quads for "other," which is primarily residential and commercial buildings. Adding approximate electricity losses (Table II) brings the totals to 122 quads for industry, 73 quads for transport, and 156 quads for "other," for a total of about 350 quads, or 370 EJ.

For the world overall in the year 2000, commercial sector energy use is approximately 30% of the "other" energy use, which amounts to a little over 30 quads (35 EJ) when electricity losses are not included. This energy use represents about 12% of the approximately 270 quads of total final energy consumption for the world. When electricity losses are included, commercial sector energy use is about 45 quads (50 EJ).

Although commercial sector energy use is only 12% of the world total, as economies develop, energy use in this sector tends to rise relative to other sectors and is one of the most difficult to reduce, due to complexities of systems, building ownership, and building uses. The rise in energy use relative to other sectors appears to result from the need for increasingly sophisticated facilities to handle activities in this sector as national economies advance, as well as from a concurrent rise in income within the sector relative to the cost of facilities.

The history of the commercial sector relative to the residential sector in the United States provides an example of this pattern of change. Specialization in services and enterprise management grew significantly in the United States throughout the last

TABLE I

U.S. Commercial Buildings, 1999; Approximate Breakout

Building use	No. of buildings (thousands)	Floor area (billions) (m^2)	Floor area (billions) (ft^2)	Building use	No. of buildings (thousands)	Floor area (billions) (m^2)	Floor area (billions) (ft^2)

TABLE II

World Sectoral Energy Consumption in 2000[a]

Sector	Without electric losses		With electric losses	
	Quads	EJ	Quads	EJ
Industry	87	92	122	129
Transport	71	75	73	77
Other	109	115	156	165
Total	267	282	351	370

[a] Values are approximate and can also vary depending on the detail in accounting for different types of losses or fuel processing. Sectors may not add to totals due to rounding.

half of the 20th century. Allowing some time to pass after World War II, so that wartime effects and rationing-induced behaviors can be discounted, energy use in the commercial sector was about 50% of residential energy use in the year 1960. This ratio grew to about two-thirds by 1980, and in the year 2000 was over 83% (Fig. 1). Residential sector energy use in the United States was 20% of total national energy use in both 1960 and 2000, whereas commercial sector use increased from 10 to 17% of the total. Thus, commercial sector energy use was about 30% of sectoral energy use in the building or "other" category in the United States in 1960, but by 2000 had grown to 45% of the building sector total.

Variations among countries and location are dramatic. Although the commercial sector in the United States accounts for about 17% of all energy use, in China it accounts for about 5%. Commercial buildings in rural areas typically are less complicated

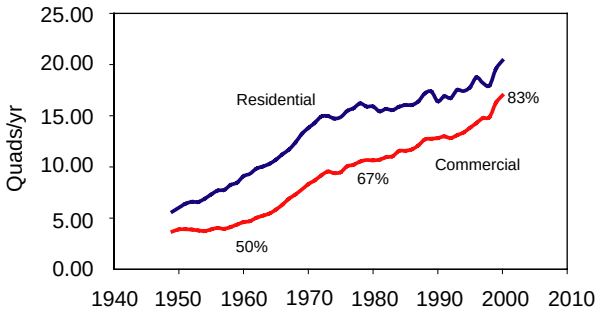

FIGURE 1 Comparison of commercial sector and residential energy use in the United States from 1960 to 2000; the ratio of commercial to residential energy use grew from 50 to 83%. Electricity losses are included.

and use less energy, as compared to those in metropolitan areas; over 80% of commercial sector energy use is in metropolitan areas.

3. MEASURING ENERGY PERFORMANCE

Interest in rating the real-life energy performance of buildings has increased in recent years, and the real-life efficiency performance rating of buildings is important for any sustainable energy future. The ability to compare the energy performance of one commercial building with that of another is important for determination of national and international energy efficiency because comparison allows meaningful measurements of potential relative improvements. This ability also may allow different classes of buildings to be analyzed together (e.g., offices and hospitals).

The European Union has been examining requirements for improving the energy performance of residential and commercial buildings, because a large potential improvement in energy performance has been determined to exist. Among the requirements examined is the establishment of a general framework for a common methodology for calculating the integrated energy performance of buildings.

The United States Environmental Protection Agency (EPA) has established an empirical energy performance rating system for some commercial building types, the Energy Star rating system, whereby a normalized energy performance rating scale is developed. The energy use of a specific building is normalized based on the factors in the method, and the normalized energy is compared to the performance rating scale. Buildings scoring in the top 25% on the scale have energy performance level that makes them eligible for consideration of award of an Energy Star label.

Commercial building energy performance, or energy efficiency, is often measured to a certain degree by building energy experts, and even many nonexperts, without using any real standards. To judge how well a specific building is doing, however, energy performance measurement should involve a comparison of building energy use to some type of standard, which in the past has typically been the energy use of other, similar buildings. The challenge over the years has been to determine a true standard for comparison and to determine what a "similar" building is. Because the historical methods of comparison had known limitations, building energy experts developed their own sense of what constitutes an energy-efficient building. This expert sense is based on experience with similar buildings, the types of activities within specific buildings, and any history of achieving reductions in energy use in comparable buildings. This expert knowledge has gaps and is not easily transferable, because it is usually based on several years of experience concerning expected patterns of energy use for different buildings and impacts of schedules, uses, geographic location, and system configurations. This expert knowledge is used to "adjust" the measure of the performance of a commercial building to provide a more informed measure of performance. However, this knowledge is ad hoc, with multiple practitioners probably arriving at differing assessments of the same building. In the end, the result is essentially a subjective expert opinion, albeit possibly a very good one, but also possibly not.

Five generic classes of building energy data analysis methods have been identified as useful in measuring the energy performance of commercial buildings:

1. Annual total energy and energy intensity comparisons.
2. Linear regression and end-use component models.
3. Multiple regression models.
4. Building simulation programs.
5. Dynamic thermal performance models.

All of these analytical approaches can be used to develop building energy performance measurement methods, but the most effective current approach in use today, based on results achieved, involves the third approach, multiple regression models. When calculating commercial building energy performance using multiple regression models, the effects of many factors can be modeled, potentially factoring out

influences such as the number of people in a building or occupant density. The Energy Star rating system develops its performance rating scales using multiple regression models.

The limitations of the other methods include their inability to cover wide ranges of buildings without an inordinate amount of data. Some of the other methods require large volumes of data to develop empirical results. In the following discussion of performance rating systems, both simple annual total energy intensity comparisons (Method 1 above) and multiple regression method information will be addressed; the first is useful both as an example and as a well-understood quantity, whereas multiple regression analysis illustrates the current state-of-the-art methodology.

4. PERFORMANCE RATING SYSTEMS

Many people confuse building simulation and energy audits or energy assessments with energy performance ratings. Energy performance ratings are less detailed and provide much less information regarding potential causes of specific energy performance. Instead, what is provided is a true indication of overall energy performance relative to similar buildings. Highly technical assessments, including calibrated simulations, are a tremendous tool for diagnosing root causes of specific building energy performance. But these approaches typically provide only very limited information about performance relative to other buildings or relative to any ranking scale based on performance of similar buildings, and their complexity makes them impractical for extensive use in rating performance.

Performance rating can be done many ways. The EPA Energy Star rating system for buildings uses a percentile rating scale of 1 to 100 for a particular building type, with a rating of 75 or greater required to qualify for an Energy Star label. The energy performance rating of 1 to 100 can be obtained simply by using the rating tool. The rating scale is developed from a regression analysis of energy use versus key characteristics of the class of buildings against which energy use is to be normalized. A simple and straightforward way of quantifying and comparing building energy performance is accomplished by using the annual total energy and energy intensity data. Annual total energy is the sum of the energy content of all fuel used by the building in one year. Energy intensity (also called energy use intensity or index, EUI) is the total energy used divided by the total floor area. It would also be possible to examine annual energy or energy intensities for individual fuels.

The strength of the total energy and energy intensity comparisons is their ease of use and widespread familiarity. However, knowledge is lacking regarding causes of variation that have been observed and the relative impacts of factors such as schedules, functional uses, and density of use on the energy performance. This general approach to rating commercial building energy performance is of interest for quick comparison of one building's energy use from one year to another or quick comparisons of many buildings, but information to adjust for at least some of the wide variation typically observed across a data set with many buildings is lacking.

In cases in which a performance rating system is desired for a specific type of building in a relatively homogeneous climate region, rating scales based on total energy or energy intensity by floor area have some practicality. In the Czech Republic, "labels" of actual, measured energy performance (energy intensity) have been studied, tested, and are now required for apartment buildings. The European Union is likely to require energy performance certificates for buildings by the year 2010. These certificates may have to be renewed every 5 years. With reasonably small ranges of climatic differences, certificates for specific types of buildings based on simple energy intensity values can be a moderately reasonable approach to an energy performance rating system. However, even with a common building type and common climate, there are other variations in key factors that should typically be considered. The basic annual energy intensity accounts for floor area, which has been found to be the most important factor to use in normalizing energy use. If multiple climates must be considered, adjustments for climatic variation, such as normalization for heating degree-days and cooling degree-days, should be included in an energy performance rating system.

Beyond floor area and climate, there will typically be variations in other important factors based on building use, e.g., hospitals and offices will have different normalization factors. Decisions on such factors can be, and at times are, arbitrary. Also, differing policy perspectives can strongly influence consideration of what parameters should be evaluated for normalization of energy performance. Rating systems of the more sophisticated, multifactor type typically consist of parameters for normalization of energy use, a normalization equation or

calculation method, and a normalized distribution of energy use. The normalized distribution is typically matched to some scale, often a percentile scale of 1 to 100, to allow a simplified rating result to be obtained. After the energy use of a building is normalized for the factors in the method, the normalized result is compared to the rating scale to determine a rating.

A generic rating system developed for the entire commercial sector in the United States included normalization factors (Table III) that adjusted for floor area, climate, amount of building cooled and heated, worker density, personal computer density, extent of food service and education/training facilities, hours open, and average adjustments for specific types of building space uses. These factors were found to account for over 70% of the variation in energy use in the entire combined U.S. commercial sector, with its wide range of building types. The percentile scale for this particular rating system (Fig. 2) was based on the building energy use index that included electricity losses.

TABLE III

Normalization Factors in a Generic Energy Performance Rating System for All U.S. Commercial Buildings

Floor area (ft^2)
Annual cooling degree days (base 65°F)
Annual heating degree days (base 65°F)
Floor area cooled is less than 25% (yes or no)
Floor area cooled is 50 to 75% (yes or no)
Floor area cooled is 75 to 100% (yes or no)
Floor area heated is 75 to 100% (yes or no)
Personal computers per 1000 ft^2
Workers per 1000 ft^2
Food seats per 1000 ft^2
Educational seats per 1000 ft^2
Hours per week open
Fraction of area that is laboratory
Fraction of area that is nonrefrigerated warehouse
Fraction of area that is food sales (grocery)
Fraction of area that is outpatient health care
Fraction of area that is refrigerated ware house
Fraction of area that is worship space
Fraction of area that is public assembly
Fraction of area that is educational space
Fraction of area that is restaurant
Fraction of area that is inpatient health care
Fraction of area that is strip shopping mall
Fraction of area that is larger shopping mall
Fraction of area that is service

Rating system analyses for specific types of buildings in the United States have found that about 90% or more of the variation in energy use in a specific building type can be normalized based on reasonable factors. As an example, for offices, in addition to floor area, climate, fraction of building heated or cooled, worker density, personal computer density, and hours of operation shown in the generic model (Table III), the number of floors was also a factor found to be important for normalization. Additional examples of the extensive information on the Energy Star rating system for specific building types can be found on the Energy Star Web site (www.energystar.gov).

Another factor that might be considered important for energy performance rating systems is the unit price of energy in a particular location. The energy unit price is significant; analyses comparing all-electric buildings with those that are not indicate an important statistical difference between the energy use distributions of these two categories, suggesting that they should not be treated as equivalent unless some adjustment is made for the difference. Study has shown that this disparity between all-electric buildings and other buildings can be accounted for fairly well by including electricity losses in total energy use as a surrogate for the typical energy unit price differential and other factors related to remote efficiency losses. But the average unit price of energy also appears to adjust fairly well for these differences between all-electric and other buildings, as well as introducing an adjustment for the local economic incentive to be efficient.

Building energy performance rating systems are important tools that offer reasonably quick building energy performance assessment without rigorous

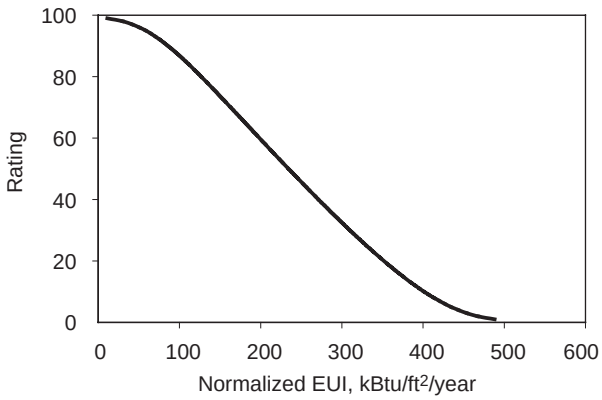

FIGURE 2 Rating scale for the entire U.S. commercial sector. Normalized annual energy use intensity (EUI) matched to percentile scale. Electricity losses are included.

evaluation. In addition, energy performance ratings provide an empirical statement of energy performance not available with other methods, even those that are more rigorous and complicated. Because documenting building energy performance has been determined to be important for many nations, understanding and improving systems for performing such ratings appear to be important for continued progress in commercial building energy efficiency.

5. ENERGY EFFICIENCY VARIATION AND IMPROVEMENT

Energy performance ratings tell what the energy performance of a building is, but if the energy performance of a building is to be improved, the causes of lower than desired performance must be understood, and methods of achieving improved performance must be determined. Causes of variation in energy performance among commercial buildings are understood to a degree, but much remains to be learned.

Estimates of potential improvements in energy efficiency of commercial buildings, i.e., the potential to reduce energy use, have, over many years, indicated that a lot has been and still could be accomplished. Issues of economic incentive and resource allocation influence the estimated savings values, but reductions of 20–40%, on average for the entire sector, appear reasonably achievable if a great enough need exists. In the European Union, a potential savings of 40% has been presented as possible. A savings of 20% of the worldwide annual commercial sector energy use of 30 quads (35 EJ) is 6 quads/yr (7 EJ/yr), which is about 2% of total world energy use. Unfortunately, energy costs are often not large enough, relative to other costs of running a business or organization, to receive major attention, so efficiency improvements have a lower priority.

Research has indicated many reasons why energy efficiency varies so much in commercial buildings. The causes of variation in efficiency can be categorized as variations in: efficiency of operation, efficiency of systems, and efficiency of equipment. Of these three, about half of the potential improvement for the sector would result from operational improvements, with the remainder from equipment and system improvements.

Many studies have shown the importance of operational improvements, with typical savings of 10–20% possible in a wide range of buildings. Other studies show significant savings from equipment and systems improvements. The United States Federal Energy Management Program is responsible for achieving reductions in annual energy intensity for most U.S. government buildings. Significant reductions have been achieved through attention to all three areas of efficiency improvement: operation, equipment, and systems. From 1975 to 1985, a reduction in annual energy intensity of about 20% was achieved. After 1985, additional goals were required by Executive Order and other means, and the annual energy intensity of U.S. government buildings is on track to reduce annual energy intensity an additional 30% by the year 2005 relative to the year 1985 (Fig. 3).

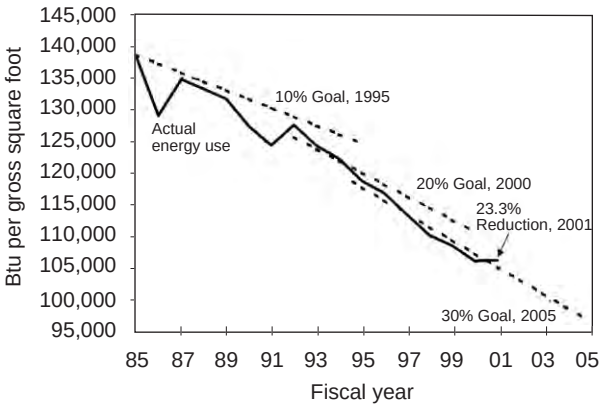

FIGURE 3 Energy efficiency progress for government buildings in the United States. Electricity losses are not included in the annual energy intensity.

The potential for improvement in energy efficiency in the commercial sector is large, if the desire to improve is there, as witnessed by the progress in U.S. government buildings. European estimates also show a large savings potential. If the sources of energy inefficiency in commercial buildings can be reduced through attention to the three major areas of efficiency improvement, about a 2% reduction in world energy use appears achievable.

6. SECTORAL DATA AND MODELING

Extensive data are collected on energy use and sectoral characteristics throughout the world. Sectoral data covering energy use of major economic energy sectors are available for many countries, and world data are available from the International

Energy Agency and from some major nations. The commercial sector, as defined here, is often called by other names, such as "general" or "tertiary," indicating the "everything else" nature of the sector, including all buildings other than residential, industrial, or agricultural.

As an example of data for a nation with one of the most specialized commercial sectors in the world, the United States collects extensive energy data for this sector, including consumption by fuel type, prices by fuel type, and expenditures by fuel type for the overall sector. The special sampling survey of 5000 to 6000 buildings that is conducted every 4 years provides detail on the annual consumption of each fuel and extensive characteristics data, allowing additional extensive analyses to be performed and supporting national modeling of energy use in this sector.

Energy data provide a historical record and are used to forecast trends into the future. Several organizations model world energy use, although often not with the commercial sector separated. Many individual nations also track historical energy use and forecast future energy use. The National Energy Modeling System (NEMS), used in the United States for energy use forecasts and other analyses, provides an example of an extensive sectoral and national modeling system. The NEMS Commercial Sector Demand Module is a simulation tool based on economic and engineering relationships; it models commercial sector energy demands, with breakout detail at the geographic level of nine census divisions, using 11 distinct categories of commercial buildings.

Projections of future energy use involve selections of equipment for the major fuels of electricity, natural gas, and distillate fuel, and for the major services of space heating, space cooling, water heating, ventilation, cooking, refrigeration, and lighting. The equipment choices are made based on an algorithm that uses life-cycle cost minimization constrained by factors related to commercial sector consumer behavior and time preference premiums. The algorithm also models demand for the minor fuels of residual oil, liquefied petroleum gas, coal, motor gasoline, and kerosene. The use of renewable fuel sources (wood, municipal solid waste, and solar energy) is also modeled. Decisions regarding the use of distributed generation and cogeneration technologies are performed using a separate cash-flow algorithm.

The NEMS Commercial Module generates midterm (20- to 30-year) forecasts of commercial sector energy demand. The model facilitates policy analysis of energy markets, technological development, environmental issues, and regulatory development as they interrelate with commercial sector energy demand. Input to this model is quite extensive, and in addition to the sectoral energy data includes building lifetime estimates, economic information such as demand elasticities for building services and market forecasts for certain types of equipment, distributed electricity generation/cogeneration system data, energy equipment market data, historical energy use data, and short-term energy use projections from another model. The primary output of the modeling process is a forecast of commercial sector energy consumption by fuel type, end use, building type, census division, and year. The module also provides forecasts of the following parameters for each of the forecast years:

- Construction of new commercial floor space by building type and census division.
- Surviving commercial floor space by building type, year of construction, and census division.
- Equipment market shares by technology, end use, fuel, building type, and census division.
- Distributed generation and cogeneration of electricity and fuels used.
- Consumption of fuels to provide district services.
- Nonbuilding consumption of fuels in the commercial sector.
- Average efficiency of equipment mix by end use and fuel type.

The NEMS Commercial Module interacts with and requires input from other modules in NEMS. This relationship of the Commercial Module to other components of NEMS is depicted schematically in Fig. 4. Not shown are the other sectoral modules and the central controlling module in NEMS that integrates and reconciles national level results for all sectors.

In contrast to such extensive sectoral models that are used to provide forecasts of energy use, the energy performance rating systems presented previously provide another type of model for the commercial sector; they allow additional understanding of current energy use and the influence of certain operating parameters of buildings. The type of information and the understanding of the commercial sector generated by different modeling approaches differ in perspective and ability to understand potential for improvements in energy efficiency. Effects of these differing perspectives are presented next.

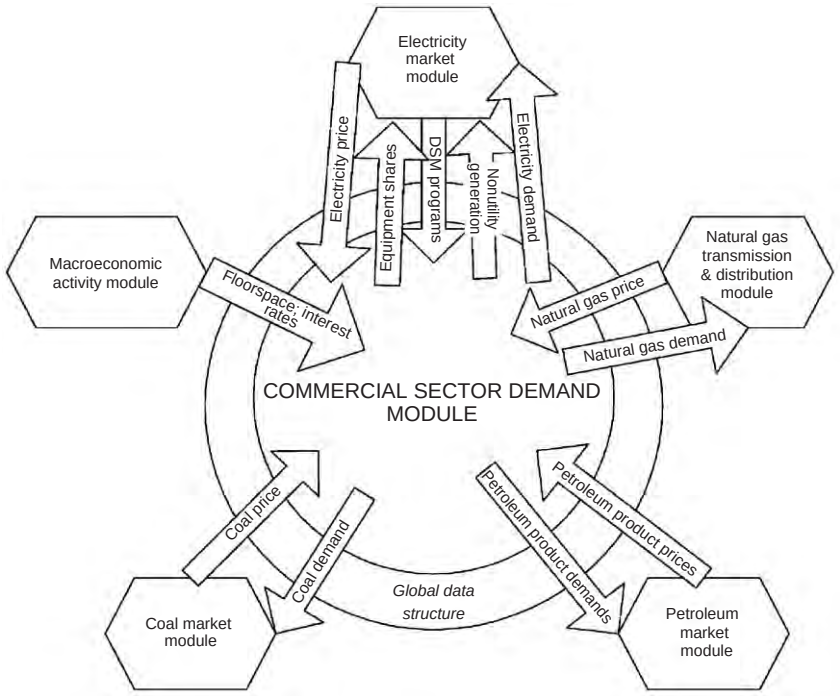

FIGURE 4 Relationship of the commercial sector and other National Energy Modeling System modules. DSM, demand-side management.

7. SECTORAL VIEWS FORMED BY MODELS

Energy models such as NEMS can be called economic-engineering models. Such models use engineering data and analysis results to feed into and partially interact with an economic model of commercial sector changes and demand for energy. Because changes in the efficiency of buildings and the energy use patterns of buildings tend to take many years to evolve, such economic-engineering models often do a good job of representing the energy use of a large group of buildings, including the entire commercial sector in a country. These models can also forecast the end uses of energy in buildings (Table IV) and are usually good at doing so.

Although NEMS forecasts about a 50% increase in U.S. commercial sector energy use between the years 2001 and 2025, the energy intensity of these buildings remains almost constant over this forecast period. This information indicates that growth in commercial sector energy use is attributed almost exclusively to growth in floor area, and that any efficiency improvements are modeled as offset by growth in end uses of energy not affected by the efficiency improvements. Clearly, with little change in annual energy intensity over a 25-year period, a tendency to limit certain types of change can be seen in this modeling approach. In addition, although the model provides a breakout of energy according to end uses such as heating, cooling, lighting, and seven other uses (Table IV), data on the impacts of the density of workers or occupants, schedule of operations, and density of personal computers in buildings are not modeled and are not known. To forecast total energy use, this type of normalization of energy is not required, because it represents a different way of looking at the sector, and normalized energy is not the desired output.

Economic-engineering models are also capable of forecasting impacts of new energy technologies and more efficient operations on energy use, but new energy technologies and impacts of those technologies on new buildings are more capably modeled in NEMS than are improvements in operations, which must typically be treated as changes in annual energy intensity. Unfortunately, this characteristic means that impacts of improvements in energy system operations are not understood and cannot be estimated well with this modeling approach.

Detailed engineering simulation models such as DOE-2, Energy Plus, and BLAST, which have the capabilities to model energy use in commercial buildings, also have difficulty modeling improvements

TABLE IV

NEMS Commercial Sector Energy End-Use Baseline and Forecast[a]

	Year						
Use	2000	2001	2005	2010	2015	2020	2025
Space heating	2.13	1.95	2.22	2.26	2.3	2.37	2.42
Space cooling	1.35	1.39	1.35	1.37	1.39	1.41	1.43
Water heating	1.15	1.12	1.21	1.26	1.3	1.35	1.39
Ventilation	0.56	0.55	0.55	0.56	0.56	0.56	0.57
Cooking	0.38	0.37	0.39	0.41	0.42	0.44	0.45
Lighting	3.34	3.31	3.54	3.73	3.81	3.87	3.89
Refrigeration	0.69	0.69	0.71	0.73	0.75	0.77	0.78

in energy system operations, because the simulation routines are all set up to model systems and components that work correctly. Simulating improvements in operations often requires knowing the answer first, and then tricking the simulation program into calculating the correct results. Again, the limitations of the models influence decisions about appropriate energy efficiency improvements for buildings. Limitations in ability to model impacts of operational improvements on energy efficiency lead to a view of the commercial sector that essentially ignores the potential of such improvements. A problem with this situation is that policy officials typically also do not receive information on the potential of operational improvements and lack an understanding of the importance of improving operations in commercial buildings. Because improvements in operations represent about half of the potential energy savings that could be achieved in the commercial sector, acceptable means of modeling impacts and potential efficiency benefits would be helpful. Until acceptable means of modeling are developed, the benefits of operational improvements must continue to be determined empirically.

Improved understanding of commercial sector energy use, and the potential of operational improvements for saving energy in commercial buildings, would result from the ability to model the effects of operational improvements on forecasts of energy use in the commercial sector. Improved understanding of the potential for energy efficiency improvements appears possible through modeling of normalized energy use for the sector, whereby adjustments for a few key factors known to cause variation in energy use in commercial buildings, together with performance rating values, could allow analysis and pursuit of scenarios of improvement toward higher efficiency ratings. Advances in modeling such as these could be important for the future, if the percentage increase in commercial sector energy use in advancing economies becomes a challenge for world energy efficiency and climate impacts.

8. DRIVING TOWARD ENERGY EFFICIENCY

As the need for energy efficiency becomes more pronounced, the drive toward efficiency in the commercial sector will be impeded by its complicated mix of building sizes and uses, the complicated systems often used in commercial buildings, and the relative lack of understanding of operations factors impacting energy use and how to achieve efficiency.

In the United States, commercial energy use has increased from 10 to 17% or more of national energy use between the years 1960 and 2000. A significant reason for this increase is the low cost of energy relative to the other costs of conducting business, but the difficulty in understanding energy systems and energy use in commercial buildings is also an important contributing factor. Policy officials often have difficulty understanding discussions of the needs for improvements in commercial buildings.

As economies advance and commercial sector energy use begins to grow relative to other sectors, an improved understanding of methods of measuring commercial energy performance, and the means of achieving efficiency improvements in this sector, will be important in any drive toward efficiency.

One warning sign of the need to increase understanding of energy performance is an increase in the use of air conditioning in commercial buildings. When air conditioning use increases, energy system complexity and indoor space quality issues also increase significantly. If air conditioning use is increasing, any proposal for increased efficiency that relies heavily on thermal insulation should be treated warily, because insulation optimization becomes more difficult, and other system complexities tend to become much more important.

A warning should be given overall for energy standards for buildings, as they currently exist around the world, because, despite the existence and use of these standards for many years, the effect of standards has been only moderate in most cases. The shortcoming of existing standards is that they rely too heavily on simulation of expected performance, without conducting true empirical studies to verify the effectiveness of what the standards achieve. One major reason such empirical studies have been conducted in only limited and mostly ineffective fashion is that an empirical method of measuring energy performance of commercial buildings, although still adjusting for legitimate building use differences, has only recently been established in concept, only for certain building types, and not with the stated intent of being a performance standard (Energy Star label for buildings). Interestingly, however, if such energy performance standards existed, energy standards currently in use, with their typically complicated requirements, would not necessarily be needed any longer as standards.

Use of energy performance certificates may be necessary to overcome the difficulty users, occupants, code and policy officials, and owners have in understanding commercial energy use and performance. Without certification of energy performance, the complexity of systems and uses makes understanding energy performance by anyone other than an expert, and even by some experts, difficult. However, without increased understanding of the most appropriate means to normalize energy use for legitimate differences in building function and use, energy performance certificates may offer an unsatisfactory solution, due to inequities that will be obvious to many, if reasonable normalizations are not applied.

Increased energy efficiency in the commercial sector is an important piece of the national efficiency strategy in advanced economies, in which the priority for efficiency must be increased. Complexities in commercial buildings have made progress in energy efficiency for this sector less than desirable in notable cases. Fortunately, methods and knowledge needed to increase success in this sector have begun to be developed, and better solutions can be offered in the near future to help increase energy efficiency in the commercial sectors of countries where the need is pressing.

9. FUTURE ENERGY PERFORMANCE AND USE

Current forecasts call for solid growth in world energy use over the next 20 years, potentially increasing 60% above current use. With the forces in place to keep energy use patterns the same, a safe, conservative assumption would be that the commercial sector will contribute about 12% to final total energy consumption in the year 2020. If world energy use grows to 600 quads, or 630 EJ, by the year 2020, and total final consumption in the energy-using sectors is about 400 quads, or 420 EJ, final consumption in the commercial sector, at 12%, would be about 50 quads/yr (or about 50 EJ), without electricity losses included. This energy use would be two-thirds more than the energy use in the year 2000.

Without significant changes in energy performance of commercial buildings, this scenario of 50 quads of commercial energy use in the year 2020 is likely to occur, absent major world upheaval. If important progress on improving the energy performance of commercial buildings in the advanced economies can be made, potentially a reduction of 2–4 quads or more in commercial sector worldwide use in 2020 (a 4–8% reduction) could be achieved. Such an achievement would require that energy performance certifications become the norm, that operational standards increase significantly, and that 25–40% of buildings in the advanced economies see significant improvements in their performance.

Methods for certifying the energy performance of commercial buildings have been developed to the conceptual and practical applications stages. However, these methods are in their infancy. Energy policy and research attention to the commercial sector have been lacking relative to the growth

observed. Without increased attention to improving commercial sector energy efficiency, energy use growth relative to other sectors will continue to make this sector a challenge when decreased energy use and emissions are sought.

Glossary

complex system A system that allows one to discern many subsystems, depending entirely on how one chooses to interact with the system.

dissipative systems All natural systems of interest for sustainability (e.g., complex biogeochemical cycles on this planet, ecological systems, human systems when analyzed at different levels of organization and scales beyond the molecular one); self-organizing open systems, away from thermodynamic equilibrium.

epistemological complexity Complexity that is in play every time the interests of the observer (the goal of the mapping) are affecting what the observer sees (the formalization of a scientific problem and the resulting model).

hierarchical systems Systems that are analyzable into successive sets of subsystems; when alternative methods of description exist for the same system.

hierarchy theory A theory of the observer's role in any formal study of complex systems.

scale The relation between the perception of a given entity and its representation.

The purpose of this article is to examine key epistemological issues that must be addressed by those willing to apply energy analysis to complex systems and particularly to the sustainability of adaptive systems organized in nested hierarchies. After a general introduction, sections 2 and 3 provide a critical appraisal of conventional energy analysis. Such a criticism is based on concepts developed in the field of hierarchy theory. Section 4 suggests an alternative view of the metaphorical message given by Prigogine's scheme in nonequilibrium thermodynamics—a message that can be used to develop innovative and alternative approaches for energy analysis. Section 5 presents the conclusions.

1. INTRODUCTION

The revolution entailed by complex systems theory is finally forcing many scientists to acknowledge that it is impossible to have a unique substantive representation of the reality. Different observers with various "scale-dependent" measuring schemes and goals (e.g., humans using either a microscope, the naked eye, or a telescope for different purposes) will perceive different aspects of a particular ontological entity. These different views do reflect the special relation established between the observer and the components of the entity observed. This predicament gets worse when dealing with hierarchically organized adaptive systems. These systems are, in fact, organized on different levels (e.g., cells, organs, individual humans, households, communities, countries). This implies that their identity is associated with the ability to express various patterns simultaneously on different scales. This implies that when doing energy analysis on these systems, wholes, parts, and their contexts require the parallel use of nonequivalent descriptive domains. That is, the

definitions of parts, wholes, and contexts referring to different levels are not reducible to each other. To make things more difficult for modelers, dissipative systems are becoming in time, meaning that their identities change in time. Their hierarchical nature entails that the pace of evolution of the identities of the parts will be different from that of the identity of the whole.

The disciplinary field of energy analysis seems to have ignored the epistemological challenge posed to the analysts by the fact that energy assessments must be a result of different perceptions and representations of the reality that cannot be reduced to each other. This problem is particularly serious considering that hierarchically organized adaptive systems, by definition, are operating across multiple scales. Not only do the energetic descriptions have to be based on the use of nonequivalent descriptive domains, but they also have to be updated in time. Thus, scientists dealing with the sustainability of complex dissipative systems adapting in time must be able to (1) individuate relevant causal relations and relevant scales in their modeling efforts, (2) use different selections of variables for representing changes in relevant attributes, and (3) continuously check the validity of these selections.

The main epistemological implication of studying systems organized across hierarchical levels and scales is that there is a virtual infinite universe of possible ways of perceiving and representing them. For example, there is virtually an infinite number of possible combinations of views of a human that can be generated when looking at him or her using microscopes, ultrasound scanners, X-ray machines, blood tests, conventional cameras, radars, and telescopes simultaneously. Any formal representation—the information space used to make models in terms of variables and formal systems of inference—must be finite and closed. This represents a huge challenge for scientists.

The main message of the new scientific paradigm entailed by complexity can be expressed using two crucial points. When dealing with the sustainability of complex adaptive systems, first, scientists must accept dealing with an unavoidable nonreducibility of models defined on different scales and reflecting different selections of relevant attributes. This implies acknowledging the impossibility of reaching an uncontested agreement on a substantive and unique description of the reality that can be assumed to be the "right" one. Second, scientists must accept dealing with incommensurability among the priorities used by nonequivalent observers when deciding how to perceive and represent nested hierarchical systems operating across scales. Nonequivalent observers with different goals will provide logically independent definitions of the relevant attributes to be considered in the model. This implies the impossibility of having a substantive and agreed-on definition of what should be considered the "most useful" narrative to be adopted when constructing the model.

This new paradigm associated with complexity, which is rocking the reductionist building, is the offspring of a big epistemological revolution started during the first half of 19th century by classical thermodynamics (e.g., by the works of Carnot and Clausius) and continued during the second half of the 20th century by nonequilibrium thermodynamics (e.g., by the works of Schroedinger and Prigogine). Both revolutions used the concept of "entropy" as a banner. The equilibrium thermodynamics represented a first bifurcation from mechanistic epistemology by introducing new concepts such as irreversibility and symmetry breaking when describing real-world processes. Then, the introduction of the new nonequilibrium paradigm implied a final departure from reductionist epistemology in that it implies the uncomfortable acknowledgment that scientists can work only with system-dependent and context-dependent definitions of entities. Put differently, food is a "high-quality" energy input for humans but not for cars. Saying that 1 kg of rice has an "energy content" of a given amount of megajoules can be misleading because this "energy input" is not an available energy input for driving a car that is out of gasoline. In the same way, the definition of what should be considered "useful energy" depends on the goals of the system that is expected to operate within a given associative context. For example, fish are expected to operate under the water to get their food, whereas birds cannot fly to catch prey below the ground.

Classical thermodynamics first, and nonequilibrium thermodynamics later on, gave a fatal blow to the mechanist epistemology of Newtonian times, introducing brand-new concepts such as disorder, information, entropy, and negentropy. However, we cannot replace the hole left by the collapse of Newtonian mechanistic epistemology just by using these concepts, as if they were "substantive" concepts that are definable in a strictly physical sense as well as context independent. For example, the concept of "negative entropy" is not a substantive concept. Rather, it is a "construction" (an artifact) associated with the given identity of a dissipative system that is perceived and represented as operating at a given

point in space and time. Therefore, the concept of negative entropy reflects the perception and representation of the "quality" of both energy inputs and energy transformations that are associated with a particular pattern of dissipation (or typology of metabolism). But this quality assessment is valid only for the specific dissipative system considered that is assumed to operate within a given associative context or an admissible environment. These can seem to be trivial observations, but they are directly linked to a crucial statement we want to make in this article. It is not possible to characterize, using a "substantive formalism," qualitative aspects of energy forms, and this is applicable to all conceivable dissipative systems operating in the reality. That is, it is impossible to define a "quality index" that is valid in relation to all of the conceivable scales and when considering all of the conceivable attributes that could be relevant for energy analysis. Conventional variables used in mechanics can be relevant attributes to define the stability of a dissipative process, but there are situations in which unconventional attributes, such as smell and color, can become crucial observable qualities (e.g., in ecology in relation to the admissibility of the expected associative context). This is the norm rather than the exception for complex adaptive systems. In this case, it is not always easy to quantify the relevance of these attributes in terms of an energy quality index.

To make things more challenging, we must bear in mind the fact that not only the observed system but also the observer is becoming something else in time. That is, an observer with different goals, experiences, fears, and knowledge will never perceive and represent energy forms, energy transformations, and a relative set of "indexes of quality" in the same way as did a previous one.

The consequences of this fact deserve attention. This entails that, on the one hand, various concepts derived from thermodynamic analysis used to generate energy indexes of quality (e.g., output/input energy ratios, exergy-based indexes, entropy-related concepts, embodied assessments associated with energy flows) do carry a powerful metaphorical message. On the other hand, like all metaphors, they always require a semantic check before their use. That is, concepts such as efficiency, efficacy, and other quality indexes are very useful in a discussion about sustainability issues. The problem is that they cannot and should not be used to provide normative indications about how to deal with a sustainability predicament in an algorithmic way. That is, policies cannot be chosen or evaluated on the basis of the maximization of a single parameter (e.g., efficiency, power, rate of supply of negentropy) or on the basis of the application of a set of given rules written in protocols to a given simplified model of the reality.

The wisdom of Carnot, well before the complexity revolution, led him to similar conclusions in 1824 that can be found in the closing paragraph of his *Reflections on the Motive Power of Fire, and on Machines Fitted to Develop That Power*:

> *We should not expect ever to utilize in practice all the motive power of combustibles. The attempts made to attain this result would be far more harmful than useful if they caused other important considerations to be neglected. The economy of the combustible is only one of the conditions to be fulfilled in heat-engines. In many cases it is only secondary. It should often give precedence to safety, to strength, to the durability of the engine, to the small space which it must occupy, to small cost of installation, etc. To know how to appreciate in each case, at their true value, the considerations of convenience and economy which may present themselves; to know how to discern the more important of those which are only secondary; to balance them properly against each other in order to attain the best results by the simplest means; such should be the leading characteristics of the man called to direct, to co-ordinate the labours of his fellow men, to make them co-operate towards a useful end, whatsoever it may be.*

2. THE ENERGETICS OF HUMAN LABOR: AN EPISTEMOLOGICAL ANALYSIS OF THE FAILURE OF CONVENTIONAL ENERGY ANALYSIS

Attempts to apply energy analysis to human systems have a long history. Pioneering work was done by, among others, Podolinsky, Jevons, Ostwald, Lotka, White, and Cottrel. However, it was not until the 1970s that energy analysis became a fashionable scientific exercise, probably due to the oil crisis surging during that period. During the 1970s, energy input/output analysis was widely applied to farming systems and national economies and was applied more generally to describe the interaction of humans with their environment by Odum, Georgescu-Roegen, and Pimentel, among others. At the IFISA workshop of 1974, the term "energy analysis" (as opposed to "energy accounting") was officially coined. The second energy crisis during the 1980s was echoed by the appearance of a new wave of interesting work by biophysical researchers and a second elaboration of their own original work by the "old guard." However, quite remarkably, after less

than a decade or so, the interest in energy analysis declined outside the original circle. Indeed, even the scientists of this field soon realized that using energy as a numeraire to describe and analyze changes in the characteristics of agricultural and socioeconomic systems proved to be more complicated than one had anticipated.

We start our critical appraisal of the epistemological foundations of conventional energy analysis using one of the most well-known case studies of this field: the attempt to develop a standardized tool kit for dealing with the energetics of human labor. This has probably been the largest fiasco of energy analysis given the huge effort dedicated to this by the community of energy analysts.

Looking over the vast literature on the energetics of human labor, one can find agreement about the need to know at least three distinct pieces of information, which are required simultaneously, to characterize indexes of "efficiency" or "efficacy":

1. *The requirement (and/or availability) of an adequate energy input needed to obtain the conversion of interest.* In the case of human labor, a flow of energy contained in food is energy carriers compatible with human metabolism.
2. *The ability of the considered converter to transform the energy input into a flow of useful energy to fulfill a given set of tasks.* In this case, a system made up of humans has to be able to convert available food energy input into useful energy at a certain rate, depending on the assigned task.
3. *The achievement obtained by the work done, that is, the results associated with the application of useful energy to a given set of tasks.* In this case, this has to do with the usefulness of the work done by human labor in the interaction with the context.

If we want to use indexes based on energy analysis to formalize the concept of performance, we have to link these three pieces of information to numerical assessments based on "observable" qualities (Fig. 1). For this operation, we need at least four nonequivalent numerical assessments related to the following:

1. *Flow of a given energy input that is required and consumed by the converter.* In the case of the study of human labor, it is easy to define what should be considered food (energy carriers) for humans: something that can be digested and then transformed into an input for muscles. If the converter were a diesel engine, food would not be considered an energy input. This implies that the energy input can be characterized and defined only in relation to the given identity of the converter using it.

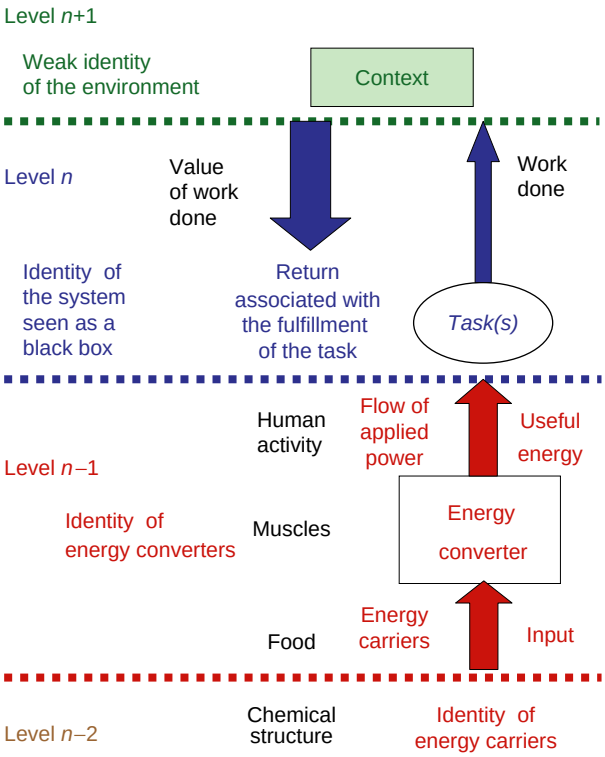

FIGURE 1 Relevant qualities for characterizing the behavior of an energy converter across hierarchical levels. From Giampietro, M. (2003). "Multi-Scale Integrated Analysis of Agroecosystems." CRC Press, Boca Raton, FL. Used with permission.

2. *The power level at which useful energy is generated by the converter.* This is a more elusive "observable quality" of the converter. Still, this information is crucial. As stated by Odum and Pinkerton in 1955, when dealing with the characterization of energy converters, we always have to consider both the pace of the throughput (the power) and the output/input ratio. A higher power level tends to be associated with a lower output/input ratio (e.g., the faster one drives, the lower the mileage of one's car). On the other hand, it does not make any sense to compare two output/input ratios if they refer to different throughput rates. In fact, we cannot say that a truck is less efficient than a small motorbike on the basis of the information given by a single indicator, that is, by the simple assessment that the truck uses more gas per mile than does the motorbike. However, after admitting that the power level is another piece of information that is required to assess the performance of an energy converter, it becomes very difficult to find a standard definition of "power level" applicable to "complex

energy converters" (e.g., to compare human workers to light bulbs or economic sectors). This is especially true when these systems are operating on multiple tasks. Obviously, this is reflected in an impossibility to define a standard experimental setting to measure such a value for nonequivalent systems. Moreover, power level (e.g., 1000 horsepower of a tractor vs 0.1 horsepower of a human worker) does not map onto either energy input flows (how much energy is consumed by the converter over a given period of time used as a reference [e.g., 1 year]) or how much applied power is delivered (how much useful energy has been generated by a converter over a given period of time used as reference [e.g., 1 year]). In fact, these two different pieces of information depend on how many hours the tractor or human worker has worked during the reference period and how wisely the tractor or human worker has been operating. This is reflected by the need to introduce a third piece of information to the analysis.

3. *Flow of applied power generated by the conversion.* The numerical mapping of this quality clearly depends heavily on the previous choices about how to define and measure power levels and power supply. In fact, an assessment of the flow of applied power represents the formalization of the semantic concept of "useful energy." Therefore, this is the measured flow of energy generated by a given converter (e.g., an engine) that is used to fulfill a specified task (e.g., water pumped out of the well). To make things more difficult, the definition of usefulness of such a task can be given only when considering the hierarchical level of the whole system to which the converter belongs (e.g., if the water is needed to do something by the owner of the pump). Put differently, such a task must be defined as "useful" by an observer operating at a hierarchical level higher than the level at which the converter is transforming energy input into useful energy. What is produced by the work of a tractor has a value that is generated by the interaction of the farm with a larger context (e.g., the selling of products on the market). That is, the definition of "usefulness" refers to the interaction of the whole system—the farm, which is seen as a black box (to which the converter belongs as a component) with its context. Therefore, the assessment of the quality of "usefulness" requires a descriptive domain different from that used to represent the conversion at the level of the converter (gasoline into motive power in the engine). This introduces a first major epistemological complication: the definition of usefulness of a given task (based on the return that this task implies for the whole system) refers to a representation of events on a given hierarchical level (the interface $n/n+1$) that is different from the hierarchical level used to describe and represent (assess indexes of efficiency of) the conversion of the energy input into useful energy (the interface $n-1/n$).

4. *Work done by the flow of applied power, that is, what is achieved by the physical effort generated by the converter.* Work is another very elusive quality that requires a lot of assumptions to be measured and quantified in biophysical terms. The only relevant issue here is that this represents a big problem regarding energy analysis. Even if assessments 3 and 4 use the same measurement unit (e.g., megajoules), they are different in terms of the relevant observable qualities of the system. That is, assessment 3 (applied power) and assessment 4 (work done) not only do not coincide in numerical terms but also require different definitions of descriptive domain. In fact, the same amount of applied power can imply differences in achievement due to differences in design of technology and know-how when using it. The problem is that it is impossible to find a "context-independent quality factor" that can be used to explain these differences in substantive terms.

The overview provided in Fig. 1 should already make clear to those familiar with epistemological implications of hierarchy theory that practical procedures used to generate numerical assessments within a linear input/output framework cannot escape the unavoidable ambiguity and arbitrariness implied by the hierarchical nature of complex systems. A linear characterization of input/output using the four assessments discussed so far requires the simultaneous use of at least two nonequivalent and nonreducible descriptive domains. Therefore, a few of these four assessments are logically independent, and this opens the door to an unavoidable degree of arbitrariness in the problem structuring (root definitions of the system). Any definition or assessment of energy flows, as input and/or output, will in fact depend on an arbitrary choice made by the analyst about what should be considered the focal level n, that is, what should be considered as a converter, what should be considered as an energy carrier, what should be considered as the whole system to which the converter belongs, and what has to be included and excluded in the characterization of the environment when checking the admissibility of boundary conditions and the usefulness of work done. A linear representation in energy analysis forces the analyst to decide "from scratch," in a

situation of total arbitrariness, on the set of formal identities adopted in the model to represent energy flows and conversions using the finite set of variables used to describe changes in the various elements of interest. This choice of a set of formal identities for representing energy carriers, converters, and the black box—the finite set of characteristics related to the definition of an admissible environment—is then translated into the selection of the set of epistemic categories (variables) that will be used in the formal model. It is at this point that the capital sin of the assumption of linear representation becomes evident. No matter how smart the analyst may be, any assessment of energy input (the embodied energy of the input) or energy output (what has been achieved by the work done) will be unavoidably biased by the arbitrary preanalytical choice of root definitions. In terms of hierarchy theory, we can describe this fact as follows.

The unavoidable preliminary triadic filtering needed to obtain a meaningful representation of the reality is at the basis of this impasse. For this filtering, we have to select (1) the interface between the focal level n and the lower level $n-1$ to represent the structural organization of the system and (2) the interface between the focal level n and higher level $n+1$ to represent the relational functions of the system. Ignoring this fact simply leads to a list of disorganized nonequivalent and nonreducible assessments of the same concepts. A self-explanatory example of this standard impasse in the field of energy analysis is given in Table I, which reports an example of several nonequivalent assessments of the energetic equivalent of 1 h of labor found in the literature.

That is, every time we choose a particular hierarchical level of analysis for assessing an energy flow (e.g., an individual worker over a day), we are also selecting a space–time scale at which we will describe the process of energy conversion (e.g., over a day, over a year, over the entire life). This, in turn, implies a nonequivalent definition of the context or environment and of the lower level where structural components are defined. Human workers can be seen as individuals operating over a 1-h time horizon where muscles are the converters, or they can be seen as citizens of developed countries where machines are the converters. The definitions of identities of these elements must be compatible with the identity of energy carriers such that individuals eat food, whereas developed countries eat fossil energy. This implies that, whatever we choose as a model, the various identities of energy carriers, parts, whole, and environment have to make sense in their reciprocal conditioning. Obviously, a different choice of hierarchical level considered as the focal level (e.g., the worker's household) requires adopting a different system of accounting for input and output.

3. THE PROBLEMATICS RELATED TO FORMAL DEFINITIONS OF ENERGY, WORK, AND POWER IN PHYSICS AND THEIR APPLICABILITY TO ENERGY ANALYSIS

In the previous case study, we have actually dealt the problematics related to formal definitions of energy, power, and work when dealing with an energetic assessment of human labor. Because this is a point carrying quite heavy epistemological implications, we would like to elaborate a bit more on it. To be able to calculate substantive indexes of performance based on concepts such as efficiency (maximization of an output/input ratio) and efficacy (maximization of an indicator of achievement in relation to an input) within energy analysis, we should be able to define, first, three basic concepts—"energy," "work," and "power"—in substantive terms. That is, we should be able to agree on definitions that are independent of the special context and settings in which these three concepts are used. However, if we try to do that, we are getting into an even more difficult situation.

3.1 Energy

Much of the innate indeterminacy of energy analysis, especially when applied to complex systems, has its roots in the problematic definition of energy in physics. As Feynman and colleagues pointed out in 1963, we have no knowledge of what energy is, and energy is an abstract thing in that it does not tell us the mechanism or the reasons for the various formulas. In practice, energy is perceived and described in a large number of different forms: gravitational energy, kinetic energy, heat energy, elastic energy, electrical energy, chemical energy, radiant energy, nuclear energy, mass energy, and so on. A general definition of energy, without getting into specific context and space–time scale-dependent settings, is necessarily limited to a vague expression such as "the potential to induce physical transformations." Note that the classical definition of energy in conventional physics textbooks, "the potential to do

TABLE I

Nonequivalent Assessments of Energy Requirement for 1 h of Human Labor

		Energy input per hour of labor

[a] The nine methods considered are (1) only extra metabolic energy due to the actual work (total energy consumption minus metabolic rate) in 1 h; (2) total metabolic energy spent during actual work (including metabolic rate) in 1 h; (3) metabolic energy spent in a typical work day divided by the hours worked in that day; (4) metabolic energy spent in 1 year divided by the hours worked in that year. (5) Same as method 4 but applied at hierarchical level of household; (6) same as method 4 but applied at the level of society; (7) besides food energy, also including exosomatic energy spent in food system per year divided by the hours of work in that year (7a at household level, 7b at society level); (8) total exosomatic energy consumed by society in 1 year divided by the hours of work delivered in that society in that year; and (9) assessing the megajoules of solar energy equivalent of the amount of fossil energy assessed with method 8.

[b] The "systems delivering work" considered are typical adult man (Man), typical adult woman (Woman), average adult (Adult), typical household, and an entire society. Definitions of "typical" are arbitrary and serve only to exemplify methods of calculation.

[c] Food energy input is approximated by the metabolic energy requirement. Given the nature of the diet and food losses during consumption, this flow can be translated into food energy consumption. Considering also postharvest food losses and preharvest crop losses, it can then be translated into different requirements of food (energy) production.

[d] We report here an assessment referring only to fossil energy input.

[e] Other energy forms, acting now or in the past, that are (were) relevant for the current stabilization of the described system even if operating on space–time scales not detected by the actual definition of identity for the system.

[f] Based on a basal metabolic rate for adult men of BMR = 0.0485 W + 3.67 MJ/day (W = weight = 70 kg) = 7.065 MJ/day = 0.294 MJ/h. Physical activity factor for moderate occupational work (classified as moderate) 2.7 × BMR. Average daily physical activity factor 1.78 × BMR (moderate occupational work). Occupational workload: 8 h/day considering work days only; 5 h/day average workload over the entire year, including weekends, holidays, and absence.

[g] Based on a basal metabolic rate for adult women of BMR = 0.0364 W + 3.47 (W = weight = 55 kg) = 5.472 MJ/day = 0.228 MJ/h. Physical activity factor for moderate occupational work 2.2 × BMR. Average daily physical activity factor (based on moderate occupational work) 1.64 × BMR. Occupational workload: 8 h/day considering work days only; 5 h/days average work load over the entire year, including weekends, holidays, and absence.

[h] Assuming a 50% gender ratio.

[i] A typical household is arbitrarily assumed to consist of one adult male (70 kg, moderate occupational activity), one adult female (55 kg, moderate occupational activity), and two children (male of 12 years and female of 9 years).

[j] This assessment refers to the United States. In 1993, the food energy requirement was 910,000 TJ/year and the work supply was 215 billion h.

[k] Assuming 10 MJ of fossil energy spent in the food system per 1 MJ of food consumed.

[l] Assuming a total primary energy supply in 1993 in the United States (including the energy sector) of 85 million TJ divided by a work supply of 215 billion h.

[m] Assuming a transformity ratio for fossil energy of 50 million EMJ/joule.

work," refers to the concept of "free energy" or "exergy," and this is another potential source of confusion. Both of these concepts require a previous formal definition of work and a clear definition of operational settings to be applied.

3.2 Work

The similar ambiguous definition of energy is also found when dealing with a general definition of work, a definition applicable to any specific space–time scale-dependent settings. The classical definition found in dictionaries refers to the ideal world of elementary mechanics: "work is performed only when a force is exerted on a body while the body moves at the same time in such a way that the force has a component in the direction of the motion." Others express work in terms of "equivalent to heat," as is done in thermodynamics: "the work performed by a system during a cyclic transformation is equal to the heat absorbed by the system." This calorimetric equivalence offers the possibility to express assessments of work in the same unit as energy, that is, in joules. However, the elaborate description of work in elementary mechanics and the calorimetric equivalence derived from classical thermodynamics are of little use in real-life situations. Very often, to characterize the performance of various types of work, we need inherently qualitative characteristics that are impossible to quantify in terms of "heat equivalent." For example, the work of a director of an orchestra standing on a podium cannot be described using the previously given definition of elementary mechanics, nor can it be measured in terms of heat. An accounting of the joules related to how much the director sweats during the execution of a musical score will not tell anything about the quality of his or her performance. "Sweating" and "directing well" do not map onto each other. Indeed, it is virtually impossible to provide a physical formula or general model defining the quality (or value) of a given task (what has been achieved after having fulfilled a useful task) in numerical terms from within a descriptive domain useful in representing energy transformations based on a definition of identity for energy carriers and energy converters. In fact, formal measurements leading to energetic assessments refer to transformations occurring at a lower level (e.g., how much heat has been generated by muscles at the interface level $n/n-1$), whereas an assessment of performance (e.g., how much the direction has been appreciated by the public) refers to interactions and feedback occurring at the interface level $n/n+1$). This standard predicament applies to all real complex systems and especially to human societies.

3.3 Power

The concept of power is related to "the time rate of an energy transfer" or, when adopting the theoretical formalization based on elementary mechanics, to "the time rate at which work is being done." Obviously, this definition cannot be applied without a previous valid and formal mapping of the "transfer of energy" in the form of a numerical indicator or of "doing the work." At this point, it should be obvious that the introduction of this "new" concept, based on the previous ones, does not get us out of the predicament experienced so far. Any formal definition of power will run into the same epistemological impasse discussed for the previous two concepts given that it depends on the availability of a valid definition of them in the first place.

It should be noted, however, that the concept of power introduces an important new qualitative aspect—a new attribute required to characterize the energy transformation—not present in the previous two concepts. Whereas the concepts of energy and work, as defined in physics, refer to quantitative assessment of energy without taking into account the time required for the conversion process under analysis, the concept of power is, by definition, related to the rate at which events happen. This introduces a qualitative dimension that can be related either to degree of organization of the dissipative system or to the size of the system performing the conversion of energy in relation to the processes that guarantee the stability of boundary conditions in the environment. To deliver power at a certain rate, a system must have two complementing but distinct relevant features. First, it must have an "adequate organized structure" to match the given task. In other words, it must have the capability of doing work at a given rate. For example, an individual human cannot process and convert into power 100,000 kcal of food in a day. Second, it must have the capability of securing a sufficient supply of energy input for doing the task. For example, to gain an advantage from the power of 100 soldiers for 1 year, we must be able to supply them with enough food. In short, "gasoline without a car" (the first feature) or "a car without gasoline" (the second feature) is of no use.

This is the point that exposes the inadequacy of the conventional output/input approach. In hierarchically organized adaptive systems, it is not

thinkable to have an assessment of energy flows without properly addressing the set of relevant characteristics of the process of transformation that are level and scale dependent in their perception and representation. The analyst must address the existence of expected differences in the perception and representation of concepts such as energy, power, and work done on different hierarchical levels and associated with the multiscale identity of the dissipative system in the first place. This means that the three theoretical concepts—energy, work, and power—must be simultaneously defined and applied within such a representation in relation to the particular typology of dissipative system (engines of cars are different from muscles in humans).

At this point, if we accept the option of using nonequivalent descriptive domains in parallel, we can establish a reciprocal entailment on the definitions of identity of the various elements (converter, whole system, energy carriers, and environment) to characterize the set of energy transformations required to stabilize the metabolism of a dissipative system.

In this case, we have two couples of self-entailment among identities:

Self-Entailment 1: The identities adopted for the various converters (on interface level n and level $n-1$) referring to the power level of the converter *define/are defined by* the identities adopted for the energy carriers (on interface level $n-1$ and level $n-2$).

Self-Entailment 2: The identities of the set of energy forms considered to be useful energy on the focal level, that is, characterization of the autocatalytic loop from within (on interface between level $n-1$ and level n) in relation to their ability, validated in the past, to fulfill a given set of tasks, *define/are defined by* the compatibility of the identities of the whole system in relation to its interaction with the larger context, that is, characterization of the autocatalytic loop from outside (on the interface between level n and level $n+1$). This compatibility can be associated with the determination of the set of useful tasks in relation to the availability in the environment of the required flow of input and sink capacity for wastes.

When using these two set of relations and identities, which depend on each other for their definitions, simultaneously, we can link nonequivalent characterizations of energy transformations across scales (Fig. 2).

Bridge 1: conversion rates represented on different levels must be compatible with each other. This implies a constraint of compatibility between the definition of identity of the set of converters defined at level $n-1$ (triadic reading: $n-2/n-1/n$) and the definition of the set of tasks for the whole defined at level $n+1$ (triadic reading: $n-1/n/n+1$). This constraint addresses the ability of the various converters to generate "useful energy" (the right energy form applied in the specified setting) at a given rate that must be admissible for the various tasks. This bridge deals with qualitative aspects of energy conversions.

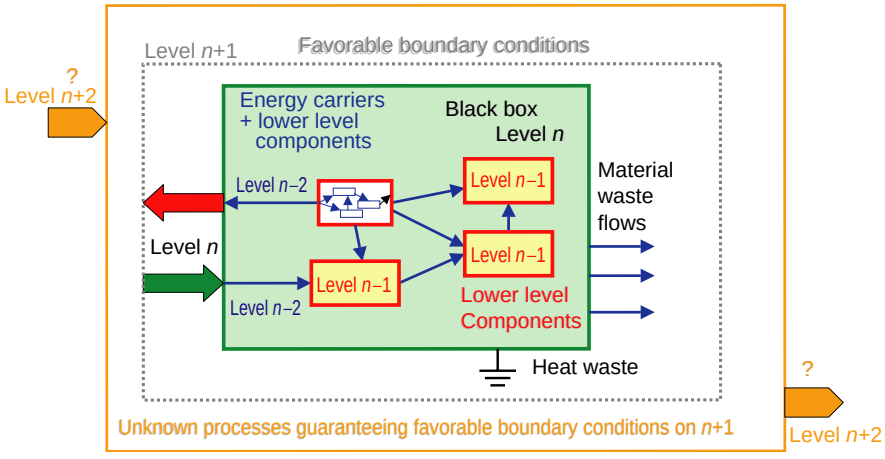

FIGURE 2 Hierarchical levels that should be considered when studying autocatalytic loops of energy forms. From Giampietro, M. (2003). "Multi-Scale Integrated Analysis of Agroecosystems." CRC Press, Boca Raton, FL. Used with permission.

Bridge 2: The flow of energy input from the environment and the sink capacity of the environment must be enough to cope with the rate of metabolism implied by the identity of the black box. This implies a constraint of compatibility between the size of the converters defined at level $n-1$ (triadic reading: $n-2/n-1/n$) and the relative supply of energy carriers and sink capacity related to processes occurring at level $n+1$. The set of identities of the input (from the environment to the converters) and output (from the converters to the environment) is referring to a representation of events belonging to level $n-2$. In fact, these energy carriers will interact with internal elements of the converters to generate the flow of useful energy and will be turned out into waste by the process of conversions. However, the availability of an adequate supply of energy carriers and of an adequate sink capacity is related to the existence of processes occurring in the environment that are needed to maintain favorable conditions at level $n+1$. Differently put, the ability to maintain favorable conditions in the face of a given level of dissipation can be defined only by considering level $n+1$ as the focal one (triadic reading: $n/n+1/n+2$).

This means that when dealing with quantitative and qualitative aspects of energy transformations over an autocatalytic loop of energy forms, we have to bridge at least five hierarchical levels (from level $n-2$ to level $n+2$).

Unfortunately, by definition, the environment (processes determining the interface between levels $n+1$ and $n+2$) is something we do not know enough about. Otherwise, it will become part of the modeled system. This means that when dealing with the stability of "favorable boundary conditions," we can only hope that they will remain the way they for as long as possible. On the other hand, the existence of favorable boundary conditions is a must for dissipative systems. That is, the environment is and must generally be assumed to be an "admissible environment" in all technical assessments of energy transformations.

Therefore, the existence of favorable boundary conditions" (interface level $n+1/n+2$) is an assumption that is not directly related to a definition of usefulness of the tasks (interface level $n/n+1$) in relation to the issue of sustainability. The existing definition of the set of useful tasks at level n simply reflects the fact that these tasks were perceived as useful in the past by those living inside the system. That is, the established set of useful tasks was able to sustain a network of activities compatible with boundary conditions (*ceteris paribus* at work). However, this definition of usefulness for these tasks (what is perceived as good at level n according to favorable boundary conditions at level $n+1$) has nothing to do with the ability or effect of these tasks in relation to the stabilization of boundary conditions in the future. For example, producing a given crop that provided an abundant profit last year does not necessarily imply that the same activity will remain so useful next year. Existing favorable boundary conditions at level $n+1$ require the stability of the processes occurring at level $n+2$ (e.g., the demand for that crop remains high in the face of a limited supply, natural resources such as nutrients, water, soil, and pollinating bees will remain available for the next year). This is information we do not know, and cannot know enough about, in advance. This implies that analyses of "efficiency" and "efficacy" are based on data referring to characterizations and representations relative to identities defined only on the four levels $n-2$, $n-1$, n, and $n+1$ (on the *ceteris paribus* hypothesis and reflecting what has been validated in the past). Because of this, they are not very useful in studying coevolutionary trajectory of dissipative systems. In fact, they (1) do not address the full set of relevant processes determining the stability of favorable boundary conditions (they miss a certain number of relevant processes occurring at level $n+2$) and (2) deal only with qualitative aspects (intensive variables referring to an old set of identities) but not quantitative aspects such as the relative size of components (how big is the requirement of the whole dissipative system—an extensive variable assessing the size of the box from the inside—in relation to the unknown processes that stabilize the identity of its environment at level $n+2$). As observed earlier, the processes that are stabilizing the identity of the environment are not known by definition. This is why, when dealing with coevolution, we have to address the issue of "emergence." That is, we should expect the appearance of new relevant attributes (requiring the introduction of new epistemic categories in the model, that is, new relevant qualities of the system so far ignored) to be considered as soon as the dissipative system (e.g., human society) discovers or learns new relevant information about those processes occurring at level $n+2$ that were not known before.

4. THE METAPHOR OF PRIGOGINE SCHEME TO CHARACTERIZE AUTOCATALYTIC LOOPS OF ENERGY FORMS IN HIERARCHICALLY ORGANIZED ADAPTIVE SYSTEMS

This section applies the rationale of hierarchical reading of energy transformations to the famous scheme proposed by Prigogine to explain the biophysical feasibility of dissipative systems in entropic terms. As Schroedinger showed, living systems can escape the curse of the second law thanks to their ability to feed on "negentropy." Differently put, living systems are, and must be, open systems that can preserve their identity thanks to a metabolic process.

This original idea has been further developed by the work of the school of Prigogine in nonequilibrium thermodynamic. These researchers introduced the class of dissipative systems in which the concept of entropy is associated with that of self-organization and emergence. In this way, it becomes possible to better characterize the concept of metabolism of dissipative systems. The ability to generate and preserve in time a given pattern of organization depends on two self-entailing abilities: (1) the ability to generate the entropy associated with the energy transformations occurring within the system and (2) the ability to discharge this entropy into the environment at a rate that is at least equal to that of internal generation. As observed by Schneider and Kay in a famous article in 1994, the possibility to have life, self-organization, and autocatalytic loops of energy forms is strictly linked to the ability of open dissipative systems to generate and discharge entropy into an admissible environment. Actually, the more such systems can generate and discharge entropy, the higher the complexity of the patterns they can sustain.

Dissipative systems have to maintain a level of entropy generation and discharge that is admissible in relation to their identity of metabolic systems. Differently put, the pattern of energy dissipation associated with their expected identity in terms of an ordered structure of material flows across hierarchical levels must be compatible with a set of favorable boundary conditions within the environment. Using the vocabulary developed by Schroedinger and Prigogine, this requires compensating the unavoidable generation of entropy associated with internal irreversibility (dS_i) by importing an adequate amount of negentropy (dS_e) from their environment. The famous relation proposed by Prigogine to represent this idea can be related as

$$dS_T \Leftrightarrow dS_i + dS_e \quad (1)$$

Relation (1) indicates that the identity of the system defined at interface level $n/n-1$ must be congruent or compatible with the identity of the larger dissipative system defined at interface level $n+1/n$. In other words, the two flows of entropy internally generated (dS_i) and "imported/exported" (dS_e) must be harmonized with change in entropy of the system (dS_T) in which the identity of the first is embedded.

Let us now try to interpret, in a metaphorical sense, the scheme proposed by Prigogine to characterize autocatalytic loops of energy forms within nested metabolic systems.

First, dS_i refers to the representation of the mechanism of internal entropy production that is associated with the irreversibility generated to preserve system identity. This assessment necessarily must be obtained using a representation of events related to a perception obtained within the black box on interface level $n-2/n-1/n$. This can be done by using a mapping of an energy form that makes it possible to represent how the total input used by the black box is then invested among the various parts (the internal working of the metabolism).

Second, dS_e refers to the representation of imported negative entropy. The term "negentropy" entails the adoption of a mechanism of mapping that has to be related to the previous choices made when representing dS_i. This term requires establishing a bridge between the assessment of two forms of energy: (1) one used to describe events within the black box in terms of dS_i (the mapping used to assess the effect of internal mechanisms associated with irreversibility) and (2) another used to describe how the metabolism of the larger system (the environment) providing favorable boundary conditions is affected by the activity of the black box. This implies using the mapping of a second energy form. This second energy form, reflecting the interference of the black box over the metabolism of the environment, has to be effectively linkable to the first energy form.

The first energy form is used to represent relevant mechanisms inside the black box. The second energy form is used to represent the effects of the interaction of the black box with its associative context. It represents the view of the metabolism of the black box from the outside.

Third, dS_T translates into a required compatibility, in quantitative and qualitative terms, of the overall interaction of the black box with the environment according to the particular selection of mapping of the two energy forms. Whenever $dS_T < 0$, the system can expand its domain of activity, either by growing in size (generating more of the same pattern, so to speak) – or by moving to another dissipative pattern (developing emergent properties). On the contrary, whenever $dS_T > 0$, the system has to reduce its activity. It can remain alive, at least for a while, by sacrificing a part of its activities. In this case, a certain level of redundancy can be burned, providing a temporary buffer, to get through critical moments and cyclic perturbations (disappearance of expected favorable conditions).

As noted earlier, it is not possible to obtain a simultaneous check in formal terms—and in a substantive way—of the relation among the three *dS*s defined on different descriptive domains. On the other hand, an autocatalytic loop of different energy forms can be used to study the forced congruence across levels of some of the characteristics of the autocatalytic loop defined on different descriptive domains (Fig. 3).

In Fig. 3A, we resume the key features of the energetic analysis of dissipative systems. In particular, we provide a different perspective on the discussion related to the representation of hierarchically organized dissipative systems (Fig. 1). That is, the network represented in Fig. 2 can be represented by dividing the components described at level $n-1$ into two compartments: (1) those that do not interact directly with the environment (aggregated in the compartment labeled "indirect" in Fig. 3A) and (2) those that interact directly with the environment by gathering environmental inputs and providing those useful tasks aimed at such a gathering (aggregated in the compartment labeled "direct" in Fig. 3A). Thanks to the existence of

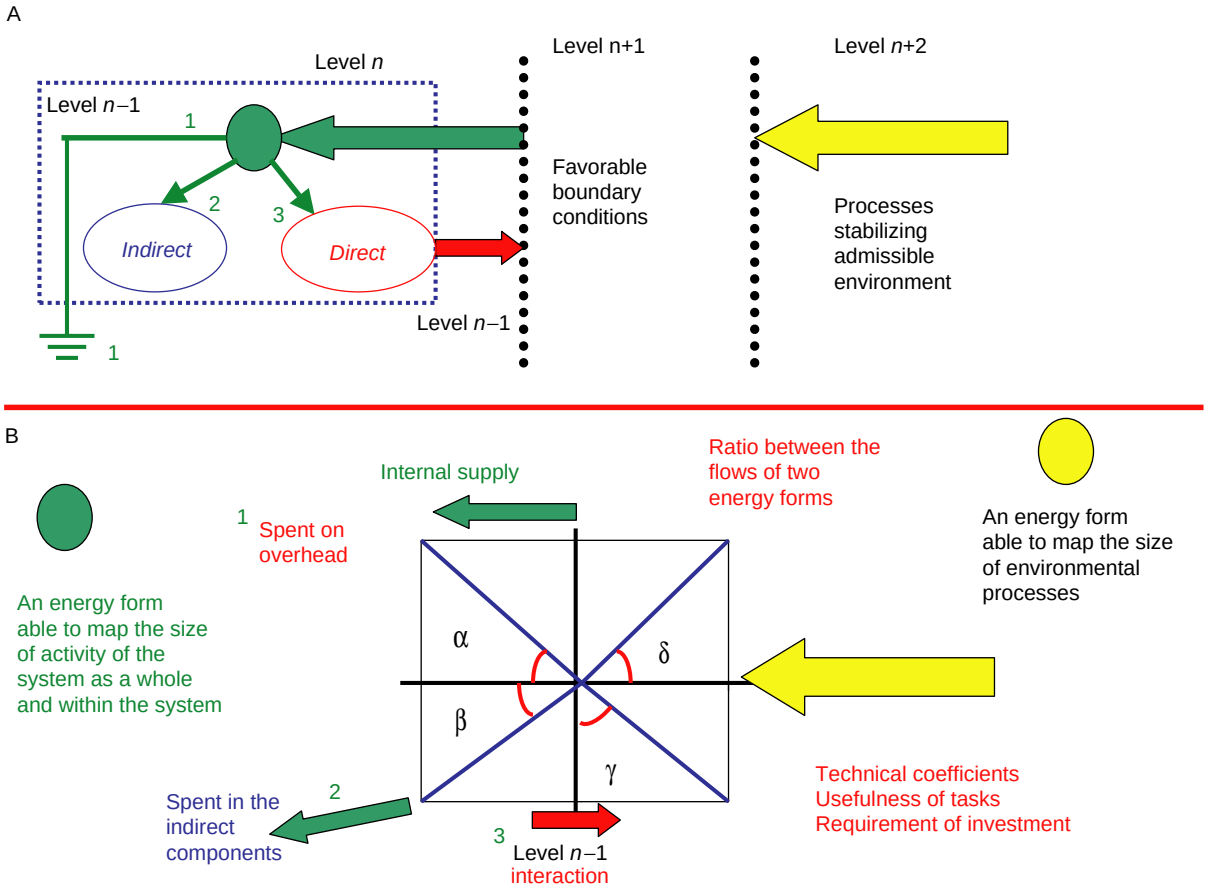

FIGURE 3 Congruence across levels of characteristics of the autocatalytic loop defined over nonequivalent descriptive domains. From Giampietro, M. (2003). "Multi-Scale Integrated Analysis of Agroecosystems." CRC Press, Boca Raton, FL. Used with permission.

favorable conditions (perceived at level $n+1$), the whole system (at level n) can receive an adequate supply of required input. This input can then be expressed in an energy form that is used as reference to assess how this total input is then invested over the lower level compartment. Therefore, we can expect that this total input will be dissipated within the black box in three flows (indicated by the three arrows in Fig. 3A): a given overhead (1) for the functioning of the whole, (2) for the operation of the compartment labeled "indirect," and (3) for the operation of the compartment labeled "direct." The favorable conditions perceived at level $n+1$, which make possible the stability of the environmental input consumed by the whole system, in turn are stabilized due to the existence of some favorable gradient generated elsewhere (level $n+2$), and this is not accounted for in the analysis. This available gradient can be exploited thanks to the tasks performed by the components belonging to the direct compartment (energy transformations occurring at level $n-1$). The return between the energy input made available to the whole system (at level n) per unit of useful energy invested by the direct compartment into the interaction with the environment will determine the strength of the autocatalytic loop of energy generated at level $n-1$ by the exploitation of a given energy resource. This integrated use of representations of energy transformation across levels is at the basis of a new approach that can be used to describe the sustainability of complex adaptive systems that base their identity on metabolic processes. In particular, three very useful concepts are (1) a mosaic effect across hierarchical levels, (2) impredicative loop analysis, and (3) narratives capable of surfing in complex time. These concepts are required to provide coherent representation of identities of energy forms generating an autocatalytic loop over five contiguous hierarchical levels (from level $n-2$ to level $n+2$). These three concepts can be used to structure the information space in a way that makes it possible to perform a series of congruence checks on the selected representation of the autocatalytic loop of energy forms.

An example of this congruence check is shown in Fig. 3. It is possible to establish a relation among the representation of parts, whole, and interaction with the environment across scales using a four-angle figure that combines intensive and extensive variables used to represent and bridge the characterization of metabolic processes across levels. The two angles on the left side (α and β) refer to the distribution of the total available supply of energy carriers (indicated on the upper part of the vertical axis) among the three flows of internal consumption. The angle α refers to the fraction of the total supply that is invested in overhead. The angle β refers to the fraction of the total supply that is spent on the operation of internal components. The value of the lower part of the vertical axis at this point refers to the amount of primary energy (the mapping related to the internal perception of energy form) that is invested in the direct interaction with the environment. The two angles on the right (γ and δ) refer to a characterization of the interaction of the system with the environment.

The selection of mapping (what set of variables have to be used in such a representation) must fulfill the double task of making it possible to relate the perception and representation of relevant characteristics of what is going on inside the black box to characteristics that are relevant to studying the stability of the environment. That is, this choice does not have the goal of establishing a direct link between a model studying the dynamics inside the black box and models studying relevant dynamics in the environment. To reiterate, this is simply not possible. This analytical tool simply makes it possible to establish bridges among nonequivalent representations of the identity of parts and wholes.

An example of three impredicative loop analyses is presented in Fig. 4. These formalizations reflect three logically independent ways of looking at an autocatalytic loop of energy forms according to the scheme presented in Fig. 3. It is very important to note that these three formalizations cannot be directly linked to each other because they are constructed using logically independent perceptions and characterizations. However, they share a meta-model used for the semantic problem structuring that made it possible to tailor in the formalization (when putting numerical assessment in it) according to the system considered.

5. CONCLUSION

The existence of both multiple levels of organization in the investigated system and different useful perspectives for looking at the reality entails the use of multiscale analysis when dealing with the sustainability of dissipative systems organized in nested hierarchies. This translates into a severe epistemological challenge for energy analysis. Innovative

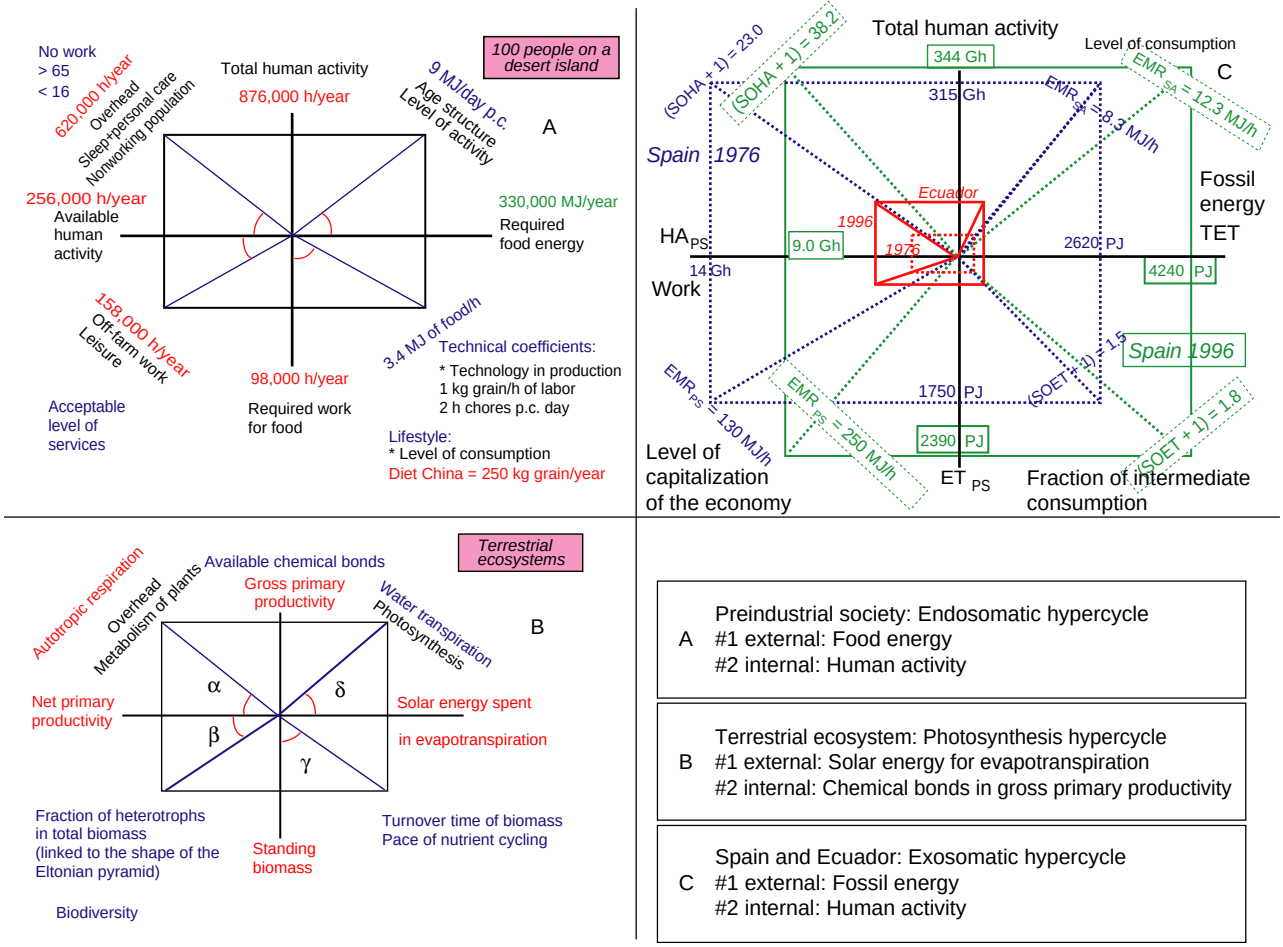

FIGURE 4 Autocatalytic loop of energy forms. From Giampietro, M. (2003). "Multi-Scale Integrated Analysis of Agroecosystems." CRC Press, Boca Raton, FL. Used with permission.

analytical methodologies can be developed taking advantage of principles derived from complex system theory and nonequilibrium thermodynamics. However, this innovative approach requires accepting two negative side effects.

First, the same autocatalytic loop can be represented in different legitimate ways (by choosing different combinations of formal identities). That is, there is no such thing as the "right model" when dealing with an analysis of the sustainability of an autocatalytic loop of energy. Rather, all models are incomplete. Analysts have the role of helping in the societal discussion about how to select narratives and models that are useful.

Second, there is an unavoidable degree of ignorance associated with any formal representation of an autocatalytic loop of energy forms. In fact, the very set of assumptions that make it possible to represent the system as viable (e.g., about the future stability of the relation between investment and return, about the future admissibility of the environment on level $n+2$, about the relevance of the selected set of attributes) guarantees that such a representation is affected by uncertainty. Both the observer and the observed system are becoming "*ceteris* are never *paribus*" when coming to the representation of the evolution in time of autocatalytic loops. The concept of entropy, in this case, translates into a sort of "yin yang" predicament for the analysis of complex adaptive systems. The more a dissipative system is successful in defending and imposing its identity on the environment, the sooner it will be forced to change it.

In short, any representation in energy terms of the predicament of sustainability for a complex dissipative system is (1) just one of many possible alternatives and (2) unavoidably affected by uncertainty, ignorance, and certain obsolescence.

Glossary

beam radiation Solar radiation that travels from the sun to Earth's surface without any scattering by the atmosphere. Beam radiation is also called direct radiation.

clearness index The fraction of solar radiation striking the top of Earth's atmosphere that is transmitted through the atmosphere to strike Earth's surface.

declination The latitude at which the sun's rays are perpendicular to the surface of Earth at solar noon.

diffuse radiation Solar radiation that has been redirected by atmospheric scattering.

extraterrestrial radiation Solar radiation striking the top of Earth's atmosphere.

global radiation The sum of beam radiation and diffuse radiation; sometimes called total radiation.

life-cycle cost The summation of all appropriately discounted costs, both recurring and nonrecurring, associated with a system or component of a system during its life span.

sensitivity analysis An investigation into the extent to which changes in certain inputs affect a model's outputs.

spinning reserve Surplus electrical generating capacity that is operating and able to respond instantly to a sudden increase in the electric load or to a sudden decrease in the renewable power.

Renewable power systems produce electricity from one or more renewable resources, and often incorporate nonrenewable power sources or energy storage devices for backup. Computer models of such systems are mathematical equations or algorithms programmed into a computer that can simulate system behavior or costs. Renewable power system designers use computer modeling to predict performance and explore different design options.

1. INTRODUCTION

Recent improvements in the economics of renewable power sources have made them competitive with conventional power sources in many situations. But the design of renewable power systems is made difficult by the novelty of the technologies, the intermittency and geographic diversity of the renewable resources on which they depend, and the large number of possible system configurations. Computer models, which are simplified mathematical representations of real systems, can help overcome these challenges. Models allow the designer to simulate the long-term performance and economics of renewable power systems, explore different design options, and test the effects of input assumptions.

This article deals with the modeling of solar, wind, small hydro, and biomass power systems suitable for small-scale (less than 1 MW) electric power generation, both stand-alone and grid-connected. The focus will be on long-term performance and economic modeling rather than dynamic modeling, which is concerned with short-term system stability and response. The material is structured to first address the modeling of each of the renewable resources, then the renewable technologies, then the power systems in which resources and technologies may be combined with each other and with more conventional power sources. In the final section, there is a description of the types of models currently available, and examples of each.

2. RENEWABLE RESOURCE MODELING

Characteristics of the renewable resources influence the behavior and economics of renewable power systems. Resource modeling is therefore a critical element of system modeling. In this section, the focus is on those aspects of each renewable resource that are important for modeling renewable power systems.

2.1 Solar Resource

Solar power technologies convert solar radiation into electricity. The goal of solar resource modeling is to estimate the amount of solar radiation available for conversion at some location, and how that amount varies over time. Four factors determine the amount of radiation striking a plane on Earth's surface: the amount of extraterrestrial radiation, the fraction of that radiation being transmitted through the atmosphere, the orientation of the plane, and shading of the plane by nearby objects such as buildings or mountains.

Extraterrestrial radiation varies in an entirely predictable fashion as Earth rotates on its axis and revolves around the sun. For any time between sunrise and sunset, the following equation gives the solar radiation incident on a horizontal plane at the top of the atmosphere:

$$G_o = G_{sc}\left(1 + 0.033\cos\frac{360n}{365}\right) \times (\cos\phi\cos\delta\cos\omega + \sin\phi\sin\delta)$$

where G_{sc} is the solar constant (normally taken as 1367 W/m^2), n is the day of the year, ϕ is the latitude (north positive), ω is the hour angle (zero at solar noon, increasing at 15° per hour throughout the day), and δ is the declination, given by

$$\delta = 23.45\sin\left(360\frac{284+n}{365}\right)$$

Integrating the extraterrestrial radiation over 1 hour gives the energy per unit area received over that hour. Integrating from sunrise to sunset gives the energy per unit area received daily. Summing this daily total for each day of the month gives the monthly total.

Atmospheric scattering and absorption reduce the amount of solar radiation striking Earth's surface to some fraction of the extraterrestrial radiation. This fraction, called the clearness index, varies stochastically in time, due principally to the fluctuating amount of water vapor and water droplets contained in the atmosphere. The equation for the clearness index is as follows:

$$k_t = G/G_o$$

where G is the radiation incident on a horizontal plane on the surface of Earth and G_o is the radiation incident on a horizontal plane at the top of the atmosphere. Atmospheric scattering affects the character as well as the amount of surface radiation. Under very clear conditions, the global radiation may be as much as 80% beam radiation and only 20% diffuse radiation. Under very cloudy conditions, the global radiation may be almost 100% diffuse radiation. Duffie and Beckman provide correlations that relate this diffuse fraction to the clearness index. The diffuse fraction is of interest to modelers for two reasons. First, the effect of surface orientation differs for beam and diffuse radiation, because beam radiation emanates only from the direction of the sun whereas diffuse radiation emanates from all parts of the sky. Second, some solar conversion devices (those that focus the sun's rays) can only make use of beam radiation.

Researchers have developed several algorithms for calculating the beam and diffuse radiation striking a surface with a particular slope (the angle between the surface and the horizontal) and azimuth (the direction toward which the surface faces), as well as means of accounting for shading from nearby objects (details can be found in the book by Duffie and Beckman, *Solar Engineering of Thermal Processes*). Most measured solar resource data are reported as global radiation on a horizontal surface, averaged for each hour, day, or month of the year. Models can use the above-mentioned algorithms to calculate the corresponding clearness indices, resolve the global radiation into its beam and diffuse components, and calculate the radiation striking a particular surface. The National Aeronautics and Space Administration

(NASA) Surface Solar Energy Web site provides satellite-measured monthly average radiation values for any location worldwide at a 1° resolution. Numerous other sources provide monthly or hourly data for more limited areas at higher spatial resolution. Several authors, including Mora-López and Sidrach-de-Cardona, have proposed algorithms for the generation of synthetic hourly radiation data from monthly averages.

2.2 Wind Resource

Wind turbines convert the kinetic energy of the wind into electricity. The goal of wind resource modeling is to describe the statistical properties of the wind at a particular location in order to estimate the amount of power a wind turbine would produce over time at that location. The wind power density, or power per unit area, depends on the air density ρ and the wind speed v according to the following equation:

$$P/A = (1/2)\rho v^3$$

The air density depends on pressure and temperature according to the ideal gas law. Air pressure varies with elevation above sea level, but does not vary significantly in time. Temperature does vary significantly with time at many locations, but because wind power density varies with the cube of the wind speed, the most significant factor in the variation of wind power with time is the fluctuating wind speed.

Driven by complex large-scale atmospheric circulation patterns and local topographic influences, wind speeds at a particular location typically exhibit seasonal, daily, and short-term fluctuations. Short-term fluctuations (on the order of minutes or seconds) can affect a wind turbine's structural loads and power quality, but they do not significantly affect long-term production or economics. The seasonal and daily patterns of wind speed are more difficult to predict than are those of solar radiation, because the wind speed is not driven by any well-defined phenomenon comparable to the solar extra-terrestrial radiation. Accurate determination of seasonal and daily patterns typically requires anemometer measurements spanning months or years.

A defining characteristic of a wind regime is its long-term distribution of wind speeds. Long-term wind speed observations typically conform well to the two-parameter Weibull distribution, the probability distribution function of which is given by

$$f(v) = \frac{k}{c}\left(\frac{v}{c}\right)^{k-1} \exp\left[-\left(\frac{v}{c}\right)^{k}\right]$$

where v is the wind speed, c is the scale parameter (in the same units as v), and k is the dimensionless shape factor. The following equation relates the two parameters c and k to the mean wind speed:

$$\bar{v} = c\Gamma\left(\frac{1}{k} + 1\right)$$

where Γ is the gamma function. The Rayleigh distribution is a special case of the Weibull distribution, with $k = 2$. The Weibull distribution provides a convenient way to characterize the wind resource, because a mean wind speed and a Weibull k factor are sufficient to quantify the energy potential. Figure 1 shows the Weibull probability distribution function for a mean wind speed of 6 m/s and three values of the shape factor k. Lower values of k correspond to broader distributions. Weibull distributions fitted to measured wind data typically have k values between 1.0 and 3.0. Stevens and Smulders have determined several methods for fitting a Weibull distribution to measured data (see Fig. 1).

The wind speed tends to increase with height above ground, an important factor when using wind measurements taken at one height to estimate the production of a wind turbine at a different height. Modelers typically assume that the wind speed's increase with height follows either a logarithmic profile or a power law profile. The logarithmic profile is given by

$$\frac{v(z_1)}{v(z_2)} = \frac{\ln(z_1/z_0)}{\ln(z_2/z_0)}$$

where $v(z_1)$ and $v(z_2)$ are the wind speeds at heights z_1 and z_2, and the parameter z_0 is the surface roughness length. The power law profile is given by

$$\frac{v(z_1)}{v(z_2)} = \left(\frac{z_1}{z_2}\right)^{\alpha}$$

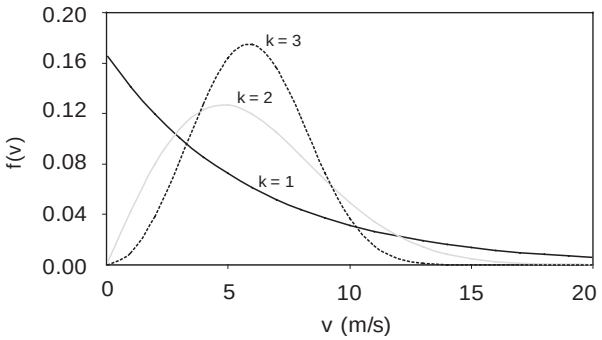

FIGURE 1 The Weibull distribution with a mean wind speed of 6 m/s and three values of k.

where α is the power law exponent. Manwell, McGowan, and Rogers have provided guidance on the selection of surface roughness length and the power law exponent, as well as a more complete examination of wind resource modeling.

2.3 Hydro Resource

Hydropower systems convert the energy of flowing water into electricity, usually by diverting a portion of a watercourse through a penstock (also called a pressure pipe) to a turbine. Hydro resource modeling aims to estimate the amount of power that a hydropower system could extract from a particular watercourse.

The ability of falling water to produce power depends on the flow rate and the head (the vertical distance through which it falls) according to the following equation:

$$P = \rho g h \dot{Q}$$

where ρ is the density of water, g is the gravitational acceleration, h is the head, and $\dot{Q}$ is the flow rate. Therefore the head (which is determined by local topography) and the available flow rate define the hydro resource at any particular location. The flow rate often varies seasonally and may in some cases vary according to the time of day, although it generally does not display the intermittency inherent to the solar and wind resources. Modelers sometimes characterize a watercourse's flow rate by computing its flow duration curve, an example of which appears in Fig. 2. This example shows that the flow rate exceeds 5 m^3/s about 37% of the time, and exceeds 10 m^3/s about 13% of the time. Flow duration curves can be created using long-term flow measurements or synthesized based on precipitation data within the catchment basin. Because most small hydro systems do not incorporate storage, the critical value is the firm flow, usually defined as the flow rate available 95 or 100% of the time. Designers typically size hydro systems based on the firm flow, or some portion thereof. The Web site www.microhydropower.net contains information on many aspects of small hydro systems, including guidance on the measurement of head and flow.

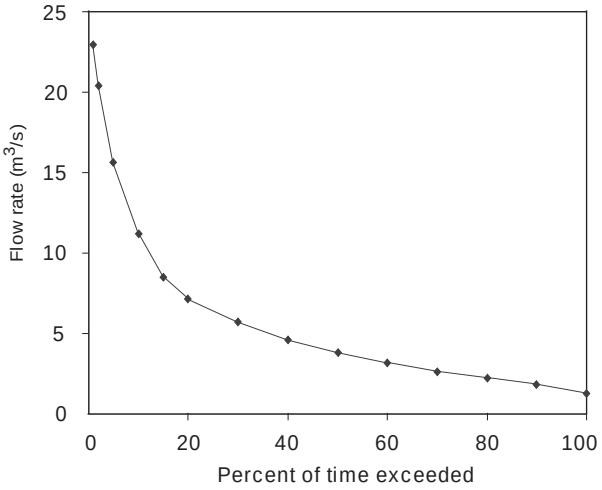

FIGURE 2 Sample flow duration curve.

2.4 Biomass Resource

Biomass power systems produce electricity from the chemical energy contained in organic matter. Many different types of biomass are suitable for power production, including wood waste, agricultural residue, animal waste, and energy crops. The goal of biomass resource modeling is to quantify the availability, price, and physical properties of the feedstock.

Three factors distinguish the modeling of the biomass resource from that of the other renewable resources. First, the amount of available biomass depends largely on human action, because the feedstock must be harvested, transported, and, in the case of dedicated energy crops, even sowed. So, although the gross amount of biomass depends on natural factors such as growing season and rainfall, the intermittency and unpredictability that characterize the other renewable resources do not apply to the biomass resource. Second, the biomass feedstock is often easily stored, further reducing intermittency and increasing flexibility. Third, the feedstock is often converted to a liquid or gaseous fuel, which can be stored and transported. As a result of these factors, biomass resource modeling typically focuses not on availability, but rather on the properties of the feedstock (such as moisture content) and the costs of delivering it in a usable form. McKendry has provided a thorough overview of the biomass resource.

3. COMPONENT MODELING

The characteristics of renewable technologies relevant to their modeling are briefly outlined here. Because renewable power systems often include some form of backup power to compensate for the intermittent nature of the renewable resources,

fossil-fueled generators, energy storage devices, and grid connection are also covered here.

3.1 Photovoltaic Modules

Photovoltaic (PV) modules convert solar radiation directly to direct current (DC) electricity, with sizes ranging from a few watts to hundreds of kilowatts. The output current of a photovoltaic module increases linearly with increasing incident global radiation, and decreases linearly with increasing module temperature. At any fixed temperature and radiation value, current (and hence power) varies nonlinearly with voltage, as shown in Fig. 3.

The peak of the power curve in Fig. 3 is called the maximum power point. The voltage corresponding to the maximum power point varies with radiation and temperature. If the photovoltaic module is directly connected to a DC load (or a battery bank), then the voltage it experiences will often not correspond to the maximum power point, and performance will suffer. A maximum power point tracker is a solid-state device that decouples the module from the load and controls the module voltage so that it always corresponds to the maximum power point, thereby improving performance. The complexity of modeling the power output from photovoltaic modules depends on the presence of the maximum power point tracker. In the absence of a maximum power point tracker, the modeler must account for the effects of radiation, temperature, and voltage. Duffie and Beckman have provided algorithms to do so. A maximum power point tracker eliminates the nonlinear dependence on voltage and allows the modeler to use the following equation for module efficiency:

$$\eta = \eta_{\text{ref}} + \mu(T_{\text{c}} - T_{\text{ref}})$$

where T_{c} is the module temperature, T_{ref} is the reference temperature, η_{ref} is the module efficiency at the reference temperature, and μ is the efficiency temperature coefficient. The efficiency temperature coefficient is a property of the module and is typically a negative number. From the efficiency, a modeler can calculate the power output of a photovoltaic module using the following equation:

$$P = \eta G_{\text{T}} A$$

where η is the efficiency, G_{T} is the global (total) solar radiation incident on the surface of the module, and A is the area of the module.

The life-cycle cost of a photovoltaic subsystem is dominated by initial capital cost. The lack of moving parts (with the rare exception of tracking systems) results in long lifetimes and near-zero operation and maintenance costs. Economic models of photovoltaic modules commonly assume 20- to 30-year lifetimes and neglect operation and maintenance costs altogether.

3.2 Wind Turbines

Wind turbines generate alternating or direct current (AC or DC) power, in sizes ranging from a few watts to several megawatts. Each wind turbine has a characteristic power curve that describes its power output as a function of the wind speed at its hub height. Figure 4 shows an example. Power curves typically display a cut-in wind speed below which the output is zero, then a section wherein the output varies roughly with the cube of the wind speed, then a section wherein the output peaks and declines due

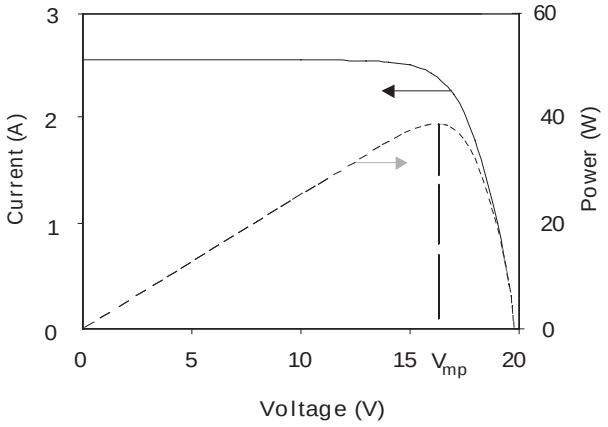

FIGURE 3 Current and power versus voltage for a typical photovoltaic module.

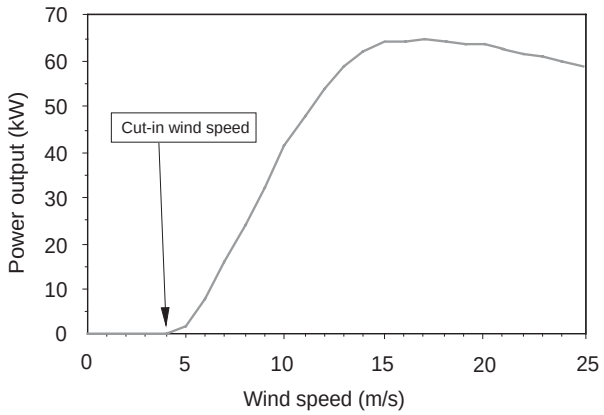

FIGURE 4 A wind turbine power curve.

to limitations designed into the turbine. The power curve describes turbine performance at a reference air density, typically corresponding to standard temperature and pressure. For a turbine operating at a different air density, the modeler can calculate its power output using the following equation:

$$P = P_{pc}(\rho/\rho_{ref})$$

where P_{pc} is the power output predicted by the power curve, ρ is the actual air density, and ρ_{ref} is the reference air density. Because the wind turbine output is so nonlinear with wind speed, and the wind speed is so variable, a modeler must exercise care when estimating the output of a wind turbine over long periods. The direct use of annual, monthly, or even daily average wind speeds causes unacceptably large inaccuracies. Time series data can be used directly only if its averaging interval is 1 hour or less. For longer term averages, the modeler must consider the frequency distribution of wind speeds.

Initial capital costs (including installation) dominate the life-cycle cost of wind turbines, but maintenance costs do occur. Economic models of wind turbines often assume a 15- to 25-year lifetime and an annual operation and maintenance cost of 1–3% of capital cost.

3.3 Small Hydropower Systems

Small hydropower systems generate AC or DC electricity from flowing water. The following equation gives the output power of a hydropower system:

$$P = \eta_{turb}\eta_{gen}\rho g h_{eff}\dot{Q}$$

where P is the output power in watts, η_{turb} is the efficiency with which the hydro turbine converts water power into shaft power, η_{gen} is the efficiency with which the generator converts shaft power into electrical power, ρ is the density of water in kg/m^3, g is the gravitational acceleration in m/s^2, h_{eff} is the effective head (the available head minus the head loss due to turbulence and friction) in meters, and $\dot{Q}$ is the volumetric flow rate through the turbine in m^3/s.

The turbine efficiency depends on the type of turbine and the flow rate. Hydro turbines fall into two broad categories, impulse turbines and reaction turbines. In an impulse turbine, water flows through a nozzle and emerges as a high-velocity jet, which strikes the turbine blades and causes them to rotate. In a reaction turbine, the flowing water surrounds the turbine blades, which are shaped such that the flowing water creates lift forces, causing rotation. Most small hydro systems use impulse turbines such as the Pelton, Turgo, or crossflow, but some low-head applications use reaction turbines such as the Francis, propeller, or Kaplan. Figure 5 shows typical efficiency curves. Although the impulse turbines exhibit near-constant efficiencies throughout their operating range, the reaction turbines (excluding the Kaplan) are much less efficient at lower flow rates. The Kaplan turbine, an adjustable-blade propeller turbine, exhibits an efficiency curve similar to that of the impulse turbines (see Fig. 5).

Friction and turbulence in the penstock cause a reduction in the water pressure upstream of the turbine. This pressure loss can be expressed as a head loss. The effective head can then be calculated by subtracting this head loss from the available head (the vertical drop from the penstock inlet to the turbine). Modelers can calculate the head loss using the standard techniques of fluid mechanics (Darcy friction factor, Moody diagram) or estimate it using rules of thumb.

Small hydro systems rarely incorporate storage reservoirs, because the economic and ecological costs of reservoirs often exceed their value in compensating for variation in the flow rate and adding a measure of control. Most run-of-river systems (ones that do not incorporate storage) have no means of restricting the flow rate though the turbine, so the flow rate in the preceding equation is simply equal to the flow through the penstock, which cannot exceed the stream flow.

Like photovoltaic modules and wind turbines, small hydro systems have high initial costs and low operating costs. The capital cost of a hydro system, which includes the cost of the required civil works plus that of the turbine and related machinery,

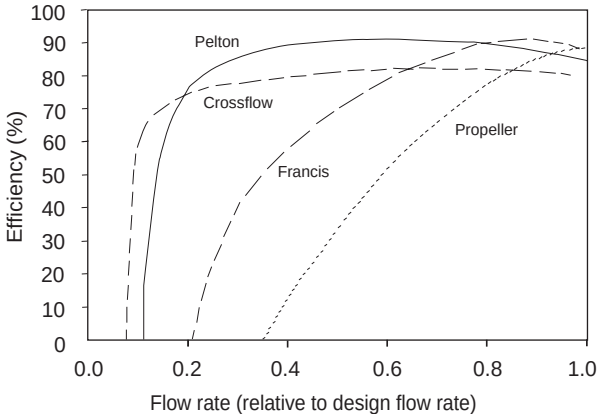

FIGURE 5 Efficiencies curves of common small hydro turbines. The Pelton and crossflow are impulse turbines; the Francis and propeller are reaction turbines. From Paish (2002), with permission.

depends very strongly on the local topography. Sites with high head and low flow generally have more favorable economics than do those with low head and high flow, because the required size of the machinery depends most strongly on the flow rate. Hydro systems are very long-lived, and lifetimes of 30 to 50 years are not uncommon.

3.4 Biomass Power Systems

The conversion of biomass into electricity typically makes use of either a thermochemical process (gasification, pyrolysis, or direct combustion), or a biochemical process (fermentation or anaerobic digestion). With the exception of direct combustion, each of these processes results in a gaseous or liquid fuel that can be used like any conventional fuel (sometimes in combination with a conventional fuel) in an internal combustion engine, microturbine, or fuel cell. In a direct combustion process, heat generated by burning biomass feedstock drives a thermal cycle. From a modeling perspective, these biomass conversion technologies are more akin to conventional forms of electrical production than to the other renewable power technologies. In particular, their ability to produce power on demand and their relatively high operating costs distinguish them from solar, wind, and hydropower technologies. The differences between biomass power and conventional power lie in technical issues (such as fuel handling and combustion characteristics) and the possibly seasonal availability of the biomass-derived fuel.

3.5 Fuel-Fired Generators

The diesel generator, an electrical generator driven by a reciprocating diesel engine, is the most common source of electric power in remote locations. Sizes range from a few kilowatts to 1 MW. Gasoline- and propane-fueled generators are also common below about 25 kW. Microturbines have become commercially available in recent years in the 25- to 250-kW size range, and fuel cells may become widespread in years to come.

Their ability to produce power on demand and their fast response to a fluctuating electric load make conventional generators valuable in stand-alone systems. When used in combination with renewable power sources, a generator can provide backup power during times of insufficient renewable output. For constant-speed reciprocating engine generators as well as microturbines, the rate of fuel consumption is well approximated by the following first-order equation:

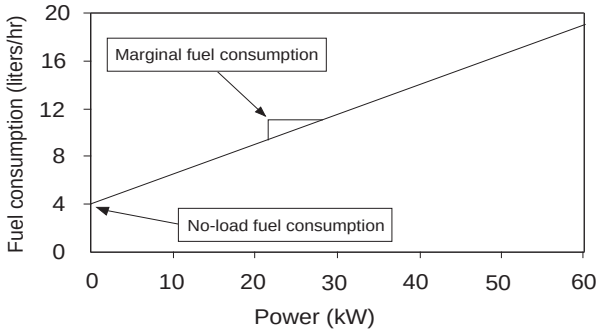

FIGURE 6 Typical generator fuel consumption curve.

$$F = F_0 + F_1 \cdot P$$

where F is the rate of fuel consumption, F_0 and F_1 are constants (the no-load fuel consumption and the marginal fuel consumption, respectively), and P is the output power of the generator. This relation is shown in Fig. 6. Skarstein and Uhlen found that, for diesel generators, the value of F_0 scales linearly with generator size. The fuel consumption of variable-speed reciprocating engine generators is better approximated with a higher order function, although they still exhibit a no-load fuel consumption.

Most models assume that a generator will need replacement (or a major overhaul) after a certain number of operating hours. To avoid engine damage, constant-speed diesel generators typically do not operate below about 30% of their rated capacity, and most other generator types have similar restrictions. Compared to renewable power sources, conventional generators have a low capital cost per kilowatt capacity, and a high operating cost per kilowatt-hour of electricity produced. Importantly, the operating cost per kilowatt-hour decreases with increasing output power. This operating cost has two components: maintenance and fuel. The maintenance cost per hour of operation is essentially independent of the output power; so on a per-kilowatt-hour basis it is inversely proportional to output power. Due to the aforementioned shape of the fuel consumption curve, the fuel cost per kilowatt-hour also decreases with output power. Generators are therefore most economically efficient when running at full capacity, a fact that has implications for power system design and operation.

3.6 Energy Storage Technologies

Energy storage devices can play an important role in stand-alone renewable power systems. In systems

without generators, they can provide backup power for intermittent renewable power sources. In systems with generators, they can save fuel and help avoid inefficient generator operation by serving the load during times of low electric demand, where the generator is least efficient. By buffering against the fluctuations in renewable power output, energy storage can also reduce the frequency of generator starts. Beyer, Degner, and Gabler found that in high-penetration wind/diesel systems (where the installed wind capacity exceeds the average load), even a very small amount of storage dramatically reduces the frequency of diesel starts.

Batteries, in particular lead-acid batteries, remain the predominant energy storage device. Many competing battery types (nickel–cadmium, nickel–metal hydride, lithium ion, sodium–sulfur, metal–air, flow batteries) surpass the lead-acid battery in one or more aspect of performance such as cycle life, round-trip efficiency, energy density, charge and discharge rate, cold-weather performance, or required amount of maintenance. In most applications, however, their lower cost per kilowatt-hour of capacity makes lead-acid batteries the optimal choice. Alternatives such as flywheels, ultracapacitors, or hydrogen storage may become commercially successful in the future, but are rare presently. In this section, the focus is exclusively on batteries.

For technoeconomic modeling, the three most important aspects of battery performance are efficiency (or losses), charge and discharge capacity, and lifetime. The simplest way to model the efficiency is to assume a constant energetic efficiency, meaning that some fixed percentage of the energy absorbed by the battery can later be retrieved. A more accurate alternative is to model the battery as a voltage source in series with a resistance. This "internal resistance" causes a difference in voltage between charging and discharging, and losses can be calculated either based on that voltage difference (charge is conserved, so 1 amp-hour of energy enters the battery at a high voltage and leaves at a lower voltage) or, equivalently, by calculating the I^2R losses directly.

The charge and discharge capacities of a battery are a measure of how quickly the battery can absorb or release energy. The simplest battery models assume unlimited charge and discharge capacities. More sophisticated models account for the fact that both the battery's state of charge and its recent charge and discharge history affect its charge and discharge capacities. The kinetic battery model, proposed by Manwell and McGowan and illustrated in Fig. 7, does this by modeling the battery as a two-tank system. The energy in one tank is available for immediate use, but the energy in the other is chemically bound. A conductance separates the two tanks and limits the rate that energy can move from one to the other. Some models also account for self-discharge that occurs within batteries, although the rate of self-discharge is typically small compared to the rates of discharge typically experienced by batteries in power systems. Regardless of the method chosen to calculate charge and discharge capacity, performance models should account for the fact that most batteries do not tolerate being discharged below a certain critical state of charge. For lead-acid batteries, this minimum state of charge ranges from about 30 or 40% for deep-discharge varieties to as much as 80% for common car batteries.

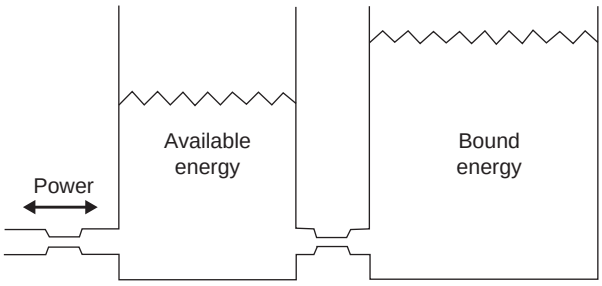

FIGURE 7 Kinetic battery model.

Spiers and Rasinkoski proposed three types of factors limiting the lifetime of a battery. Primary factors include the cycle life (governed by the amount of energy cycled through the battery) and the float life (governed by internal corrosion). Secondary factors include effects such as sulfation of lead-acid batteries caused by extended periods at low states of charge. Catastrophic factors include manufacturing defects, misuse, and freezing. Because secondary factors normally have little effect and catastrophic failures can be prevented, simple battery lifetime models typically account only for the primary factors. Spiers and Rasinkoski suggest calculating the float life and the cycle life, and assuming that the battery lifetime will be equal to the lesser of the two. The float life can be either assumed constant or calculated based on the average ambient temperature. Spiers and Rasinkoski suggest a simple formula for this calculation. The cycle life can be modeled most simply by assuming that a fixed amount of energy can cycle through the battery before it needs replacement, a good assumption for most lead-acid batteries. Alternatively, one could determine the number of cycles of different depths experienced by

the battery per year, and then refer to the battery lifetime curve (cycles to failure versus depth of discharge) to calculate the resulting years of lifetime. Downing and Socie have proposed two algorithms for counting cycles. The effect of temperature on the storage capacity, charge/discharge capacity, and internal resistance may be significant for certain modeling applications. Perez has offered insight into this and other aspects of battery performance.

3.7 AC/DC Converters

Renewable power systems commonly comprise a mixture of AC and DC loads and components, and hence require AC/DC conversion. Solid-state inverters and rectifiers typically perform this conversion, although some systems use rotary converters. For technoeconomic modeling, the important performance characteristics of a conversion device are its maximum capacity and its efficiency. Another characteristic important for modeling an inverter is whether it can operate in parallel with an AC generator; those that cannot are sometimes called "switched inverters."

Sukamongkol *et al.* have proposed that the power flow through solid-state inverters may be modeled by the following equation:

$$P_O = \alpha(P_I - \beta)$$

where P_O is the output power, P_I is the input power, and α and β are constants. The value of β, often called the "standing losses," is small compared to the capacity of the inverter. Many models therefore ignore standing losses and assume a constant inverter efficiency. The same treatment applies to rectifiers. Solid-state inverters typically exhibit efficiencies near or above 90%, with rectifier efficiencies slightly lower. Rotary converters typically have slightly lower efficiencies, compared to solid-state converters.

3.8 Grid Connection

Distributed generation systems supply electricity to grid-connected energy consumers and either store the excess or sell it back to the utility. Such systems may also supply heat, in which case they are called cogeneration or combined heat and power (CHP) systems. The utility rate structure (or tariff structure) often determines the economic viability of distributed generation systems. This rate structure typically consists of an energy charge (on the number of kilowatt-hours purchased per billing period) and a demand charge (on the peak demand within the billing period). Both may vary according to season, time of day, quantity, or other factors. Some utilities allow the sale of excess electricity back to the grid, usually at the utility's avoided cost or according to a net metering scheme whereby the customer pays for net monthly or annual consumption. Utilities may also assess an interconnection charge (a one-time fee for connecting a power system to the grid) or standby charges (monthly or annual fees for providing backup power).

4. SYSTEM MODELING

Several characteristics of renewable power technologies combine to complicate the process of designing renewable power systems. The principal virtue of renewable power sources, that they do not require fossil fuel, makes them suitable for many remote and off-grid applications. Such "stand-alone" systems require careful design because of the need to balance electrical supply and demand. Models can help by simulating the performance of a system to determine its viability, robustness, and stability.

The intermittent and seasonal nature of renewable resources often makes it necessary (or at least advantageous) to combine renewable power sources with each other, with conventional power sources such as diesel generators, and with energy storage technologies such as batteries. Hence renewable power systems frequently comprise several dissimilar components, often both AC and DC. Models can help both in simulating the complex behavior of a composite system and in evaluating the many different possible combinations of component types and sizes.

Renewable power sources typically have high capital costs and low operating costs, in contrast to most conventional (fossil-fueled) power sources. Any fair comparison of the relative economics of conventional and renewable sources of energy must therefore consider operating costs in addition to initial capital costs. This requires more sophisticated economic modeling than may be necessary when simply choosing between conventional power sources.

The design of renewable power systems involves many variables, some inherently uncertain. Computer models can help the system designer take this uncertainty into consideration. A model may, for example, allow a designer to assess the technical and economic implications of an increase in fuel price,

growth in electric demand, or an inaccurate estimate of wind speed.

4.1 Temporal Variability

Renewable power systems experience two kinds of temporal variability. Seasonal or long-term variability results from the cyclic annual pattern of the renewable resources. Short-term variability, which applies in particular to systems comprising solar or wind power, results from the hour-to-hour, even second-to-second, intermittency in the solar radiation, wind speed, and electric load. Both types of variability influence power system design.

The seasonal variability of resources often makes it impossible to rely on a single renewable power source year-round without backup power from a fuel-fired generator or utility grid. If stream flow declines sharply during the winter, for example, a diesel generator may be needed to supplement the output of the hydro turbine for part of the year. The degree to which different resources complement each other also affects the optimal combination of power sources. For example, a combination of wind and solar power will more likely be optimal if wind speeds peak during the winter (so that increased wind power output makes up for decreased solar power output) than if they peak during the summer.

Short-term variability has wide-ranging implications for system design and operation. It is the principal factor in determining the optimal amount of energy storage, and an important consideration when sizing dump loads (which manage excess renewable power) and AC/DC converters. Short-term variability also plays a role in the control of backup generators, which must modulate their output in response to fluctuations in the renewable output and electric demand.

4.2 Component Selection and Sizing

A power system designer must choose which power sources the system should comprise, decide whether to include energy storage, and select an appropriate size for each system component. This process of selecting the best system configuration from a long list of possibilities is an optimization problem well suited to computer modeling. The objective is typically to minimize the cost of energy or the total system cost, subject to any number of constraints. For stand-alone systems, the principal constraint is normally that the system must supply some fraction of the annual electric demand, often 100%. Other constraints may limit such parameters as fuel usage, emissions, or generator run time.

The optimal system design varies widely, depending on the magnitude and character of the electric demand, the quality of the renewable resources, and several economic factors. Relevant economic factors may include component costs, fuel price, interest rate, and, in the case of grid-connected systems, the utility rate structure. Models allow the designer to explore the many different possible system configurations in search of the optimum. Some models perform the optimization procedure by simulating multiple different system configurations and comparing them based on user-specified criteria. Others simply simulate one system at a time, in which case the designer can perform the optimization process manually.

4.3 System Operation and Control

For some renewable power systems, the designer must also consider the method of operation. A small photovoltaic/battery or wind/battery system needs no complicated control logic, other than appropriate constraints on battery charging and discharging. The system simply charges the battery with excess renewable power and discharges the battery when necessary. Similarly straightforward control logic would apply to a grid-connected photovoltaic system or a low-penetration wind/diesel system in which the diesel always operates and the wind power simply saves fuel. But a high-penetration wind/diesel system, in which the wind power may occasionally exceed the electric load, needs control logic to determine if and when the diesel can safely shut down without risking a loss of load. Spinning reserve is an important consideration in such decision-making. The manner in which the controller makes dispatch decisions can affect both the economics and the optimal design of the power system.

Control strategies are also important for any system comprising more than one dispatchable power source. A stand-alone power system that includes both a generator and a battery bank is one example. Two common control strategies for such a system are load following and cycle charging. Under the load-following strategy, whenever the generator operates, it produces only enough power to serve the load (surplus renewable power charges the batteries). Under the cycle-charging strategy, whenever the generator operates, it produces excess power to charge the battery bank. Barley and Winn have presented a thorough analysis of these two strategies

and their variations, and proposed a design chart to help select the better of the two, depending on the configuration and economics of the system.

Other examples of systems comprising more than one dispatchable power source include a stand-alone system containing multiple diesel generators, or a grid-connected biomass-fueled generator. In either case, the system must depend on some control strategy to decide how to operate various power sources that may differ in cost, fuel source, efficiency, thermal output, noise, or emissions. Modeling can help the system designer explore the consequences of different control strategies.

4.4 Economic Modeling

Economics frequently figure prominently in system design. Even when nonmonetary factors are involved, economic figures of merit can help in selecting among design options. To account properly for both initial capital costs and recurring operating costs, economic models should consider the time value of money. One approach is to calculate the present value of all cash flows (annual fuel payments, maintenance costs, grid power costs, component replacement costs, etc.) that occur within the project lifetime. This yields the system's total life-cycle cost. An equivalent approach is to annualize all one-time costs and add them to the recurring annual costs to calculate the system's total annualized cost. This number divided by the total energy delivered annually to the load yields the levelized cost of energy. For system retrofits, when an investment in renewable energy results in future cost savings, the payback period and internal rate of return are also useful figures of merit.

When calculating life-cycle cost it is helpful to make use of two economic concepts, the present value of a future cash flow and the present value of a sequence of equal annual cash flows. The present value of a cash flow occurring N years in the future is found by multiplying by the present worth factor (PWF), given by

$$PWF = 1/(1+i)^N$$

where i is the annual discount rate. Inflation can be factored out by using the real annual discount rate, given by

$$i = (i' - f)/(1+f)$$

where i' is the nominal interest rate and f is the inflation rate.

The present value of a sequence of equal annual cash flows is equal to the annual cash flow divided by the capital recovery factor (CRF). This factor is given by

$$CRF = i(1+i)^N/[(1+i)^N - 1]$$

where N is the number of years over which the annual cash flows occur. The capital recovery factor is also used to calculate the equivalent annualized value of a one-time cash flow (for a more complete discussion of these factors and economic modeling in general, see DeGarmo *et al.* or any introductory economics text).

4.5 Sensitivity Analysis

Regardless of how carefully a designer models the cost and performance of a power system, uncertainty in key inputs invariably causes actual and modeled results to differ. In a wind/diesel system for example, if the actual average wind speed turns out to be lower than the estimate used during modeling, the system will likely consume more fuel than predicted, hence the life-cycle cost will be greater than predicted. Similarly, an underestimate of the diesel fuel price over the project lifetime will also result in an underestimate of life-cycle cost.

A modeler can take this uncertainty into consideration by performing multiple simulations under different input assumptions. For example, the modeler could analyze the system cost and performance using several different values of fuel price to establish the sensitivity of key outputs to that input. The results of such a sensitivity analysis are often plotted as a spider graph such as the one shown in Fig. 8. This example shows how the cost of energy varies with changes in particular input variables. The modeler calculated the cost of energy assuming five different values of fuel price: a best estimate, plus two values above and two values below that best estimate. The modeler did the same for two more input variables, the average wind speed and the average solar radiation. The graph shows that the cost of energy increases with increasing fuel price, and decreases with increasing wind speed or solar radiation. Changes in wind speed have a more dramatic effect on the cost of energy than do changes in solar radiation.

For a more formal treatment of uncertainty, a modeler can make use of the techniques of decision analysis, a field devoted to decision-making in the presence of uncertainty. The canonical decision analysis approach is to assign probabilities to multiple

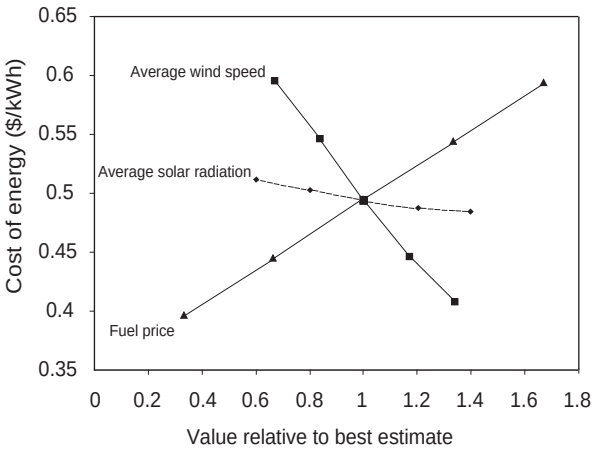

FIGURE 8 Spider graph showing results of a sensitivity analysis for a small photovoltaic/wind/diesel system.

input scenarios, simulate each scenario, and then calculate the resulting probability-weighted average value of any output variable. This "expected value" represents the best estimate of that output variable given the uncertainty in the inputs. When applied to the power system design problem, decision analysis can help select a system that is optimal not just for a fixed (and often dubious) set of input assumptions, but rather with consideration of a wide range of possible scenarios and their attendant risks. None of the models presented in the next section has a built-in decision analysis capability, but any one of them could help inform the decision analysis process by simulating input scenarios.

5. MODELS FOR RENEWABLE POWER SYSTEM DESIGN

Many available computer models simulate the performance and economics of renewable power systems. Each model uses representative load and resource data to predict the performance of the system, typically over a 1-year period. Performance parameters of interest may include the amount of energy produced by a renewable power source, the amount of fuel consumed by a generator, the amount of energy cycled through the batteries, or the amount of energy purchased from the grid. It is common to extrapolate these performance data over many years to calculate economic figures of merit such as life-cycle cost or cost of energy.

Models can be categorized as statistical models or time series models according to the technique used to predict system performance under highly variable conditions of load and renewable resources. Statistical models consider large time intervals (monthly or annual) and rely on statistical techniques to predict the outcome of the short-term variability occurring within each time interval. Time series models approach the issue of variability by dividing the year into time steps of 1 hour or less and simulating the behavior of the system at each time step.

5.1 Statistical Models

Statistical models usually account for seasonal variability by simulating system performance separately for each month of the year. But to account for short-term variability, they depend on some form of statistical manipulation. For example, a common technique when simulating a stand-alone PV/battery system is to calculate the loss-of-load probability each month. This is the probability that the system will experience a supply shortage at some time during the month, a scenario that may occur after the load exceeds the PV output long enough to drain the battery bank completely. A model can calculate the loss-of-load probability using information about the variability of the solar resource and its correlation with electric load. If the loss-of-load probability exceeds some user-specified critical value, the system is unacceptable.

Compared to time series models, statistical models tend to be simpler to use and quicker to provide results. Their simplicity stems partly from their limited input requirements; they require monthly or annual average load and resource data, rather than the hourly data required by most time series models. They also tend to simulate system performance and cost using less detailed algorithms that require fewer, more easily obtainable inputs. This input simplicity makes statistical models relatively easy to learn. It also means that a designer can quickly assemble the necessary load, resource, and component data to analyze a particular system. A further advantage of statistical models over time series models is their generally faster computation speed; most produce outputs virtually instantaneously. The combination of faster assembling of inputs and faster production of outputs makes statistical models ideal for quick system comparisons and cost estimates.

The simplicity of statistical models, however, comes at the cost of reduced accuracy. Because they rely on simplifying assumptions, statistical models sometimes overlook important aspects of real system behavior. For example, when modeling a system

comprising diesel generators, a statistical model may assume that the generator's fuel consumption is linear with power output, meaning the generator's efficiency is constant. Although greatly simplifying system modeling, this assumption neglects the fact that generators are much less efficient at low loads, a fact that has important implications for the control and economics of the system. Their reduced accuracy means that statistical models often cannot reliably model the behavior of complex systems such as high-penetration wind/diesel systems. In such systems, details for which a simplified model cannot account may have a substantial impact on both performance and economics.

Statistical models also tend to allow less flexibility in the configuration of the system. Because of their inability to simulate complicated systems, for example, statistical models typically allow a designer to simulate at most one renewable power source and one dispatchable generator. They typically cannot analyze systems comprising multiple renewable power sources, multiple generators, or other advanced features such as cogeneration. An additional drawback of statistical models is that despite using fewer and generally simpler inputs, a small number of their inputs can be difficult to understand and to estimate. A statistical model may, for example, require the user to specify the degree to which the electric load correlates with the solar radiation, or the fraction of the wind turbine output that will have to be dumped as excess. Time series models require neither of these inputs; the solar and load correlation is unnecessary because the model has access to the hourly solar and load data, and a time series simulation can determine the wind turbine's excess energy fraction.

In summary, statistical models offer simplicity and speed at the cost of accuracy and flexibility. They are suitable for prefeasibility analyses of many types of renewable power systems. In fact, certain uncomplicated systems (such as PV/battery or grid-connected PV) may require no further modeling. However, in the design of more complex systems, particularly those requiring sophisticated control strategies or careful balancing of electrical supply and demand, statistical modeling should be supplemented with time series modeling.

Several statistical models for renewable power system design are currently available and may be accessed on the Internet. PVSYST, created by the University of Geneva, can simulate PV/battery and grid-connected PV systems. Orion Energy's NSol! can simulate these systems as well as PV/generator/battery systems. RETScreen, created by Natural Resources Canada, can simulate these systems as well as grid-connected wind, low-penetration wind/diesel, and small hydro systems.

5.2 Time Series Models

The premise of time series modeling is that by simulating system performance at a sufficiently fine temporal resolution, the effects of short-term variability can be modeled directly. Time series models typically perform annual simulations using a 1-hour time step, and assume that the time-dependent variables (electric load and renewable resources) remain constant within that time step. Shorter time steps lead to improved accuracy but increased computation time. That, along with the difficulty of obtaining higher resolution resource and load data, explains why most models use a 1-hour time step.

At the core of time series modeling is the energy balance performed each time step. In this energy balance, the model calculates the available renewable power, compares it to the electric load, and simulates how the system would deal with any surplus or deficit. In the case of insufficient renewable power, the model may draw power from the grid, dispatch one or more generators, or discharge the battery bank to avoid unmet load. In the case of an oversupply of renewable power, the model may sell power to the grid, charge the battery bank, serve an optional load, or dissipate the excess power in a dump load. When making such dispatch decisions, time series models typically refer to some preset operating strategy, and many models allow the comparison of several different strategies so that the user can determine which is optimal for a particular application.

The division of the year into many short intervals allows time series models to simulate even complex systems accurately. As a result, time series models allow the modeler to simulate a wide variety of system types, sometimes comprising multiple renewable power sources, multiple generators, battery storage, and grid connection. With this flexibility, a modeler can evaluate many more design options than is possible with a statistical model.

Hourly simulations require hourly load and resource data. The limited availability of such data can hinder the use of time series models, although several algorithms exist for synthesizing hourly load, solar radiation, and wind speed data from more readily available monthly or annual average data. Virtually all time series models, for example, allow

the user to construct hourly load data from typical daily load profiles. Algorithms that synthesize hourly solar and wind data typically require monthly averages plus a few parameters. Some models integrate such algorithms directly into their interfaces, but external resource data generators can produce data suitable for any time series model.

The computation time required to simulate annual system performance with a time series model depends strongly on whether the model tracks the voltage of the DC components. This DC bus voltage can fluctuate widely over time, in contrast to the AC bus voltage, which is fixed by the system controller. Because of the feedback effect between the DC bus voltage and the performance of batteries, photovoltaic modules, and DC wind turbines, calculating the DC bus voltage requires an iterative solution procedure within each time step. Models that track the DC bus voltage therefore typically require many seconds or a few minutes of computation time per simulation. Models that simply track power flows without calculating voltage do not require this iteration, and so can simulate systems much faster.

Several time series models for renewable power system design are available and may be accessed on the Internet. PV-DesignPro, a product of Maui Solar Energy Software Corporation, can model stand-alone or grid-connected systems comprising PV modules, wind turbines, batteries, and a generator. PV*SOL, created by Valentin EnergieSoftware, can model stand-alone and grid-connected systems comprising PV modules, batteries, and a generator. PV*SOL uses a statistical modeling approach to perform a quick initial simulation, then a time series modeling approach for a more accurate final simulation. HOMER, a product of the National Renewable Energy Laboratory, can model systems comprising PV modules, wind turbines, small hydro, biomass power, batteries, hydrogen storage, grid connection, and as many as three generators, serving any combination of AC, DC, and thermal loads. HOMER also performs optimization and sensitivity analysis. Hybrid2, created by the National Renewable Energy Laboratory and the University of Massachusetts, can model stand-alone systems comprising PV modules, wind turbines, batteries, and as many as eight generators, with a time step as short as 1 minute. Hybrid2 also models a wide variety of different system control and load management strategies. Though it is a time series model, Hybrid2 incorporates some aspects of statistical modeling to account for the short-term variability occurring within each time step.

6. CONCLUSIONS

In the design of renewable power systems, significant complexity arises due to the intermittent nature of renewable power sources, the large number of possible system configurations, the uncertainty in key input parameters, and the need to compare different design options on the basis of life-cycle cost. Computer modeling can help the system designer to account for the many factors affecting the performance and economics of renewable power systems, to evaluate diverse design options, and to explore multiple input scenarios.

Various computer models are currently available for use in renewable power system design. Statistical models, offering speed and ease of use, are well suited to the type of prefeasibility analyses commonly performed early in the design process. Time series models, generally simulating renewable power systems of a wider variety and with a higher accuracy than statistical models, are suitable for more precise modeling later in the design process.

Glossary

end-use efficiency Substituting technological sophistication for energy consumption through (1) obtaining higher efficiency in energy production and utilization and (2) accommodating behavior to maximize personal welfare in response to changing prices of competing goods and services.

energy conservation The wise and thoughtful use of energy; changing technology and policy to reduce the demand for energy without corresponding reductions in living standards.

energy intensity The amount of energy consumed to produce a given economic product or service; often measured as the ratio of the energy consumption (E) of a society to its economic output (gross domestic product, GDP), measured in dollars of constant purchasing power (the E/GDP ratio).

energy services The "ends," or amenities, to which energy is the "means," e.g., space conditioning, lighting, transportation, communication, and industrial processes.

externalities The environmental, national security, human health, and other social costs of providing energy services.

least-cost strategy A strategy for providing individual and institutional energy consumers with all of the energy services, or amenities, they require or want at the least possible cost. It includes the internal economic costs of energy services (fuel, capital, and other operating costs) as well as external costs.

The history of energy conservation reflects the influence of technology and policy on moderating the growth of demand for energy. It traces the evolution of concepts of conservation from curtailment of energy use to least-cost strategies through end-use efficiency. Through understanding the past efforts to address the need for energy conservation, the future potential of the role for energy conservation in the global economy is better understood.

1. INTRODUCTION

Just as beauty is in the eye of the beholder, energy conservation means different things to different people. Concerned about deforestation in Pennsylvania, Benjamin Franklin took heed of his own advice ("a penny saved is a penny earned") by inventing the Franklin stove. In his *Account of the New Invented Fireplaces*, published in 1744, Franklin said "As therefore so much of the comfort and conveniency of our lives for great a part of the year depend on this article of fire; since fuel is become so expensive, and (as the country is more clear'd and settle'd) will of course grow scarcer and dearer; any new proposals for saving the wood, and for lessening the charge and augmenting the benefit of fire, by some particular method of making and managing it, may at least be thought worth consideration." The Franklin stove dramatically improved the efficiency of space heating. In Franklin's time, however, others viewed energy consumption as a signal of economic progress and activity. This view was epitomized by company letterheads picturing a factory with chimneys proudly billowing clouds of smoke!

Viewed as a matter of how much energy it takes to run an economy—often referred to as a society's energy intensity—energy conservation has been with us since the middle of the 20th century. Between 1949 and 2000, the amount of energy required to

 © 2004 Elsevier Inc. All rights reserved.

produce a (1996 constant) dollar of economic output fell 49%. Much of this improvement occurred by the combined effects of improved technology (including increased use of higher quality fuels in new technologies, such as high-efficiency gas turbines) and perceptions of higher energy costs after the oil shocks of the 1970s, when energy intensity began to fall at an average rate of 2% per year. (Fig. 1).

Although largely oblivious to long-term improvements in energy intensity, consumers undoubtedly felt the oil shocks, and came to equate energy conservation with waiting in long lines to purchase gasoline. For many people, even to the present day, energy conservation connotes curtailment or denial of the services energy provides, e.g., turning down the heat on a cold winter's day, turning off the lights, or driving lighter cars at slower speeds. This viewpoint came into sharp focus one night during the 1973 oil embargo, when one author (Gibbons), director of the newly established Federal Office of Energy Conservation, fielded a call from an irate Texan who proclaimed that "America didn't *conserve* its way to greatness; it *produced* its way to greatness!"

For purposes of this article, we accept and adapt the term "wise and thoughtful use" for energy conservation. This term implies that, when technically feasible and economically sound, a society will use technology and/or adopt social policy to reduce energy demand in providing energy services. It also implies that society's effort to bring energy supply and energy demand into balance will take into full account the total costs involved. Market prices for energy are generally less than its total social cost due to various production subsidies and nonmarket costs, or externalities, such as environmental impacts and security requirements. This approach has been labeled a "least-total cost" strategy for optimizing the investment trade-off between an increment of supply versus an increment of conservation.

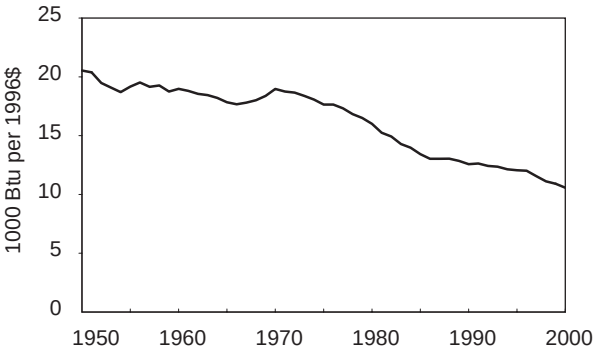

FIGURE 1 Energy use per dollar of gross domestic product. From the U.S. Energy Information Administration, *Annual Review of Energy 2000*.

2. DECADE OF CRISIS: 1970s

Events of the late 1960s highlighted many of the external costs of energy production and consumption. Many of the worsening problems of air and water pollution were directly attributable to energy use. The growth in the power of the Organization of the Petroleum Exporting Countries (OPEC) and increasing tensions in the Middle East contributed to a growing wariness of import dependence. High projected electric demand growth exacerbated worries not only about coal and the environment, but also about the sheer amount of capital investment that was implied. Gas curtailments began to show up along with spot shortages of heating oil and gasoline. And, surprising to many in the energy field, there were growing doubts about the nuclear option.

2.1 Rethinking Energy Demand

Those forces converged to trigger work on improved and alternative energy sources as well as on the dynamics and technologies of demand. Public support for analysis of conservation strategies came at first not from the "energy agencies" but from the National Science Foundation (NSF). In 1970, Oak Ridge National Laboratory (ORNL) researchers (who were well-sensitized to the vexing problems of coal and fission) seized on the opportunity provided by the NSF to investigate demand dynamics and technologies. The owner/operator of ORNL, the Atomic Energy Commission (AEC), was not keen on the idea but accepted the new direction for research as "work for others"!

It quickly became apparent that despite declining energy prices in previous years, energy efficiency had been slowly improving. Technology relevant to efficient use was advancing so impressively that more efficiency was economically attractive in virtually every sector of consumption. Further examination at ORNL and elsewhere showed that such improvements would accelerate more rapidly if energy prices were to rise and/or if consumers became better informed. For example, it was demonstrated that cost-effective technical improvements in refrigerators could double the energy efficiency of household refrigerators for a very modest price increment (Fig. 2). Clearly, major environmental benefits would also accrue from more conservation.

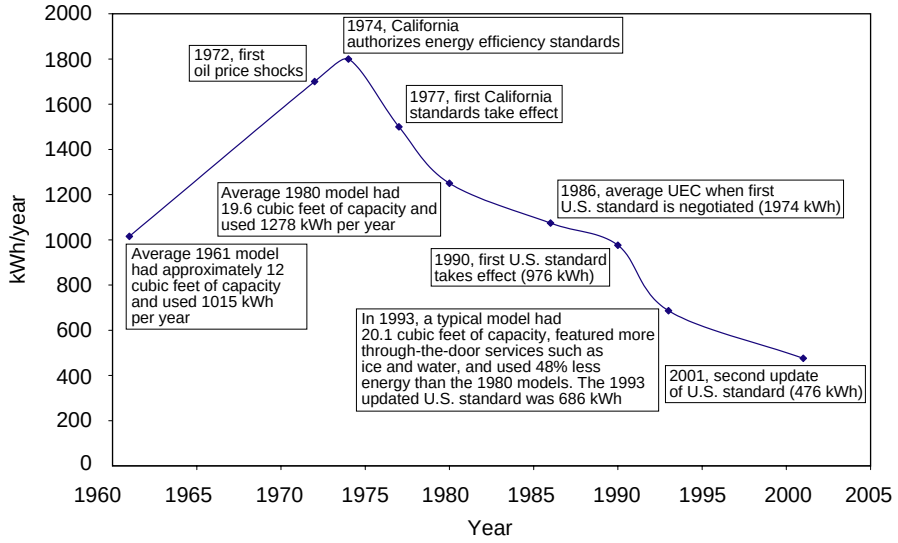

FIGURE 2 Changes in energy demand of refrigerators in the United States since 1961. UEC, unit energy consumption (kWh/year). From the Lawrence Berkeley National Laboratory.

The environmental concerns of the 1960s prompted the first serious efforts to project future energy demand. Scenario analyses, prepared by many different authors throughout the 1970s, produced a wide range of estimates, helping to shape a diverse range of views on the importance of conservation. Eleven forecasts of consumption made during the 1970s turned out to be remarkably consistent but ludicrously high, even for 1985 (ranging from 88 to 116 quads—the actual number was 75 quads). Prior to the oil embargo of 1973, most projections of U.S. energy consumption for the year 2000 fell in the range of 130–175 quads. The actual number turned out to be about 100 quads. Some of the difference can be attributed to lower than anticipated economic growth, but the dominant difference is due to the unexpected role of conservation.

Limits to Growth, published in 1972, was the first analysis to capture the public's attention. This computerized extrapolation of then-current consumption trends described a disastrous disjuncture of the growth curves of population and food supply and of resource use, including energy, and pollution. One scenario climaxed in a collapse mode, the sudden and drastic decline in the human population as a consequence of famine and environmental poisoning. This apocryphal report correctly made the point that exponential growth in finite systems is unsustainable, but its macroeconomic model failed because it did not consider responses to resource prices or advances in technologies.

A Time to Choose: America's Energy Future, a group of scenarios commissioned by the Ford Foundation and published in 1974, became notable, and controversial, for its "zero energy growth" (ZEG) scenario. This ZEG scenario clearly was meant to show that energy growth could technically be decoupled from economic growth. ZEG called for a leveling off in energy demand at about 100 quads per year shortly after 1985. In addition to those economically feasible measures taken by 1985, reduced demand would be effected by means of energy consumption taxes and other constraints on use. Taxes would increase the price of fuels so that substitution of energy-saving capital investments could be made economical while simultaneously encouraging shifts to less energy-intensive services. *A Time to Choose* also included a "technical fix" scenario that estimated 1985 consumption at 91 quads by coupling a microeconomic model with analysis of the engineering potential for conservation as a response to increased energy price and government policies. In 1976, Amory Lovins published a far more controversial and attention-grabbing scenario called "Energy Strategy: The Road Not Taken" in the journal *Foreign Affairs*. Lovins advocated a "soft energy path" based on three components: (1) greatly increased efficiency in the use of energy, (2) rapid deployment of "soft" technologies (diverse, decentralized, renewable energy sources), and (3) the transitional use of fossil fuels. His assertion that the "road less traveled" could bring America to greatly reduced energy demand (less than 50 quads per

year in 2025) is both venerated and despised to this day.

These private sector analyses competed with scenarios developed or commissioned by government agencies for the attention of energy policy makers throughout the 1970s. *Guidelines for Growth of the Electric Power Industry*, produced by the Federal Power Commission (FPC) in 1970, was a classic study of energy demand based largely on an extrapolation of past trends. The FPC had credibility because of its 1964 success in predicting 1970 electricity demand, but its forecast of a doubling of energy demand from 1970 to 1990 was dramatically far from the mark. The Atomic Energy Commission made more accurate estimates in *The Nation's Energy Future*, published in 1973, but it mistakenly forecast U.S. independence from imported oil by 1980—no doubt caused or at least influenced by President Nixon, who was determined to achieve energy independence before the end of his term.

In 1975, the U.S. National Academy of Sciences established a Committee on Nuclear and Alternative Energy Strategies (CONAES). The CONAES Panel on Demand and Conservation published a path-breaking paper in the journal *Science* in 1978: "U.S. Energy Demand: Some Low Energy Futures." The CONAES scenarios not only incorporated different assumptions for gross domestic product (GDP) and population growth, but also, for the first time, incorporated varied assumptions about energy prices. The lowest CONAES estimate, based on a 4% annual real price increase coupled with strong nonmarket conservation incentives and regulations, came in at only 58 quads for 2010. The highest estimate, based on a 2% annual real price increase coupled with a rapidly growing economy, came in at 136 quads for 2010. This study clearly illustrated the importance in scenario analysis of assumptions about everything from income, labor force, and the rate of household formation, to worker productivity, energy productivity, energy price, income, and energy substitutability in scenario analysis. It also highlighted the importance of capital stock turnover in energy futures, in that the largest technical opportunities for increased efficiency derive from new stock, where state-of-the-art technology can be most effectively employed. The CONAES project had a major influence on all of the energy modeling work that followed.

2.2 Oil Shocks

In October 1973, the United States helped Israel beat back the Yom Kippur invasion by Egypt and Syria. OPEC (dominated by Arab oil producers) retaliated with an oil embargo on the United States and a 70% oil price increase on West European allies of the United States. Homeowners were asked to turn down their thermostats and gas stations were requested to limit sales to 10 gallons per customer. Illumination and speed limits were lowered, and the traffic law allowing a right turn on a red light came into use. Gasoline lines, conspiracy theories, and recession followed in rapid succession. As Adlai Stevenson once observed, "Americans never seem to see the handwriting on the wall until their backs are up against it." We perceived the wall behind our backs and responded accordingly—for a brief spell. American humor also surfaced. Some wonderful cartoons depicted innovative ways to save energy—for example, by sleeping with a chicken, which has a normal body temperature of 107°F, and public interest highway signs appeared proclaiming "Don't be fuelish!"

OPEC lifted the embargo in 1974, but political unrest in the Middle East again precipitated a major oil price increase in 1979. When anti-Western Islamic fundamentalists gained control of Iran, oil production in that nation dropped off dramatically and U.S. crude oil prices tripled. These price increases also led to skyrocketing inflation and recession, and rekindled interest in energy efficiency.

2.3 Policy Responses

The need to curtail energy consumption in response to U.S. vulnerability to oil supply disruptions dominated energy policy in the 1970s. In the summer of 1973, President Nixon, anticipating possible shortages of heating oil in the coming winter, and summer gasoline shortfalls, established the Office of Energy Conservation to coordinate efforts to cut energy consumption in federal agencies by about 5%, raise public attention to the need for increased efficiency, encourage private industry to give greater attention to saving energy, and devote more federal research and development to efficiency. After the first oil shock, President Nixon urged voluntary rationing and pushed for a commitment to U.S. energy independence by 1985. President Carter emphasized the importance of conservation in the effort to achieve energy independence, but appeared to equate conservation with wearing a sweater in a chilly White House. Early actions by our political leaders certainly contributed to a negative association of conservation with sacrifice. But they also contributed to an atmosphere conducive to serious public and private sector actions to incorporate efficient end-use

technologies in the U.S. economy. Congress enacted legislation to create standards for Corporate Average Fuel Economy (CAFE) and building energy performance. They also created a cabinet-level Department of Energy (DOE) by merging the functions of preexisting agencies scattered throughout government. In response to an analysis by the congressional Office of Technology Assessment, Congress explicitly included energy conservation in the DOE's new mandate.

3. DECADE OF NO- AND LOW-COST OPTIONS: 1980s

The combination of the oil price shocks with increasing public concern about the environmental consequences of energy use prompted policy makers to take a serious look at policy tools for decreasing energy demand growth during the 1980s. Faced with higher oil prices, industrial and commercial oil consumers also sought out cost-effective investments in energy conservation during this decade. A plethora of no- and low-cost options were ripe for the picking, and progressive industries did just that, with great success at the bottom line.

3.1 Policy Tools

At the beginning of the 1980s, energy analysts converged on a set of principles for a comprehensive energy policy that had conservation at its core. These principles included the following ideas:

1. Consider the production and use of energy as means to certain ends, not as goals in and of themselves. Remember always that, given time and the capital for adjustment, energy is a largely substitutable input in the provision of most goods and services.
2. Application of technical ingenuity and institutional innovation can greatly facilitate energy options.
3. Energy decisions, like other investment decisions, should be made using clear signals of comparative total long-run costs, marginal costs, and cost trends.
4. It is important to correct distorted or inadequate market signals with policy instruments; otherwise, external costs can be ignored and resources can be squandered. This correction includes internalizing in energy price and/or regulation, to the extent possible, the national security, human health, and environmental costs attributable to energy.
5. Investment in both energy supply and utilization research and development is an appropriate activity for both the public and private sectors, because costs and benefits accrue to both sectors.
6. There are other, generally more productive, ways (for example, assistance with insulation or lighting retrofits, fuel funds, or even refundable tax credits) to assist underprivileged citizens with their energy needs, rather than subsidizing energy's price to them.
7. In a world characterized by tightly integrated economies, we need to increase our cognizance of world energy resource conditions and needs with special regard for international security as well as concern for the special needs of poor nations.

By the mid-1980s, the national energy situation had begun to reflect some of these ideas. CAFE standards reached their peak (27.5 miles per gallon) in 1985. Congress created the Strategic Petroleum Reserve (SPR) to respond to energy supply emergencies. Oil and gas price deregulation was virtually complete, but that was only the first step in internalizing the costs of energy consumption. Energy prices still did not reflect the manifold environmental costs of production and use, the costs of defending Middle East oil production and shipping lanes, the costs of purchasing and storing oil to meet emergencies, or the impacts of U.S. competition for scarce oil resources on developing nations. As the price of imported oil decreased, U.S. policy makers were lulled into complacency about the nation's energy strategy. A dearth of energy research and development expenditures symbolized this declining interest. Before the end of the decade, however, Congress passed the National Appliance Energy Conservation Act, which authorized higher appliance efficiency standards and efficiency labeling that have significantly impacted the market for energy-efficient appliances.

3.2 Private Sector Activities

Immediately following the oil shocks, private sector efforts to save energy focused on changing patterns of energy use within the existing infrastructure, such as lowering thermostats. Most actions involved investments in technology, however—either retrofits of existing technology, such as insulating existing homes, or new investments in technology, such as energy-efficient new construction or autos with improved mileage. Later in the 1980s, energy efficiency gains accrued as incidental benefits to

other, much larger investments aimed at improving competitiveness of U.S. products in world markets.

All in all, energy efficiency investments in the 1970s and the 1980s turned out to be generally easier and much more cost-effective than finding new sources of energy. Nongovernmental institutions helped to keep the conservation ball of progress rolling, especially in the residential and commercial sectors, with information to increase awareness of cost-effective conservation opportunities, rebates, and prizes. In the first decade after the oil shocks, industry cut energy requirements per unit of output by over 30%. Households cut energy use by 20% and owners and operators of commercial buildings cut energy use per square foot by more than 10%. Transportation energy efficiency steadily improved as CAFE requirements slowly increased fleet average mileage. However, political maneuvering by car companies resulted in excepting "light trucks," including sport utility vehicles (SUVs), from the mileage requirements for passenger cars. This has resulted in a major slow down of improvement in fleet performance.

Some surprising partnerships formed to promote energy efficiency. For example, the Natural Resources Defense Council designed a Golden Carrot Award to encourage production of a superefficient refrigerator. In response, 24 major utilities pooled their resources to create the $30 million prize. Whirlpool won the competition and collected its winnings after manufacturing and selling at least 250,000 units that were at least 25% more efficient than the 1993 efficiency standard required. By the end of the 1980s, energy efficiency improvements lost momentum. One reason was the decline in oil prices: corrected for inflation, the average price of gasoline in 1987 was half that in 1980. Natural gas and electricity prices also fell, and the price-driven impetus for consumers and businesses to conserve was diminished.

3.3 Lessons from Experience

By the end of the decade, conservation advocates were urging policy makers to take several lessons from the experiences of 1970 and 1980s:

1. First and foremost, that energy conservation worked. Nothing contributed more to the improved American energy situation than energy efficiency. By the late 1980s, the United States used little more energy than in 1973, yet it produced 40% more goods and services. According to one estimate, efficiency cut the nation's annual energy bill by $160 billion.
2. Oil and gas price controls are counterproductive. Price increases of the 1970s and 1980s sparked operating changes, technology improvements, and other conservation actions throughout the United States.
3. Technological ingenuity can substitute for energy. A quiet revolution in technology transformed energy use. Numerous efficient products and processes—appliances, lighting products, building techniques, automobiles, motor drives, and manufacturing techniques—were developed and commercialized by private companies. Energy productivity rose as more efficient equipment and processes were incorporated into buildings, vehicles, and factory stock.
4. Complementary policies work best. The most effective policies and programs helped overcome barriers to greater investment in conservation—barriers such as the lack of awareness and low priority among consumers; lack of investment capital; reluctance among some manufacturers to conduct research and to innovate; subsidies for energy production; and the problem of split incentives, exemplified by the building owner or landlord who does not pay the utility bills but does make decisions on insulation and appliance efficiency.
5. The private sector is the primary vehicle for delivering efficiency improvements, but government–industry cooperation is essential.

Many activists advocated adoption of a new national goal for energy intensity in order to regain momentum toward a secure energy future. The United States achieved a 2.7% annual rate of reduction in energy intensity between 1976 and 1986. The DOE was predicting, however, that U.S. energy intensity would decline at less than 1% per year through the rest of the 20th century. This is the rate of improvement now widely assumed as part of "business as usual." Recognizing that economic structural change had also influenced this rapid improvement and that many of the least expensive investments in efficiency had already been made, the present authors and others, including the American Council for an Energy Efficient Economy, nonetheless recommended a goal of reducing the energy intensity of the U.S. economy by at least 2.5% per year into the 21st century. For the United States, even with an apparently disinterested Administration, it is now proposed that energy intensity over the next

decade be improved by 18% (roughly the average yearly gain over the past two decades).

4. DECADE OF GLOBALIZATION: 1990s

The United States went to war for oil at the beginning of the 1990s. Oil prices initially spiraled upward, temporarily reinvigorating interest in conservation investments. That interest dwindled as quickly as prices fell. Still, after an inauspicious beginning, during the economic boom of the late 1990s, with major investments in new capital stocks, energy intensity dropped at an average rate of over 2% per year.

The role of carbon emissions in global climate change began to dominate the debate over energy in the 1990s. Although U.S. total energy consumption far outstripped any other country's, consumption was projected to grow at much higher rates in the developing countries, and U.S. policy makers shifted their attention to U.S. participation in international cooperation on energy innovation. In 1993, the U.S. government and the U.S. automobile industry forged an unprecedented alliance under the leadership of President Clinton and Vice President Gore. The partnership included seven federal agencies, 19 federal laboratories, and more than 300 automotive suppliers and universities and the United States Council for Automotive Research, the precompetitive research arm of Ford, DaimlerChrysler, and General Motors. The Partnership for a New Generation of Vehicles (PNGV) supported research and development of technologies to achieve the program's three research goals: (1) to significantly improve international competitiveness in automotive manufacturing by upgrading manufacturing technology; (2) to apply commercially viable innovations resulting from ongoing research to conventional vehicles, especially technologies that improve fuel efficiency and reduce emissions; and (3) to develop advanced technologies for midsized vehicles that deliver up to triple the fuel efficiency of today's cars (equivalent to 80 miles per gallon), without sacrificing affordability, performance, or safety. The research plan and the program's progress were peer-reviewed annually by the National Research Council. PNGV made extraordinary progress toward achieving its aggressive technical goals. In March 2000, PNGV unveiled three concept cars demonstrating the technical feasibility of creating cars capable of getting 80 miles per gallon. All three cars employ some form of hybrid technology that combines a gasoline- or diesel-powered engine with an electric motor to increase fuel economy. The three major automakers also confirmed their commitment to move PNGV technology out of the lab and onto the road by putting vehicles with significant improvements in fuel economy into volume production and into dealers' showrooms. Work continues on technologies that might contribute to the full achievement of goals for the 2004 prototype.

In 1999, the President's Committee of Advisors on Science and Technology (PCAST) issued recommendations for improving international cooperation on energy conservation. Reflecting a growing national consensus, they reported that efficient energy use helps satisfy basic human needs and powers economic development. The industrialized world depends on massive energy flows to power factories, fuel transport, and heat, cool, and light homes, and must grapple with the environmental and security dilemmas these uses cause. These energy services are fundamental to a modern economy. In contrast, many developing-country households are not yet heated or cooled. Some 2 billion people do not yet have access to electric lighting or refrigeration. The Chinese enjoy less than one-tenth as much commercial energy per person as do Americans, and Indians use less than one-thirtieth as much. Raising energy use of the world population to only half that of today's average American would nearly triple world energy demand. Such growth in per capita energy use coupled with an increase by over 50% in world population over the next half-century and no improvement in energy efficiency would together increase global energy use more than four times. Using conventional technologies, energy use of this magnitude would generate almost unimaginable demands on energy resources, capital, and environmental resources—air, water, and land.

Energy-efficient technologies can cost-effectively moderate those energy supply demands. For example, investments in currently available technologies for efficient electric power use could reduce initial capital costs by 10%, life-cycle costs by 24%, and electricity use by nearly 50%, compared to the current mix of technologies in use. Modest investments in efficient end-use technologies lead to larger reductions in the need for capital-intensive electricity generation plants. Conversely, when unnecessary power plants and mines are built, less money is available for factories, schools, and health care.

In the language of economics, there is a large opportunity cost associated with energy inefficiency. It is both an economic and environmental imperative that energy needs be satisfied effectively. Incorporating energy efficiency measures as economies develop can help hold energy demand growth to manageable levels, while reducing total costs, dependence on foreign sources of energy, and impacts on the environment. Ironically, energy is most often wasted where it is most precious. Developing and transition economies, such as in China, the world's second largest energy consumer, use much more energy to produce a ton of industrial material compared to modern market economies. Developing-nation inefficiency reflects both market distortions and underdevelopment. Decades of energy subsidies and market distortions in developing and transition economies have exacerbated energy waste. Energy efficiency requires a technically sophisticated society. Every society in the world, including the United States, has at one time encouraged energy inefficiency by controlling energy prices, erecting utility monopolies, subsidizing loans for power plant development, and ignoring environmental pollution. Many nations, including the United States, continue these wasteful practices. These subsidies and market distortions can seriously delay technological advances, even by decades, compared to best practice. The worldwide shift to more open, competitive markets may reduce some of the distortions on the supply side, but will do little to change the inherent market barriers on the demand side.

China, India, Brazil, Russia, and other developing and transition economies are building homes and factories with outdated technology, which will be used for many decades. In cold northern China and Western Siberia, for example, apartments are built with low thermal integrity and leaky windows and are equipped with appliances half as efficient as those available in the United States. Developing nations thus tend to build in excessive energy costs, lock out environmental protection, and diminish their own development potential. There are important exceptions. Progress can be both rapid and significant. Over recent decades, China has, through energy-sector reform and pursuit of least-cost paths via energy efficiency opportunities, made unprecedented progress in energy intensity reduction, faster than any developing nation in history. China has held energy demand growth to half of its rate of overall economic growth over the past two decades (Fig. 3). This example demonstrates that economic development can proceed while restraining energy demand growth; indeed, by employing cost-effective energy-efficient technologies, funds are freed for investment in other critical development needs. Energy efficiency can thus be a significant contributor to social and economic development.

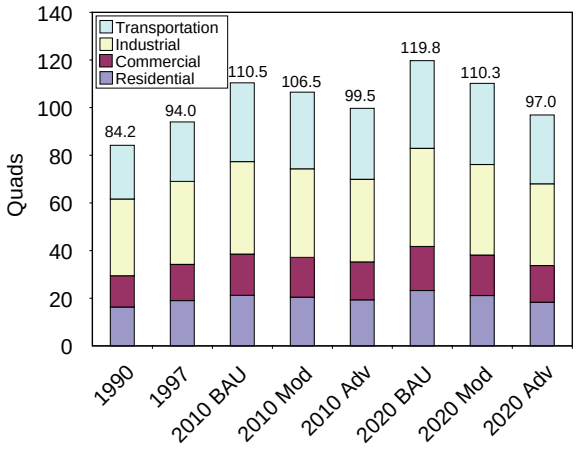

FIGURE 4 Primary energy consumption by sector. BAU, Business-as-usual model, compared to moderate (Mod) and advanced (Adv) conservation models. From Interlaboratory Working Group (2000).

5. DECADES AHEAD

Energy projections indicate differences in U.S. energy demand in 2020 between the high and low scenarios of approximately 25 quads (Fig. 4). The difference between these scenarios is substantially due to differing assumptions about development and deployment of energy-efficient technologies. The differences also reflect the plausible range of key consumption-driving factors that, operating over 20 years, can have a profound influence. These factors

include economic growth rate and the (rising) urgency to cut emissions of greenhouse gases in order to slow global climate change.

5.1 Cultural Barriers to Conservation

Sadly, there remains a persistent struggle between advocates of energy supply and conservation advocates. On the supply side, the energy industry is massive and concentrated, wielding great political influence (e.g., obtaining tax subsidies, allowing unhealthy levels of environmental emissions). On the conservation side, the relevant industry is diffusely spread over the entire economy, and energy efficiency is seldom the primary concern. Furthermore, decisions regarding the energy efficiency of appliances (e.g., heating, ventilation and air-conditioning systems and refrigerators) are frequently made (e.g., by developers, not consumers) on the basis of minimum first cost rather than life-cycle cost, thus generally favoring lower efficiency.

Two streams of progress over the past 50 years have combined to accentuate the attention given to energy conservation. First, steady and ubiquitous advances in technology (such as computers and various special materials) have enabled remarkable improvements (lower cost, higher efficiency) in productivity, including energy. Second, there has been a growing awareness of major direct and indirect externalities associated with energy production and conversion. Although such externalities (e.g., health, ecological stress, climate change, and air and water pollution) are now widely recognized, they still are not generally incorporated into national economic accounts. Instead, various standards, regulations, and policies have been developed or proposed to reflect the external costs by acting as a "shadow price," in order to level the playing field of price signals.

Despite its profound impacts, the conservation revolution has resulted in only a fraction of its ultimate potential. Here are some of the reasons:

1. Lack of leadership. Whereas an energy consumer can make short-term adjustments to save energy (driving slower, driving fewer miles and traveling less, adjusting the thermostat, or turning off lights), these mostly have the unpopular effect (other than saving money) of curtailing the very energy services that we seek. Sadly, such heroic short-term curtailment measures are too often posed as the essence of conservation rather than emergency measures. On national television, President Carter advocated energy conservation as a moral imperative, but delivering his speech while wearing a sweater and sitting by an open fire connoted sacrifice and denial of comfort. Worse yet, President Reagan referred to conservation as being hot in summer and cold in winter! In the short run, curtailment is about all anyone can do, but if we stop there, we lose by far the most impressive opportunities. After the shocks of the 1970s subsided, attention shifted to the more substantial but also more challenging task of capturing longer term opportunities.

2. Time lags. The largest opportunities for energy conservation derive from incorporating more efficient technologies into new capital investments (e.g., cars, buildings, appliances, and industrial plants). These logically accrue at a rate that reflects depreciation of existing capital stock, ranging from years to many decades. Just as for the case of major transitions in energy systems, the major opportunities for conservation inherently require decades to be fully achieved.

3. Discount rates. With a few exceptions, capital purchase decisions tend to favor minimum first cost, rather than minimum life-cycle cost. Generally, the minimum first-cost model corresponds to the least energy-efficient model. Thus the "least-cost" solution is typically not taken by most consumers and this slows the rate at which efficiency is gained.

5.2 Remaining Potential for Conservation of Energy Resources

Liquid fuels, so attractive because they can be stored and transported with relative ease, loom as a global challenge because the main supply (petroleum) is very unevenly distributed geographically and is often concentrated in insecure locations. Technologies for petroleum conservation are steadily improving, from elegant, new methods of exploration and production to highly efficient combustion in motors and turbines. Thus the petroleum resource base, although headed for depletion in this century, can be stretched (conserved) by a variety of technologies. Advances in high-temperature and low-corrosion materials now enable a variety of combustion turbines that can be employed to generate electricity with 60% or better thermodynamic efficiency—double the best-practice several decades ago.

Probably the greatest challenge for liquid fuel conservation for the future is in the transportation sector. Technology, the auto industry, public policies, and consumer preference all play important roles. The industry is most profitable in making large,

heavy and powerful cars and SUVs; consumers in the United States presently have a love affair with the image of power, ruggedness, and convenience with little regard for efficiency. And the record shows that U.S. public policy is to keep fuel price below total cost. Advances in automotive efficiency such as hybrid-electric/advanced diesel and fuel cells could help alleviate the situation. For example, over the past decade, work on streamlining, electrical power control systems, high-compression/direct-injection engines, electric drive trains, etc. has resulted in the recent market entry of hybrid cars that are very popular and have about 50% better mileage; in addition, rapid advances in fuel cell technology promise within a decade or so more conservation as well as lower environmental emissions. However, there seems to be little reason to hope for major gains in efficiency without major increases in fuel price or its equivalent shadow price (performance regulation such as CAFE).

Electricity generation is getting very efficient and the technologies that use electricity are also advancing. The world is still electrifying at a rapid pace. Electricity can now be generated from diverse energy sources and with diverse sizes of generators. Source diversity means inherent resilience of the system and capability for disaggregated generation means that "waste heat" from generators can be more readily utilized (cogeneration). Electricity is such a high-quality and versatile energy form that it is likely it will continue to increase in market share. Thus further advances in the efficiency of conversion and use of electricity should find ready markets.

The historic succession of energy sources over the past 150 years has led to progressively higher hydrogen-to-carbon (H/C) ratios for the fuels (e.g., coal, followed by oil, followed by natural gas). Global climate protection argues that we need to move with dispatch toward even higher H/C ratios in the coming decades. This implies a combination of removal (sequestering) of carbon from combustion releases, increased carbon recycle (e.g., renewable fuels from biomass), direct use of solar energy, and increased use of nuclear energy. Under this scenario, hydrogen becomes the most likely candidate for the derived fuel. This underscores the promise of high-efficiency fuel cells for energy conversion to electricity.

The amount of conservation achieved through advancing technology has been outstanding over the past half-century. Many more gains are possible, but we can also discern limits dictated by limits imposed by natural law. Carnot's thermodynamic rule for efficiency of heat engines is one limit. On the other hand, fuel cells give an opportunity to bypass Carnot. Success in this area could effectively enable a doubling of the useful work out of a unit of energy compared to an internal combustion engine, and with basically no environmental emissions. Success beckons but will require many technical advances in special materials and also in providing an acceptable primary energy source—probably hydrogen—all at a much lower production cost than now. The artificially low current price of gasoline constitutes a serious barrier to market entry of the new technologies.

Human ingenuity in the form of technological innovation will continue to provide new options to society. Energy conservation, which derives from sophisticated and elegant technologies, has every chance to continue paying big dividends to technologically capable societies. Conservation enables humanity to receive more "goods" along with fewer "bads." But most things have limits. Ultimately, we must recognize the folly of trying to follow an exponential path of population growth and resource consumption in its present form. We must equip ourselves with new tools, including conservation, and move with dispatch on a journey toward sustainability in the 21st century. There is little time to spare.

Glossary

caloric theory The theory that heat is a substance that flows into or out of a body as it is heated or cooled; this theory was replaced by the notion of the conservation of energy around 1850.

conservation of energy The notion that in a closed system, energy cannot be created or destroyed but can only be converted into other forms.

energy The capacity of a body to do work; it comes in various forms that can be converted into each other.

ether A medium that was assumed to fill space to explain the propagation of light, heat, and electromagnetic waves; it was discarded during the early 20th century.

heat engine Any device that takes heat and converts it into mechanical work.

mechanical equivalent of heat A constant that expresses the number of units of heat in terms of a unit of work.

mechanical theory of heat The theory that heat consists of the motions of the particles that make up a substance.

perpetual motion The fallacious theory that a machine, producing work, can be operated without any external source of power; it was discussed by philosophers and sold to kings but has been ignored by engineers since ancient times.

vitalism The theory that life depends on a unique force and cannot be reduced to chemical and physical explanations; this theory has been discarded.

work done Measured by force multiplied by the distance through which its point of application moves.

The modern principle of the conservation of energy emerged during the middle of the 19th century from a complex of problems across the sciences, from medicine to engineering. It was quickly accepted as a principle of nature and was applied to problems in mechanics and electromagnetism, and then in other sciences, even when it was not the most useful approach. It survived challenges even into the 20th century.

1. MOTION AND MECHANICS BEFORE 1800

Some ancient philosophers and most engineers assumed that perpetual motion was impossible, but nobody examined the efficiency of machines. The latter did not become central to engineering until the 18th century, after exhaustive metaphysical and methodological debates about motion and mathematics as necessary components of a comprehensive philosophy of nature. Natural philosophers and mathematicians argued over the conditions under which particular conservation laws were valid, and through these debates motion and collisions drew more attention from engineers and mathematicians.

In Rene Descartes's natural philosophy, the universe consisted of matter, whose quantity was measured by size, and motion. Collisions between particles was the mechanism for change, and the total amount of motion in the universe remained constant, although motion could be lost or gained in each collision. Descartes also assumed that the natural motion of bodies was linear—not circular—and was a vector. In collisions, the quantity of motion, size multiplied by velocity, could be transferred from one particle to another. The force of a

particle was its size multiplied by the square of its velocity. Although Descartes modeled his philosophical method on geometry, very little mathematics was contained within it. It was left to later generations to put his philosophy of nature into mathematical form.

One of the most successful was Isaac Newton, who began as a follower of Descartes and ended as his scientific and philosophical rival. In his explorations of Descartes's system, Newton became dissatisfied with Cartesian explanations of cohesion and other phenomena. He eventually accepted the reality of the concept of "force," banned by Descartes as "occult," as acting on micro and macro levels. Newton's universe was as empty as Descartes's was full, and God was necessary to keep His vast creation going. In such a universe, conservation laws and collisions were not of central importance. Yet Newton introduced a measure of force, momentum, that became part of the debates on conservation laws in mechanics.

One of the first entries in this debate was that of the Cartesian Christian Huyghens, who examined circular motion and the collisions of perfectly "hard" (perfectly elastic) bodies. He demonstrated that in such collisions, the sum of the magnitude of the bodies multiplied by the square of the velocity was a constant. However, for Huyghens, this expression was mathematically significant but not physically significant.

This pattern was repeated as 18th century continental mathematicians debated the measure of force and the quantities conserved in collisions. Gottfried Leibniz argued that Descartes's measure of force was insufficient. According to Leibniz, a body dropped a certain distance acquired just enough force to return to its original position, and this was a truer measure of force. Descartes had confused motive force with quantity of motion. Force should be measured by the effect it can produce, not by the velocity that a body can impress on another. In perfectly hard body collisions "vis viva," living force ($\frac{1}{2}mv^2$) was conserved. Central to subsequent debates were the experimental results of Giovanni Poleni and Wilhelm s'Gravesande, who measured the depths of the indentations left by metal balls dropped at different speeds into clay targets. If balls of different masses but the same size were dropped, the indentations remained the same. Lighter balls left the same indentations if they were dropped from heights proportional to 1/masses. s'Gravesande's experiments also showed that the force of a body in motion was proportional to v^2, that is, to its vis viva. He also did some elegant experiments in which hollow metal balls were filled with clay to investigate collisions of "soft" bodies. The results only fueled debates about the conditions over which measure of force was appropriate, mv or $\frac{1}{2}mv^2$.

s'Gravesande began his experiment to prove Newton's theories were correct, but the experiments seemed to Cartesians to support their point of view. Despite this evidence, s'Gravesande remained a Newtonian; for him, $\frac{1}{2}mv^2$ remained a number of no physical significance. Mathematicians in these debates over force included Madame de Chatelet, who published a French translation of Newton's *Principia* just 2 years after she had published *Institutiones* to spread Leibniz's ideas among French mathematicians. The subject of vis viva became a part of ongoing debates in the salons and Paris Academie des Sciences over Newtonian or Cartesian natural philosophy and the accompanying politics of each of those institutions.

Nothing was resolved, and mathematicians eventually moved on to other problems. They were inclined to use whatever physical principles seemed the most appropriate in their quest to develop the calculus using mechanical problems of increasing sophistication. Mechanics, or problems within it, became the instrument to display mathematical expertise and brilliance rather than explorations into physical problems. A perfect illustration of this is the work of Jean Louis Lagrange. By considering a four-dimensional space and using calculus, Lagrange reduced solid and fluid dynamics to algebra. He began with the fundamental axiom of virtual velocity for mass particles,

$$\sum m\frac{d\vec{v}}{dt}\cdot\delta\vec{r} = \sum \vec{F}\cdot\delta\vec{r},$$

where m is mass, v is velocity, $\delta\vec{r}$ is virtual displacement, and $\vec{F}$ is the applied force acting on a particle. Lagrange then introduced generalized coordinates, $q_1 \ldots q_n$, and generated the equations,

$$\frac{\partial T}{\partial q_i} - \frac{d}{dt}\left(\frac{\partial T}{\partial \dot{q}_i}\right) - \frac{\partial \Phi}{\partial q_i} = 0,$$

where T is the vis viva and Φ is a function. Thus, he succeeded in making rational mechanics as abstract, general, and algebraic as possible. No diagrams, geometry, or mechanical reasoning graced the pages of his text. It consisted "only of algebraic operations."

2. CALORIC THEORY AND HEAT ENGINES

During the 18th century, French engineers developed entirely different, yet mathematical, approaches to mechanics. Mathematicians had used problems on the construction of bridges, the construction of pillars, and the design of ships to explore the calculus. The education of French engineers began to include some calculus to solve engineering problems, especially in those schools of engineering within branches of the military. Here they developed an independent approach to the understanding of structures and the operations of machines.

Out of this tradition emerged Lazare Carnot, whose 1783 treatise on the efficiency of machines also began with the principle of virtual velocities. From this, he developed a relationship among the moment of activity, force multiplied by distance (work), and vis viva. He concluded that to get the maximum "effect" from the cycles of a machine, it was necessary to avoid inelastic impact in the working of its parts. During the 1820s, his son Sadi turned the same analytical approach toward the new "machine" that was revolutionizing the economy of Great Britain, the steam engine. As Carnot noted, removing this source of power would "ruin her prosperity" and "annihilate that colossal power." By this time, steam engines had been used in Britain for more than a century as pumps for mines. More recently, through the development by James Watt of the separable condenser and a governor, the steam engine became a new driving force for machinery. By the 1830s, the use of steam power and associated machinery was integrated into American and British cultures as a measure of the "civilized" states of societies.

Carnot wanted to establish the conditions under which maximum work could be produced by a heat engine. He stripped the heat engine down to its essential elements and operations. Through a series of examples, he demonstrated that successive expansions and contractions from heating and cooling—not heat alone—produced the motive power. Steam was not unique; any substance that expanded and contracted could be a source of power. Gases generally afforded the most expansion and contraction on heating and cooling. Carnot thought of heating and then cooling as the "reestablishment of equilibrium" in caloric and the substance of heat as the source of motive power. Therefore, he began to search for the general conditions that would produce the maximum motive power, and in principle, this could be applied to any heat engine.

Sadi Carnot used the same approach as his father and other French engineers in analyzing machines by looking at infinitesimal changes. In this case, the temperatures of the heat source and sink differed only slightly from that of the working substance. Carnot examined the changes in temperature and pressure of the working substance in a complete cycle of the engine, again a familiar approach in French engineering. Initially, the body is in contact with the heat source, and its piston rises and its volume expands at a constant temperature. It is then removed from this source, and the expansion continues without any heat input and the temperature of the working substance decreases to that of the heat sink. Placed in contact with the cooler body, the gas is compressed at constant temperature and then is removed and further compressed until the cycle is closed and the working substance attains the temperature of the heat source. The Carnot cycle is then complete. However, Carnot's analysis of its operation was in terms of caloric theory. In the first operation, the caloric is removed from the heat source to the working substance, and motive power is produced as the caloric attains the temperature of the heat sink. Equilibrium is restored as the caloric again reaches the temperature of the heat source. Using the incomplete image of a waterfall used to drive machinery, the caloric is conserved. It has fallen from one temperature to a lower one, and in this fall we can extract motive power just as we do from the gravitational fall of water.

The caloric theory of heat was accepted across Europe by the latter part of the 18th century. Experimental research into heat occupied many chemists across Europe and had an important place in the development of the reformed chemistry of Antoine Lavoisier. "Airs" (gases) were also the object of avid research throughout Europe by many chemists from before the flight of the Montgolfier brothers in 1784 through the first third of the 19th century. Caloric theory drew these two strands of research together. During the 1780s, Lavoisier had measured the specific heats of a number of substances with Pierre Simon de Laplace. These experiments were aspects of Lavoisier's research on airs and heat. In another series of such experiments, Lavoisier studied digestion and animal heat. Using an ice calorimeter, he demonstrated that respiration was a slow form of combustion and predicted heat outputs that agreed with his experimental results. Both Lavoisier and Laplace believed that heat was a

material substance that manifested itself in two forms: free caloric (detected by thermometers) and latent caloric. Laplace and Simon Poisson developed caloric theory mathematically by assuming that the caloric, Q, in a gas was a function $Q = f(P, \rho, T)$, where P is the pressure, T is the temperature, and ρ is the density of the gas. Manipulating the partial differential equations in a theory of adiabatic compression, this general equation led to relationships in accord with known experimental results such as the ratio of the specific heats of gases. Caloric was connected to the notion of work through Laplace's theory. Free heat was vis viva, combined (latent) heat was the loss of vis viva, and heat released was an increase in vis viva. Caloric theory was sophisticated and was taught at the Ecole Polytechnique when Sadi Carnot was a student, although toward the end of his short life he rejected it to explore the idea that heat was the motion of particles.

Carnot used the latest experimental results on the properties of gases to demonstrate his contentions and then discussed the limitations of heat engine design at the time. He concluded that because of gases' great expansion and contraction with heating and cooling, and because of the need for large differences in temperature to gain the most motive power, gases were the only feasible working substances for heat engines. He used current research on gases to demonstrate that any gas might be used.

Although Carnot's small treatise, *Reflections on the Motive Power of Heat,* received a good review from the *Revue Encyclopedique,* only one engineering professor at the Ecole Polytechnique developed Carnot's ideas. Emile Clapyeron gave geometrical and analytical expression to Carnot's analysis, creating the first pressure–volume (PV) diagram of a Carnot cycle. In his analysis, this cycle was reduced to an infinitesimally small parallelogram for the case pursued by Carnot. Again using the results from work on the properties of gases, Clapyeron obtained an expression for the "maximum quantity of action" developed in a cycle from the area within the parallelogram of the heat cycle for a perfect gas heat engine. Again, the analytical expressions were in terms of general expressions for heat, $Q = Q(P, V, T)$, $P = P(V, T)$, and $V = V(P, T)$. In the concluding paragraphs of his memoir, Clapyeron described the mechanical work available from his heat engine in terms of the vis viva the caloric developed in its passage from the boiler to the condenser of the engine. Many of his expressions were independent of any particular theory of the nature of heat and remained valid even as their physical explanation changed during the 1850s.

The works of both Carnot and Clapyeron sank into oblivion. Carnot died young and tragically in an asylum, but his oblivion was partially political. His father, Lazare, had enthusiastically embraced the French Revolution, was important in its early wars, and rose to prominence in Napoleon's regime. He remained loyal to Napoleon until the end and died in exile. The Carnot name (except that of his brother, a prominent politician), was politically tainted even into the 1830s. And however useful caloric might be for engineers, among scientists the caloric theory held less interest during this decade. They extended the wave theory of light to heat, and through it they explained other scientifically pressing problems such as the conduction and radiation of heat.

So deep was Carnot's oblivion that in 1845 William Thomson, a young ambitious Scottish academic, could find no copies of his treatise in Paris. Thomson had recently graduated Second Wrangler and first Smith's Prizeman from Cambridge University and was actively seeking the empty chair in natural philosophy at Glasgow University. The Glasgow that Thomson grew up in was Presbyterian and was the center of heavy industry (especially shipbuilding) and chemical engineering in Great Britain. Although his father was a distinguished professor of mathematics at Glasgow, the younger Thomson needed the support of the rest of the faculty and of the town representatives to ensure his election. He had to cultivate the image of the practical experimenter rather than flaunt his mathematical abilities, hence Thomson's sojourn at the laboratory of Henri Victor Regnault, well known for his empirical studies of steam engines. These were the circumstances that led Thomson to search out Carnot's work. Undaunted, Thomson made full use of Clapyeron's publications in a series of papers (published in 1847 and 1850) extending Clapyeron's analysis. In his first paper he postulated an absolute zero of temperature implied by Clapyeron's analysis and put forward the notion of an absolute scale of temperature. Both emerged from the mathematical forms independent of their physical interpretation. Thomson's brother, James, noted that one of the results of Clapyeron's work was that the freezing point of water decreased with an increase in pressure. William Thomson confirmed this through experiments done at Glasgow. The position of caloric theory seemed to be becoming firmer once again. However, in the middle of this theoretical and experimental triumph, Thomson went to the 1847

annual meeting of the British Association for the Advancement of Science (BAAS), where he heard a paper given by James Joule on experiments whose results contradicted caloric theory.

3. EQUIVALENCE OF HEAT AND WORK

Joule was the son of a very successful brewer in Manchester, England. He was educated privately and with ambitions to spend his life in science. His first papers dealt with "electromagnetic engines," and in the course of his experiments he focused on what we now call Joulean heating in wires carrying electric currents. This drew attention to the production of heat in both physical and chemical processes. From his experiments and a developing theory, he concluded that an electric generator enables one to convert mechanical power into heat through the electric currents induced into it. Joule also implied that an electromagnetic "engine" producing mechanical power would also convert heat into mechanical power. By 1843, he presented his first paper to the British Association for the Advancement of Science (BAAS) on the "mechanical value of heat." Joule believed that only the Creator could destroy or create and that the great agents of nature, such as electricity, magnetism, and heat, were indestructible yet transformable into each other. As his experiments progressed, he elaborated his mechanical theory of nature. Important to observers, and to Thomson, was Joule's idea that mechanical work and electricity could be converted into heat and that the ratio between mechanical work and heat could be measured. In a series of papers on the mechanical equivalent of heat presented annually to BAAS and politely received, Joule labored alone until the stark reactions of Thomson in 1847. Some scientists could not believe Joule's contentions because they were based on such small temperature changes. Presumably, their thermometers were not that accurate. However, Thomson understood that Joule was challenging caloric theory head on. Until 1850, Thomson continued publishing papers within a caloric framework and an account of Carnot's theory. He had finally located a copy of the treatise. Clearly, he began to doubt its validity, noting that more work on the experimental foundations of the theory were "urgent," especially claims that heat was a substance. It took Joule 3 years to convince Thomson of the correctness of his insight. Only in 1850 did Thomson concede that heat was convertible into work after he read Rudoph Julius Emmanuel Clausius's papers and those of William McQuorne Rankine on heat. He then reinterpreted some parts of his caloric papers that depended on heat as a substance in terms of the interconversion of heat and work. Also, he rederived and reinterpreted his expression for the maximum amount of work that could be extracted from the cycle of a perfect heat engine and other results and then gave his version of the second law of thermodynamics.

4. CONSERVATION OF ENERGY

Others had come to conclusions similar to those of Joule before Thomson. One of the most notable was Hermann von Helmholtz. Trained as a physician while studying as much mathematics and physics as possible, his doctoral dissertation was a thorough microscopic study of the nervous systems of invertebrates. His mentor was Hermann Mueller, who (along with Helmholtz's fellow students) was determined to erase vitalism from physiology. Their goal was to make physiology an exact experimental science and to base its explanatory structures in physics and chemistry. Helmholtz managed to continue his physiological research while a physician in the Prussian army, where he was dependent on his army postings and his early research on fermentation and putrefaction was cut short by the lack of facilities. He turned to a study of animal heat and the heat generated by muscular action and found that during contraction chemical changes occurred in working muscles that also generated heat. In the midst of this research, Helmholtz published "On the Conservation of Force." This paper displayed the extent of his mechanical vision of life and his commitment to a Kantian foundation for his physics. Central forces bound together the mass points of his theory of matter. These commitments resurfaced during the 1880s with his work on the principle of least action.

With considerable pressure brought to bear on the ministry of education and the Prussian military, Helmholtz was released from his army obligations and entered German academic life. He never practiced medicine again, yet his research over the subsequent two decades began with questions in physiology that expanded into studies on sound, hearing, and vision. His work on nerve impulses in 1848 developed into a study of electrical pulses and then into a study of the problem of induction before

growing into a critical overview of the state of the theory of electricity during the 1870s.

The closeness of Helmholtz's work in physics and physiology is evident in his paper on the conservation of force. He had actually stated the principle earlier (in 1845) in a paper reviewing the work of Humphry Davy and Antoine Lavoisier on animal heat. He concluded that if one accepts the "motion theory of heat," mechanical, electrical, and chemical forces not only were equivalent but also could be transformed one into each other. This assumption bound together results already known from chemistry, electricity, and electromagnetism. The structure of this review formed the outline of Helmholtz's 1847 paper. He added a theory of matter that he believed demonstrated the universality of the principle of conservation. Helmholtz began in metaphysical principles from which he extracted specific physical results. In his model, force was either attractive or repulsive. Change in a closed system was measured by changes in vis viva expressed as changes in the "intensity of the force," that is, the potential of the forces that acted between the particles, $\frac{1}{2}mv_1^2 - \frac{1}{2}mv_2^2 = \int_r^R \varphi dr$, where m is the mass of the particle, whose velocity changes from v_1 to v_2, and ϕ is the intensity of the force, whose measure is constructed by looking at changes in v^2. Because both velocities and forces were functions of the coordinates, Helmholtz expressed these last changes as $\frac{1}{2}md(v^2) = Xdx + Ydy + Zdz$, where $X = (x/r)\phi$. He demonstrated that for central forces, vis viva was conserved and, thus, so was the intensity of the force. He then expanded the argument to a closed system of such forces. The unifying concept in the paper was "tensional force" and its intensity ϕ. This allowed Helmholtz to extend his argument to electricity to obtain the "force equivalent" of electrical processes. In this case, the change in vis viva of two charges moving from distance r to R apart was $\int_1^2 \frac{1}{2}md(v^2) = -\int_r^R \varphi dr$, where he identified ϕ with Gauss's potential function, to which Helmholtz gave physical meaning. However, he did not give this entity a new name. He was reinterpreting physically a well-known approach used when mathematizing a physical problem. Unlike mathematicians, Helmholtz drew important physical conclusions from his equations, including the Joulean heating effect. He also included Franz Neumann's work on electrical induction in his conceptual net. Helmholtz used examples from chemistry and electricity to argue that heat was a measure of the vis viva of thermal motions, not a substance. He used a broad range of experimental results across the sciences to illustrate the plausibility of his contentions.

Helmholtz had difficulty in getting these speculations into print. They eventually appeared as a pamphlet. The thrust of the speculations went against prevailing standards in the emerging field of physics. German physicists had rejected grand speculative visions of nature and its operations for precision work in the laboratory, from which they assumed theoretical images would emerge. The model of this new approach was Wilhelm Weber. In Weber's case, precise, painstaking numerical results, analyzed in detail for possible sources of error, led to a center-of-force model that explained the range of electrical phenomena he had researched experimentally. Neumann was known for his careful experiments on crystals and their optical properties. Helmholtz presented his mechanical model before his analysis of the experimental work of others that ranged across disciplinary boundaries. This approach also dissolved the recently hard-won academic and specialist designation of physics in German academia.

Helmholtz was not the only German claimant to the "discovery" of the principle of conservation of energy. After his graduation in 1840, Julius Robert Mayer, a physician, became a doctor on a ship bound for the East Indies. Mayer noted the deeper color of venous blood in the tropics compared with that in Northern Europe. He interpreted this as more oxygen in the blood, with the body using less oxygen in the tropics because it required less heat. He speculated that muscular force, heat, and the chemical oxidation of food in the body were interconvertible forces. They were not permanent but were transformable into each other. On his return, Mayer learned physics to demonstrate the truth of this conviction and then set about to calculate the mechanical value of a unit of heat. To do this, he looked at the works on the thermal properties of gases and took the difference between the two principal specific heats as the amount of heat required to expand the gas against atmospheric pressure. This heat was transformed into work, and from this he computed the conversion factor between heat and work. Further memoirs followed, extending his use of available experimental results from the chemistry and physics of gases. Mayer even included the solar system. He argued that meteorites falling under gravity built up enormous amounts of mechanical force that yielded considerable amounts of heat on impact. This could account for the sun's seemingly inexhaustible supply of heat.

Mayer also encountered difficulties in publishing his work. His first paper of 1842, "Remarks on the

Forces of Inorganic Nature," was published in a chemistry journal rather than a physics journal. As with Helmholtz, the combination of metaphysics and calculations derived from other people's experiments was not acceptable in the physics community in the German states. In addition, Mayer did not have the academic credentials or connections of Helmholtz. In fact, Mayer had to underwrite the publication of his later papers. At the end of the decade, Mayer suffered personal tragedy and in 1850 tried to take his own life. He was confined to a series of mental institutions. However, from 1858 onward, he began to gain recognition for his work from his colleagues, including Helmholtz, and he received the Copley Medal from the Royal Society in 1871.

So far, there were several approaches leading to the statement of the first—and even the second—law of thermodynamics. None of these claimants replaced Carnot's and Clapyeron's work mathematically from a thermodynamic point of view except the work of Clausius. In his 1850 paper, Clausius began from the observation that the conduction of heat is possible only from a hotter to a colder body. This led him logically to replace Carnot's principle, that heat is conserved in the cycle of a perfect heat engine, to that of the equivalence of heat and work. As a consequence, when work is done, heat is consumed in any heat engine. Although he kept many of the mathematical forms developed by Clapyeron, Clausius assumed that the mathematical characteristics of the functions that entered into his equations determined the physical characteristics of his system. In analyzing the Carnot cycle, Clausius chose the perfect gas as his physical system and looked at the state of the gas as it traversed an infinitely small cycle. Following Clapyeron, he constructed the heat added or expended for each leg of the cycle and constructed an expression for the inverse of the mechanical equivalent of heat, A, as the ratio of the heat expended over the work produced. To construct an expression for the work done in completing the cycle, Clausius calculated the expressions for the heat added at each leg in the cycle and constructed

$$\frac{d}{dt}\left(\frac{dQ}{dV}\right) - \frac{d}{dV}\left(\frac{dQ}{dt}\right) = \frac{A \cdot R}{V},$$

where dQ is the heat added, V is the volume of the gas, and R is the gas constant. Arguing mathematically that Q could not be a function of A and t so long as they were independent of each other, the right-hand side of the equation must be zero. This brought the equation into the form of a complete differential,

$$dQ = dU + A \cdot R\left(\frac{a+t}{V}\right)dV,$$

where $a + t =$ the absolute temperature and $U = U(V, t)$, is the heat necessary for internal work, and depends only on the initial and final states of the gas. The second term on the right-hand side, the work done, depended on the path taken between the initial and final states of the gas. Clausius then introduced $1/T$, where T is the temperature that, as a multiplier of dQ, makes a complete differential of the form $Xdx + Ydy$. He applied this combination of physics and mathematics to the behavior of gases and saturated vapors, with the latter being of great interest due to the engineering importance of steam engines during the mid-19th century. In this analysis, he restated the results, some mathematically equivalent to those of Clapyeron and Thomson, but interpreted them in terms of the equivalence of heat and work. At the end of this first paper, he gave an initial statement of the second law of thermodynamics.

Therefore, there are several different paths and claimants to some statements equivalent to the first law of thermodynamics. During the decades immediately following 1850, many others were championed as "discoverers" of the principle of the conservation of energy among the engineers and scientists working on related problems. These claims came in the wake of a change in language from the equivalence of heat and work to the conservation of energy. Some of the assertions gave rise to bitter complaints, especially the contentions of Peter Guthrie Tait's, whose *Thermodynamics* trumpeted Joule as the "discoverer" of the equivalence of heat and work yet readily recognized Helmholtz's priority in the matter of the first law. Mayer's work was recognized belatedly by Helmholtz and Rankine against Joule's claims. Mayer published an estimate of the mechanical equivalent of heat a year before the appearance of Joule's first value. And so it went. A great deal was at stake in these disagreements, which reflected on industrial prowess as well as on intellectual authority in the growing political and industrial rivalry between Germany and Great Britain. Using hindsight, later historians also tried to claim some of the credit for other Europeans.

5. ENERGY PHYSICS

A decade before the development of the mechanical meanings of the conservation of energy, Thomson,

Clausius, and Helmholtz had extended its reach into electrostatics, thermoelectricity, the theory of electromagnetism, and current electricity. During the 1860s, one of the more important applications of this new approach was the establishment of an absolute system of electrical units. Again this involved national prestige given that the Germans already had their own system based on the measurements of Weber. The BAAS committee included Thomson, James Clerk Maxwell, and the young electrical engineer Fleming Jenkin. Maxwell and Jenkin measured resistance in absolute (mechanical) units and deduced the others from there.

So far, what existed were disparate statements and uses for energy, none of which shared a common language or set of meanings. Thomson and Tait created that language for energy in their 1868 textbook on mechanics, *A Treatise on Natural Philosophy*. The text was directed to the needs of their many engineering students. During the 19th century, numerous new technical terms were coined, many of which derived from ancient Greek, and energy was no exception. Derived from the Greek word *ενεργεια*, energy was commonly used for people who demonstrated a high level of mental or physical activity. Also, it expressed activity or working, a vigorous mode of expression in writing or speech, a natural power, or the capacity to display some power. More technically, Thomson and Tait used energy as the foundation of their 1868 text. They claimed that dynamics was contained in the "law of energy" that included a term for the energy lost through friction. They introduced and defined kinetic and potential energy and even claimed that conservation of energy was hidden in the work of Newton. William Whewell grumbled about the book's philosophical foundations, but it was translated into German as well as being widely used in Great Britain.

Conservation of energy was becoming the foundation for teaching physics as well as for new approaches in research in the physical sciences. Thomson considered that conservation of energy justified a purely mechanical vision of nature and tried to reduce all phenomena, including electromagnetic phenomena, to purely mechanical terms. In his early papers in electromagnetism, Maxwell used conservation of energy in constructing and analyzing mechanical models as mechanical analogues to electrical and magnetic phenomena. He then abandoned this mechanical scaffolding and established his results on general energetic grounds, including his electromagnetic theory of light. In defense of his approach to electromagnetism, Maxwell criticized Weber's action-at-a-distance approach as being incompatible with the conservation of energy. In 1870, Helmholtz began a systematic critique of Weber's electrical theory and repeated Maxwell's judgment that he located in Weber's use of velocity-dependent forces. Helmholtz had first stated this criticism in his 1847 paper on the conservation of force, and it became a starting point for alternative approaches to electromagnetism among German physicists. These included Neumann and Bernard Riemann, who developed the notion of a retarded potential. By 1870, this criticism undermined the validity of his work and Weber was forced to answer. He demonstrated that, indeed, his theory was compatible with conservation of energy.

Clausius was the first to try to develop an expression for the laws of thermodynamics in terms of the motions of the molecules of gases. His models were mechanical, whereas the later ones of Maxwell and Ludwig Boltzmann were statistical. Maxwell became more interested in the properties of gases, such as viscosity, heat conduction, and diffusion, relating them to statistical expressions of energy and other molecular properties. Boltzmann developed a statistical expression for the first and second laws of thermodynamics. During the late 19th century, thermodynamics itself was subject to great mathematical manipulation, which in some hands became so remote from physics that it once again became mathematics.

By the time of Maxwell's death in 1879, the conservation of energy had become a principle by which physical theories were judged and developed. This was particularly true in Great Britain, where "energy physics" propelled the theoretical work of most physicists. Much of this work, such as that of Oliver Lodge, was directed toward the development of Maxwell's electromagnetism, although the work was expressed as mechanical models. Lodge also drew up a classification of energy in its varied physical forms, from the level of atoms to that of the ether. He also used an economic image for energy, equating it with "capital." He extolled John Henry Poynting's reworking of Maxwell's *Treatise* in 1884 and saw it as a new form of the law of conservation of energy. In his treatment of the energy of the electromagnetic field, Poynting studied the paths energy took through the ether. He investigated the rate at which energy entered into a region of space, where it was stored in the field or dissipated as heat, and found that they depended only on the value of the electric and magnetic forces at the boundaries of the space. This work was duplicated by Oliver Heaviside,

who then set about reworking Maxwell's equations into their still familiar form. The focus was now firmly on the "energetics" of the electromagnetic field.

The emphasis on energy stored in the ether separated British interpretations of Maxwell's work from those on the continent, including that of Heinrich Hertz. However, energy in the German context became the foundation for a new philosophy of and approach to the physical sciences, energetics. Initiated by Ernst Mach, energetics found its most ardent scientific advocate in Wilhelm Ostwald. The scientific outcome of Ostwald's work was the development of physical chemistry. Yet his dismissal of atoms led to clashes with Boltzmann, and during the 1890s his pronouncements drew the criticism of Max Planck. Planck had, since his dissertation during the 1860s, explored the meaning of entropy, carefully avoiding atoms and molecules. He was forced into Boltzmann's camp in his research on black body radiation, essentially a problem of the thermodynamics of electromagnetic radiation. Planck was not alone in understanding the importance of the problem; however, other theorists were tracking the energy, whereas Planck followed the entropy changes in the radiation.

6. ENERGY IN 20TH CENTURY PHYSICS

As an editor of the prestigious journal *Annalen der Physik,* Planck encouraged the early work of Albert Einstein, not only his papers in statistical mechanics but also those on the theory of special relativity. Planck then published his own papers on relativistic thermodynamics, even before Einstein's 1907 paper on the loss of energy of a radiating body. Two years before this, Einstein had investigated the dependence of the inertia of body on its energy content. In this case, the mass of the body in the moving system decreased by E/c^2, where E is the energy emitted as a plane wave and c is the velocity of light. Einstein concluded that "the mass of a body is a measure of its energy content." Einstein constructed his relativistic thermodynamics of 1907 largely on the foundation of Planck's work and reached the conclusion that $dQ = dQ_0\sqrt{(1 - v^2/c^2)}$, where dQ is the heat supplied to the moving system, dQ_0 is that for the system at rest, and v is the velocity of the moving system to that at rest.

Thus, the law of conservation of energy was integrated into relativity theory. However, its passage through the quantum revolution was not as smooth. In 1923, Niels Bohr expressed doubts about its validity in the cases of the interaction of radiation and matter. This was after Arthur Holly Compton explained the increase in the wavelengths of scattered X rays using the conservation of energy and momentum but treating the X rays as particles. The focus of Compton's research, the interaction of radiation and atoms, was shared with many groups, including that around Bohr in Copenhagen, Denmark. Bohr did not accept Einstein's particle theory of light, even with the evidence of the Compton effect. By using the idea of "virtual oscillators" that carried no momentum or energy, Bohr, H. A. Kramers, and John Slater (BKS) hoped to maintain a wave theory of the interaction of radiation and matter. To do so, they had to abandon the idea of causality, the connection between events in distant atoms, and the conservation of energy and momentum in individual interactions. Struggling with the meanings of the "BKS theory" became crucial in the development of Werner Karl Heisenberg's formulation of quantum mechanics. However, the BKS theory was bitterly opposed by Einstein as well as by Wolfgang Pauli, who, after a brief flirtation with the theory, demonstrated its impossibility using relativistic arguments.

Conservation laws were reinstated at the center of physical theory. Conservation of energy became the criterion for abandoning otherwise promising theoretical approaches during the late 1920s and early 1930s in quantum field and nuclear theory. In the latter case, Pauli posited the existence of a mass-less particle, the neutrino, to explain beta decay. The neutrino remained elusive until the experiments of Ray Cowan and Fred Reines during the 1950s. Conservation of energy also governed the analysis of the collisions of nuclear particles and the identification of new ones, whether from cosmic rays, scattering, or particle decay experiments. Relativistic considerations were important in understanding the mass defects of nuclei throughout the atomic table. The difference between the measured masses and those calculated from the sum of the masses of their constituent particles was explained as the mass equivalence of the energy necessary to bind those components together.

7. ENERGY CONSERVATION BEYOND PHYSICS

Beyond physics, conservation of energy became a foundation for other sciences, including chemistry

and meteorology, although in this case the second law of thermodynamics was more powerful in explaining vertical meteorological phenomena. In the natural sciences, the most dramatic demonstration of the conservation of energy's usefulness was in the study of animal heat and human digestion. The production of heat as synonymous with life can be seen in the aphorisms of Hippocrates during the fifth century BCE. In Galen's physiology, developed during the second century AD, the source of bodily heat was the heart. Heat was carried in the arterial system throughout the body, where it was dissipated through the lungs and the extremities. Aspects of Galen's physiology remained in William Harvey's explanation of the function of the heart. Yet Harvey's experiments, published in 1628 as *Anatomical Experiments on the Motion of the Heart and Blood in Animals,* demonstrated the circulation of the blood and the pumping action of the heart. This mechanical function of the heart became part of Descartes's mechanical philosophy that changed debates over the source of heat in the body. Was it generated in the heart or from friction as the blood flowed through the vessels of the body? Harvey's argument that the lungs dissipated the heat from the body fitted into this mechanical vision of the body.

During the 18th century, Descartes's mechanistic vision of the body was replaced by vitalism based on chemical experiments. This was the vitalism that Helmholtz sought to root out from medicine during the 1840s. The experiments were those performed on "airs" consumed and expended by plants that vitiated or revived the atmosphere. Combined with these experiments were others showing that combustion and respiration made the atmosphere less able to sustain life, usually of birds and small mammals. After the introduction of Lavoisier's reform of chemical nomenclature, which also carried with it a new theory of chemistry and chemical reactions, experiments on animal chemistry became more quantitative and lay within his new theoretical framework. Treadmill studies by Edward Smith in 1857 demonstrated that muscles derived energy, measured by heat output, from foods not containing nitrogen. However, Justus Leibig's idea that bodily energy derived from muscle degradation was not easily deposed. It took the mountain-climbing experiments of Adolph Fick and Johannes Wislicenus in 1866 and the analysis of them by Edward Frankland to finally displace Leibig's theory. Frankland pointed out that Fick and Wislicenus's results could be interpreted by looking at the energy involved in combustion in a unit of muscle tissue and considering the work output the equivalent of this energy. Conservation of energy was necessary in understanding the dynamics of the human body. Frankland also showed that the energy the body derived from protein equaled the difference between the total heat of combustion and the heat of combustion of the urea expelled, with the urea being the pathway for the body to rid itself of the nitrogen in proteins. Thus, conservation of energy entered the realm of nutrition, biophysics, and biochemistry. In later experimental studies, W. O Atwater measured, by a whole body calorimeter, that the heat given off by the human body equaled the heat released by the metabolism of the food within it. Even when the complexities of the pathways of amino acids and other sources of nitrogen were understood, along with their routes through the digestive system, conservation of energy remained the foundation for interpreting increasingly complex results.

Thus, conservation of energy has proved to be crucial for analyzing the results of experiments across—and in some cases beyond—the scientific spectrum. There have even been experiments—so far unsuccessful—aimed at measuring the mass of the soul on its departure from the body.

4. Energy Conservation as Preservation of Resources

Glossary

conservative force The force that allows a potential energy to be constructed. A conservative force that acts along a closed path does no work. See potential energy.

district heating The use of waste heat from energy generation for space heating within a specified distance of the generating plant.

first law of thermodynamics The statement that the total internal energy of a system is changed both by heat transferred into or out of a system and the work done by or on a system. The principle of conservation of energy was at first applied only to mechanical systems (conservation of mechanical energy). When it was realized that thermal energy was another form of energy, the reason for the "disappearance" of energy from frictional work was realized.

heat Thermal energy that is transferred between reservoirs at different temperatures.

hybrid An automobile that has both a gasoline motor and an electric motor. It is more fuel efficient than a pure gasoline engine because braking recharges the battery and because the gasoline motor can be shut off when it is not accelerating the car.

industrial ecology An approach to design of industrial systems that uses analogies to biological systems to minimize energy and resource demand. The focus of industrial ecological design is thus on the physical parameters such as minimization of resource flows and efficiency of energy budgets.

potential energy A potential energy $U(\mathbf{r})$ can be constructed as

$$U(\mathbf{r}_2) - U(\mathbf{r}_1) = -\int_{\mathbf{r}_1}^{\mathbf{r}_2} \mathbf{F} \bullet d\mathbf{r}.$$

The conservative force F does work that is independent of the path taken. In this case, only the end points of the motion matter, and because only the difference in potential energy is defined physically, the potential energy $U(\mathbf{r})$ may only be defined up to an overall constant. In many cases, this constant is fixed by the choice $U(\mathbf{f}) = 0$, as is usually the case for the electrical potential energy between two charges q_1 and q_2:

$$U(\mathbf{r}) = \frac{1}{4pe0}\frac{q_1 q_2}{\mathbf{r}}.$$

principle of conservation of energy The idea that the total energy of the universe is conserved (it is neither created nor destroyed). The homogeneity of the universe with respect to time translations is a symmetry of nature. As a consequence of this symmetry, the universe's energy is conserved. For example, it is axiomatic for science that an experiment, prepared identically, will return the same result no matter when the experiment is performed.

second-law efficiency The actual work performed divided by the available work. The available work is the maximum amount of work along any path that a system (or a fuel) can attain as it proceeds to a specified final state that is in thermodynamic equilibrium with the atmosphere.

Second Law of Thermodynamics There are many formulations of the second law. A useful one is that there is no way to get work from a single temperature reservoir (one at a fixed temperature). Clausius proved that systems that are isolated will move toward equilibrium with their surroundings.

thermal systems A system that depends on the temperature. Heat transfer is a central feature of thermal systems.

waste heat Thermal energy transferred to the low-temperature reservoir in a thermal engine.

The physical principle of conservation of energy always holds. It reflects the homogeneity of physical laws with respect to time. In the context of thermal systems, this principle is known as the First Law of Thermodynamics. Energy obtained through thermal transformations is subject to a maximal efficiency due to the second law of thermodynamics, which severely constrains the utility of thermal energy as it is transformed to other kinds of energy. Not all sorts

 © 2004 Elsevier Inc. All rights reserved.

of energy have the same ease of use, even though it is always possible to transform one into another. High-quality energy is the most versatile, and thermal energy the least versatile. Energy conservation in ordinary speech refers to preservation of resources the provision of energy resources more efficiently or at lower cost. Many opportunities still exist for reducing costs by raising efficiencies, by encouraging cooperation so that waste is minimized, and by rethinking traditional designs. The transportation and agricultural systems may have the best prospects for increasing energy efficiency.

1. ENERGY PRELIMINARIES

Energy is defined as the capacity to do work, but as a practical matter, energy is difficult to measure with a machine (but it is easy to calculate). Work is defined by the differential relation

$$dW = \mathbf{F} \bullet d\mathbf{r},$$

where $d\mathbf{r}$ is an infinitesimal displacement of the massive object subject to the force **F**. If the force is constant, we find that the work done in displacing the object by $\Delta\mathbf{r}$ is

$$\Delta W = \mathbf{F} \bullet \Delta\mathbf{r} = \mathbf{F}|\Delta\mathbf{r}|\cos\theta,$$

where θ is the angle between **F** and $\Delta\mathbf{r}$. In many texts, this relation is simplified to read

$$\Delta W = \mathbf{F}_{||} d = \mathbf{F} d_{||},$$

where $\mathbf{F}_{||}$ is the component of the force along the displacement direction, d is the total distance traveled, and $d_{||}$ is the displacement component along the direction of the force. A key to understanding energy is to recognize that different forms of energy may be transformed into other forms of energy. In some cases, the work that has to be done against a force to move an object from one particular point A to another particular point B is the same, no matter what way the work is done. The work does, of course, depend on which points are used as end points, but not on the path traversed between them. In such a case, the force is called conservative. The gravitational force is an example of a conservative force. For such a conservative force, work may be done against the force to move a massive object from one position to another. This work represents the change in energy of the massive object. For example, a person may pick up an object that is on the floor (such as a fork) and put it on a table. If the external force on the object is **F** (in this case, **F** would be the gravitational force on the fork, otherwise known as the fork's weight), the work the person does opposing **F** to pick the fork up is

$$-\int_{\mathbf{r}_1}^{\mathbf{r}_2} \mathbf{F} \bullet d\mathbf{r}.$$

If the fork were to fall off the table onto the floor, we would expect that work to reappear somehow (as some other form of energy, perhaps). It has the potential to reappear if the fork is put into a position to fall, and so this energy is known as gravitational potential energy.

In general, there are many types of potential energy; the general potential energy of a particle is defined as

$$U(\mathbf{r}_2) - U(\mathbf{r}_1) = -\int_{\mathbf{r}_1}^{\mathbf{r}_2} \mathbf{F} \bullet d\mathbf{r}.$$

Potential energy may only be defined for a conservative force. For a conservative force **F**, this integral is independent of the path and can be expressed in terms of the end points only; here these are the starting and ending positions $\mathbf{r}_1$ and $\mathbf{r}_2$. It should be clear from the definition of potential energy that only differences in potential energy matter.

Energy in science is measured in the International System of Units as the product of the units of force and distance (newtons times meters); this energy unit is given the special name joule (1 J = 1 N m), but many other energy units exist. The most common are the British thermal unit (1 Btu = 1055 J), the kilowatt-hour (3.6×10^6 J = 3.6 MJ), and the kilocalorie [food calorie] (1 kcal = 4186 J). The quadrillion Btu ("quad") is often used to describe American energy use. In 2001, this was 98.5 quads (1.04×10^{20} J, or 104 EJ).

We may recognize two uses of the phrase energy conservation. One use is scientific and refers to the physical principle taught in school and essential to contemporary understanding of nature; this is discussed in Section 2. A background in thermal physics, which bridges the two uses of the word, is sketched in Section 3. The other use of the word refers to the preservation or wise use of energy resources and is discussed in detail in Section 4.

2. THE PHYSICAL PRINCIPLE OF ENERGY CONSERVATION

The impetus for the principle of energy conservation originally is the observation that in simple systems on Earth, one may define an energy of position (the gravitational potential energy) and connect it to

another form of energy, kinetic energy. For a simple mechanical system with no friction, using Newton's second law ($\mathbf{F} = m\mathbf{a}$), we recast the work as

$$\int_{r_1}^{r_2} \mathbf{F} \bullet d\mathbf{r} = \int_{r_1}^{r_2} m\mathbf{a} \bullet d\mathbf{r} = m \int_{r_1}^{r_2} \mathbf{a} \bullet d\mathbf{r}$$
$$= m \int_{t_1}^{t_2} \mathbf{a} \bullet \frac{d\mathbf{r}}{dt} dt = m \int_{t_1}^{t_2} \mathbf{a} \bullet v dt$$
$$= m \int_{v_1}^{v_2} v \bullet dv = \frac{1}{2} m v_2^2 - \frac{1}{2} m v_2^1.$$

The quantity $T = \frac{1}{2} mv^2$ is called the kinetic energy (it represents energy associated with the motion of a massive object). With this nomenclature, we find from the definition of potential energy that

$$U(\mathbf{r}_2) - U(\mathbf{r}_1) = -[T_2 - T_1],$$

and rewriting slightly, we obtain

$$T_2 + U(\mathbf{r}_2) = T_1 + U(\mathbf{r}_1).$$

Note that the quantity on the left refers only to position 2, while that on the right refers only to position 1. Since 1 and 2 were completely unspecified, this equation states a general result: in such a simple system, the quantity $T + U$ must be a constant (or conserved). This is referred to as conservation of mechanical energy (and of course, "conservative force" is a retrodiction that follows from the observation of conservation of mechanical energy).

More generally, the total potential energy is the sum of all the potential energies possible in a given situation. There is no new physics in the principle of conservation of mechanical energy. Everything follows from Newton's laws (refer back to the introduction of kinetic energy and potential energy).

It was natural to physicists to expand this idea by including every possible form of energy and to believe that the total amount of energy in a closed system is conserved. As a consequence of work by the German mathematical physicist Emmy Noether, it became clear that each conservation law (such as that of energy or momentum) is connected to a symmetry of the universe. The law of conservation of momentum is connected to translation invariance, the law of conservation of energy to temporal invariance. This means, respectively, that moving an experiment in a reference frame and repeating it when prepared identically has no effect of the observed relations among physical quantities, and that doing an experiment prepared identically at different times should produce identical results.

From these observations it is clear that relations among reference frames are essential to consider if discussing conservation laws. In the early 20th century, Albert Einstein worked to understand such relations in the context of electromagnetism and extended it beyond electromagnetism to more general physical situations. Einstein created two theories, the special theory of relativity (1905) regarding transformation among inertial reference frames, and the general theory of relativity (1915), which allowed extension of special relativity to accelerated (non-inertial) reference frames.

In special relativity, in an inertial frame of reference an energy-momentum four-vector p^μ consisting of a time component (E/c) and spatial momentum components p_x, p_y, and p_z, may be defined that satisfies $p^\mu p_\mu = m^2c^2$, which is an expression of energy conservation in special relativity (written in more conventional notation as $E^2 - p^2c^2 = m^2c^4$). That is, the fact that the vector product of two four-vectors is invariant leads to conservation of energy. In special relativity, there is a special frame of reference for massive objects known as the rest frame; in that frame $p = 0$, so the relativistic energy equation is $E = mc^2$, a rather widely known result. All massive objects have energy by virtue of possessing mass, known as mass-energy.

The relativistic energy relation $E^2 = p^2c^2 + m^2c^4$ may be recast as $E = \gamma mc^2$ for massive objects (and, of course, as $E = pc$ for massless objects), where the relativistic momentum is $\mathbf{p} = \gamma m\mathbf{v}$ and $\gamma = \left[1 - \left(\frac{v}{c}\right)^2\right]^{-1/2}$. In this case, the kinetic energy is $T = (\gamma - 1)mc^2$ because T plus mass-energy (mc^2) must be equal to total energy E.

In general relativity, the connection to the Noether theorem is clearer, as one defines a so-called stress-energy tensor, $T^{\mu\nu}$. The stress-energy tensor describes momentum flow across space-time boundaries. The flow (technically, flux) of the stress-energy tensor across space-time boundaries may be calculated in a covariant reference frame and the covariant derivative of the stress-energy tensor turns out to be zero. This means that energy is conserved in general relativity.

There is no proof of the principle of conservation of energy, but there has never so far been disproof, and so it is accepted. It is a bedrock of modern physics. In physics, as in other sciences, there is no possibility of proof, only of disproof. The cycle of model (hypothesis), prediction, experimental investigation, and evaluation leads to no new information if the experimental result is in accord with the prediction. However, if there is disagreement between prediction and experiment, the model must be replaced. Over the historical course of science, faulty

models are thrown away and the surviving models must be regarded as having a special status (until shown to be false as described earlier). Special relativity, general relativity, and conservation of energy are theories that have withstood the test of time. (In fact, by superseding Newton's law of universal gravitation, Einstein's theory of General Relativity shows where Newton's successful theory's boundaries of applicability are.)

3. THERMAL SYSTEMS AND ENERGY

As mentioned in Section 1, energy comes in many forms, all of which may be transformed into other forms of energy. Someone who knew only the physics principle of conservation of energy could be forgiven for wondering why people were speaking of energy conservation and meaning something else entirely. Why was generalization of mechanical energy conservation so difficult? The reason lies with the characteristics of thermal systems.

3.1 Thermal Energy

To help clarify the issues involved, let us consider a simple system: a box resting on flat ground to which a rope is attached. The rope is pulled by a person so that the force on the box is constant. Anyone who has actually done such an experiment (a class that contains virtually the whole human population of Earth) knows that, contrary to the assertion that the kinetic energy increases, it is often the case that the speed of the box is constant (the kinetic energy is constant).

What is missing is consideration of the friction between the box and the ground. Figure 1 shows the situation. In Fig. 1A, the rope's force on the box (caused by the person pulling the rope) is shown and the box is moving along the ground. However, many forces that act on the box are not shown. Figure 1B shows the free body diagram for the box, including all the forces that act. The box has weight, **W**, which must be included. The ground pushes directly upward to prevent the box from falling through the surface with a force $\mathbf{F}_{\text{ground on box}}$ and exerts a frictional force **f** on the box; and, of course, a force is exerted by the person on the rope, and hence the rope exerts a force on the box, **F**.

The presence of the frictional force is what is responsible for the lack of change in the kinetic

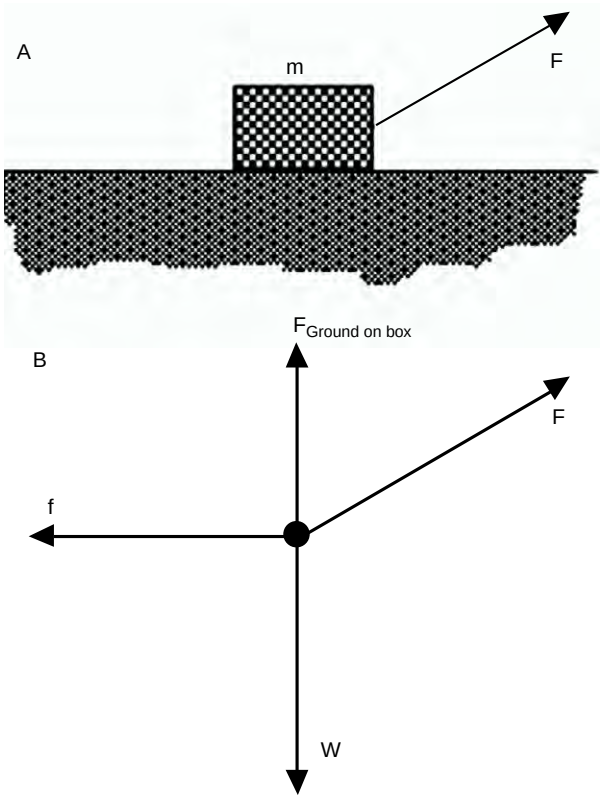

FIGURE 1 (A) A box being pulled along the ground. (B) A free body diagram showing all forces acting.

energy. That is, the speed can be constant because the horizontal components of the two forces add to zero. So where has all the work done gone? It has apparently disappeared from the mechanical energy. In fact, the work is still there, but thermal energy, the random motion of the atoms in the box has increased at the expense of the work done. In Fig. 2, an energy bar chart representation shows what has happened: The thermal energy of the system has increased.

Thermal energy is a new form of energy that must be considered in working with conservation of energy. In fact, the consideration of thermal energy was first codified by the physicist Sadi Carnot in the early part of the 19th century. We might call the 19th century the century of thermal energy because of the work of other giants of thermal physics such as Boltzmann, Clausius, Joule, Kelvin, Maxwell, Planck, and many others who created the science of thermodynamics.

3.2 Thermodynamics: The Zeroth Law

Systems involving measurements of temperature or exchanges of thermal energy are thermal systems.

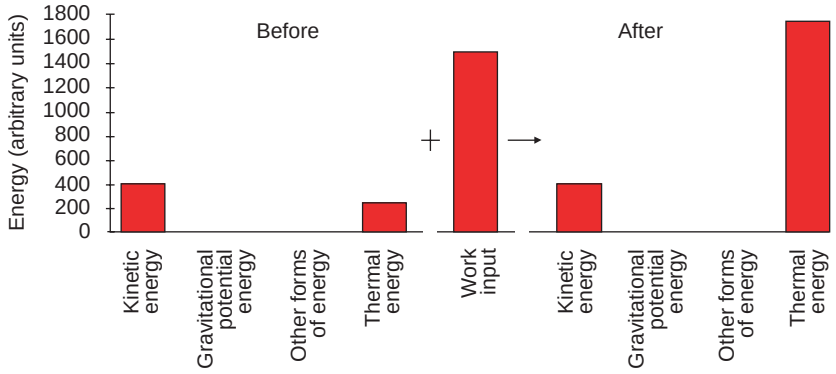

FIGURE 2 An energy bar chart representation of the change in energy of the box because energy is brought into the box system from outside by the rope.

Thermal systems are characterized by their temperatures. Temperature is determined by the mean of the random motions of the atoms making up a material. A device that measures temperature is known as a thermometer. Temperatures are measured by assigning numbers to systems we designate as cold or hot and by using the idea of thermal equilibrium.

If a spoon from the drawer is put into a pot of boiling water, thermal energy will flow from hot water to cooler spoon. Thermal energy is exchanged between the water and the spoon, but eventually the spoon and water do not exchange any more energy. Thermal equilibrium is the state in which there is no net interchange of thermal energy between bodies. The spoon comes to thermal equilibrium with the boiling water.

Temperatures are measured by allowing the thermometer and the system to come to thermal equilibrium. Two bodies are said to be in a state of thermal equilibrium if there is no net interchange of thermal energy between those bodies when they are brought into thermal contact. The measurement of the temperature of the thermometer therefore also gives a measurement of the temperature of the system.

The most common temperature scale used on Earth, and often used in science, is the Celsius scale. It sets the zero temperature at the freezing point of water and sets 100°C at the boiling point of water at sea level under standard conditions. The choice of the boiling end point is arbitrary scientifically. As virtually everyone living in the temperate regions of Earth knows from personal experience, there are temperatures below zero using this scale. A brisk day might have a temperature around 10°C, and a very hot day a temperature around 40°C. Human body temperature is 37°C. Comfortable room temperature is about 20°C.

In science, the arbitrariness of the Celsius scale makes it less useful in communication. Lord Kelvin devised a temperature scale, known as the absolute temperature or the Kelvin temperature scale, that begins with the lowest temperature possible in the universe as 0 K (absolute zero) and has a temperature of 273.15 K at the triple point of water (the temperature at which ice, water, and water vapor are in thermal equilibrium). With this definition, the kelvin interval is the same as the degree Celsius (1 K = 1°C).

3.3 Thermodynamics: The First Law

In the 18th century, steam engines began to contribute mechanical energy to replace human labor. Carnot began to study various engines that operate, as steam engines do, between two different temperatures. In a steam engine, burning fuel boils water to make steam, which pushes a piston, turning the steam's thermal energy to mechanical energy. That mechanical energy can be used in a machine. In early steam engines, the spent steam was vented to the air, the piston retracted, and the cycle began again (modern steam engines work slightly differently). The spent steam's thermal energy was released from the system.

The word "heat" refers to energy in transit between bodies at two different temperatures. It is one of the most misused words in physics. Heat is not a separate form of energy, but an artifact of the transfer of thermal energy to a body. There is no heat content to a body, as was first shown in 1798 in an experiment carried out by the American inventor Benjamin Thompson (1753–1814), also known as Count Rumford. As the person in charge of making cannon for the king of Bavaria, he was able to bore channels for the shot in cannon; there was need for

cooling water as long as the boring proceeded. There was no end to the amount of heat being transferred.

Any thermal engine operates between two temperatures. It is useful to think of the original steam at the higher temperature and the air at the lower temperature as temperature reservoirs, or large "containers" of thermal energy, so large that taking some or adding some leaves the system unchanged. A thermal engine runs through a cycle in which thermal energy is taken in at the high temperature reservoir, work is done, and thermal energy is exhausted at the low temperature reservoir.

Of course, energy is conserved in this cycle. The energy the system takes in from the high temperature is equal to the sum of the work done by the system and the energy the system exhausts to the low temperature reservoir. As applied to thermodynamics, the principle of conservation of energy is known as the first law of thermodynamics. From the first law of thermodynamics, no machine is possible that could create energy from nothing.

3.4 Thermodynamics: The Second Law

We define the efficiency of any energy transformation as

$$\text{Efficiency} = \frac{\text{energy output}}{\text{energy input}};$$

for a machine that produces work from other forms of energy, this relation would be

$$\text{Efficiency} = \frac{\text{work output}}{\text{energy input}}.$$

In the case of a heat (or thermal) engine, the first law of thermodynamics reads

$$\text{Energy input at } T_H = \text{Work output} + \text{Energy output at } T_L.$$

As a result, the efficiency is

$$\text{Efficiency} = \frac{\text{energy input at } T_H - \text{energy output at } T_L}{\text{energy input at } T_H},$$

clearly less than 100%. Note that the necessity of exhausting thermal energy as heat to the low-temperature reservoir necessitates a severe restriction on the efficiency of a heat engine. This also has deleterious consequences, because this so-called waste heat must be absorbed by the local environment (usually local water is used as the low temperature reservoir) and can adversely affect aquatic life.

Carnot studied a special cycle (Fig. 3) in which the thermal energy is absorbed at the high temperature, the system expands, then the system contracts as thermal energy is exhausted at the low temperature. This cycle is known as the Carnot cycle. By studying this special Carnot cycle, which was the most efficient cycle that could possibly exist between the two temperatures, Carnot could find the maximum possible efficiency in terms of the absolute temperatures of the reservoirs for a heat engine operating between these two temperatures.

The second law of thermodynamics, originally conceived by Rudolf Clausius, is the statement that any real thermal engine is less efficient than the Carnot cycle. (There are many other formulations of the second law.) The Carnot efficiency is found to be

$$\text{Maximum possible efficiency of a heat engine} = \frac{T_H - T_L}{T_H}.$$

Again, because of the need to exhaust thermal energy at the low temperature, the efficiency of even the ideal Carnot engine is restricted. For example, suppose that a heat engine (an electric generator) operates between a high temperature of 500°C and a low temperature of 20°C (room temperature). The maximum possible efficiency of operation is

$$\text{Maximum possible efficiency of a heat engine} = \frac{773.15\,\text{K} - 293.15\,\text{K}}{773.15\,\text{K}} = 0.621(62.1\%).$$

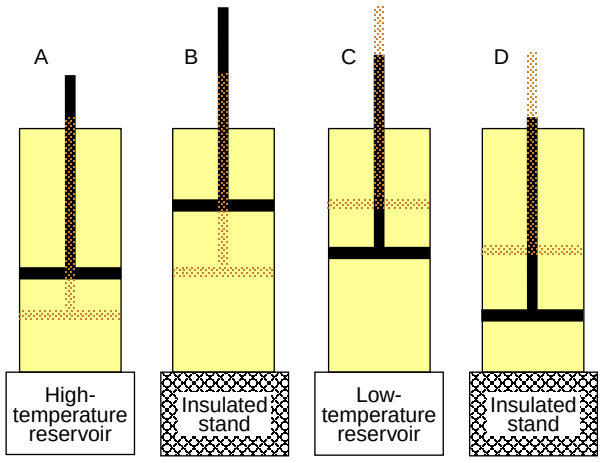

FIGURE 3 The four parts of the Carnot cycle. (A) The system expands, drawing in thermal energy, at absolute temperature T_H while it is attached to a high-temperature reservoir. (B) The system is isolated, so no energy enters or leaves, and the system expands further, lowering the absolute temperature from T_H to T_L. (C) At absolute temperature T_L, the system contracts as the piston pushes inward, transferring thermal energy to the low-temperature reservoir. (D) The system is isolated, so no energy enters or leaves, and the system contracts back to the original volume.

Real electric generators average about 33% efficiency, much lower than the maximum possible (Carnot) efficiency.

3.5 Quality and Second-Law Efficiency

It may be seen from the above that when transforming thermal energy into other forms of energy, the amount available is not the total energy available, but is smaller. However, if work is done by an agent, *all* the work is available; if electrical energy is available, *all* of it may be transformed directly into other, usable, forms of energy. Thermal energy is said to be low-quality energy because of its limitations in the conversion process, while work and electrical energy are high-quality energy.

Thermal energy may be used directly in space heating and in cooking, but if we want to run a motor with it, not all the thermal energy would be available to us. It would make sense to use forms of energy (if available) that could deliver all their energy to the motor. Conversely, if we want to increase the temperature of a room, it is silly to use high-quality energy to do it.

While the equation for efficiency is found using the first law of thermodynamics, the American Physical Society study "Efficient Uses of Energy" points out that the second law of thermodynamics, which shows that the Carnot engine operating between two temperatures is the most efficient, allows us to compare the actual efficiency to the theoretical maximum efficiency for producing a given amount of work; this is called the second-law efficiency for the system. For real thermal systems, the second-law efficiency measures how much room for improvement remains.

4. ENERGY CONSERVATION AS PRESERVATION OF RESOURCES

Often exhortations to conserve energy or other resources such as land or water are heard. Many people view the probable effect of the requested conservation measures in their daily lives as having to "do without" something desirable. Conservation might represent "personal virtue" through sacrifice; it involves paying a personal price. It may represent the religious idea of stewardship. Alternatively, they may see these measures as making their lives more complicated in a world that already seems full of intimidating tasks. They are interested in living their lives, in having life be as comfortable and convenient as possible.

Energy conservation here refers to the provision of the same level of goods or services with a smaller drain than at present on stored energy resources. In their common perceptions about conservation, those people who are wary of conservation efforts are both wrong and right. They are wrong because people who conserve energy are not sacrificing or doing without but are benefiting from increased efficiency or reduced costs. However, they are right because this reorientation may have a cost in personal convenience since it may involve additional time, thought, or change in habits.

In the following, we discuss possibilities for "energy conservation" with the understanding that, physically, energy is always conserved as discussed in Section 2; we are discussing here reduction of waste and increase of efficiency of the economic and physical system. The reliance on thermal systems for transforming energy makes the second-law efficiency a good measure of the efficacy of a proposed conservation measure. The following examples show how it has been or may in the future be possible to provide the same services at reduced monetary and energy cost.

4.1 Space Conditioning

Space heating and cooling are responsible for a considerable amount of energy use. In the United States in 1993, 4.3×10^{17} J of electricity, representing 1.3×10^{18} J of thermal energy, 3.9×10^{18} J of thermal energy from natural gas, and 1.3×10^{18} J of thermal energy from kerosene, fuel oil, and liquefied petroleum gas (a total of 6.5×10^{18} J = 6.5 EJ of thermal energy) was used for residential space heating. Another 1.50 EJ was used for residential air conditioning, of which 18% (0.26 EJ) was used for room air conditioners. This represents over 8% of national energy use. Commercial buildings in the United States in 1995 used 8.3 EJ of thermal energy as electricity, 2.1 EJ of thermal energy from natural gas, and 0.25 EJ of thermal energy from fuel oil, a total of 10.6 EJ of thermal energy, roughly 10% of national energy use. The great majority of energy use is for space conditioning (4.1 EJ) and lighting (3.3 EJ).

In the aftermath of the 1973 energy crisis, many buildings were built with more attention paid to energy-conserving features, resulting in a lowered energy use per area, but this impetus was lost with a return to cheap oil in the 1980s and 1990s, and in early 1990s commercial buildings were built to use

one-third more energy per square meter than average 1980s buildings.

Clearly, with over 10% of United States energy use committed to space conditioning, systematic savings could have a great impact. Savings are available from installation of replacement glazing, increased insulation, and replacement of antiquated heating and cooling systems.

Active and passive solar energy systems have been used for millennia to achieve space conditioning at little or no cost, and these methods continue to hold promise of reduced reliance on fossil fuels and uranium. Passive systems are characterized by construction methods that allow people to cool rooms during the day and heat by night through thermal storage—for instance, in masonry walls—of energy from the sun. Use of surrounding vegetation to help maintain house temperature has been common since humans began building shelters. Natural ventilation systems are also passive in nature. Active solar systems use some fossil energy to pump fluids, but the main input is free energy from the sun.

Heat pumps, especially groundwater-based heat pumps, use a heat engine in a clever way. Groundwater is about the same temperature the year around, and in the winter it is much warmer than the ambient air in colder climates, while in summer it is much cooler than the ambient air. In winter, the heat pump is run by taking in thermal energy at the groundwater low-temperature reservoir, doing work on it, and exhausting the thermal energy plus the work at the high-temperature reservoir (the room). Only the extra energy (the work input) must be supplied by fossil fuels. The advantage of this system is that the user pays only for the work done, and the extra energy used to heat the space is the "free" thermal energy in groundwater or the atmosphere. In summer, the heat pump works backward, taking thermal energy from the high-temperature reservoir (the room), doing work, and exhausting thermal energy to the low-temperature reservoir (the groundwater). Commercial freestanding heat pumps use the atmosphere as the reservoir and can be substantially less efficient than groundwater-based heat pumps.

In cold weather, much ambient thermal energy is transferred out of buildings, where it is desirable to keep it, to the outside through walls and windows. In warm weather, ambient thermal energy is transferred from outside to inside, where it is undesriable, again through the walls and windows. Advanced technology can contribute to reduced fossil energy use through design of various types of windows—low emissivity coatings, double- or triple-glazed windows with evacuated spaces, or smart window coatings that can act as an insulating shade. Aerogel-based insulating materials may also contribute to future energy savings in buildings, as they already have for appliances.

Air conditioners have become more efficient over the years since the 1970s energy crisis. The state of California has led the way by mandating increasingly efficient room and home air conditioning units, and the federal government has followed. The rollback of Clinton administration seasonal energy efficiency ratio (SEER) regulations by the incoming Bush administration (which may have been illegal, since the rules had been published in the *Federal Register*) was a setback to this trend. The payback time for the increased cost of a SEER-13 unit over a SEER-12 unit is a little over 1 year. Fortunately, because it has such a large population, California's energy-efficiency regulations tend to drag the rest of the nation along despite federal foot-dragging, and even the rolled-back SEER targets are far above the average SEER of 5 to 6 in 1994. The efficiency regulation might actually be looked at as an antipoverty regulation, because the least-efficient units (having the lowest purchase price) are bought by landlords, while the typically lower-income tenants must pay the electric bills. Wealthier Americans tend to buy the higher-SEER units because they themselves pay their electricity bills.

4.2 District Heating

In many European cities and some older American cities, electric utilities use the waste heat from the boilers or heat exchangers to keep buildings warm in the cooler months of the year. Hot water is circulated through pipes through nearby buildings, and cooler water returns to the utility. This is known as district heating because an entire region can be served by this system. In the United States, 5.6×10^{17} J (0.56 EJ) of energy was distributed as district heating in 1995.

Savings are possible because of economy of scale (one central heating system instead of many individual systems), the reduced maintenance per unit of output characteristic of a larger system, and because the waste heat would have to be disposed of by other means were it not used for this useful purpose. District heating is only feasible when there is a large but compact region having a relatively large population density through at least part of the day. This is more characteristic of European and Asian conditions than American or African ones.

4.3 Illumination

As noted earlier, commercial buildings use a substantial amount of energy for lighting, roughly 3% of total American energy use. Lighting is also an important part of household and commercial energy consumption. There are many ways of saving fossil energy. For example, commercial buildings may be built with daylighting features, in which the architect designs the space and the windows such as clerestories to provide light to workspaces during the day (clearly lamps are needed when it is not light enough outside, but in most locations days are not severely overcast most of the time).

Incandescent lighting, in which a filament is heated to a white-hot temperature and the resulting light is used, converts only about 5% of the electric energy into radiant energy. Ordinary fluorescent lighting is four times as efficient, converting about 20% of the electric energy into radiant energy. The development of electronic ballasts for fluorescent bulbs in the 1970s after the first energy crisis contributed significantly to fluorescents' energy efficiency advantage.

In the 1990s, compact fluorescent bulbs became available. Now these bulbs, while more expensive than incandescent bulbs to buy, deliver light for a longer time and use much less electricity and so are much cheaper to use. Consider a 100 W incandescent bulb that costs \$0.25 in a package of four bulbs for \$1, and a 23 W compact fluorescent that delivers about the same amount of light but costs \$4.95. The cheap incandescent bulb last on average 500 hours, while the compact fluorescent lasts 10,000 hours. That means it takes 20 incandescent bulbs to replace the compact fluorescent, at a cost of \$5 (the same as the price of the compact fluorescent bulb). However, over 10,000 hours of operation, compact fluorescent use costs (at a rather typical 8 cents per kilowatt-hour)

$$23\,\mathrm{W} \times 10,000\,\mathrm{hours} \times \$0.08/\mathrm{kWh} = 230 \times \$0.08 = \$18.40,$$

while incandescents' use cost

$$100\,\mathrm{W} \times 10,000\,\mathrm{hours} \times \$0.08/\mathrm{kWh} = 1000 \times \$0.08 = \$80.00.$$

Obviously, it is much more rational for a homeowner or businessperson to use the compact fluorescent. However, inertia—the resistance to change—and the high initial cost has limited compact fluorescents' market penetration, only about 10% of lighting sales. The Department of Energy has estimated that a complete switch to compact fluorescents would save the United States about 32 billion kilowatt-hours of electric energy annually, or 0.36 EJ of fossil fuel energy—the equivalent of the output of almost four 1000 MW generating plants.

4.4 Appliances

In the aftermath of the energy crises of the 1970 s and 1980 s, attention turned to energy use in appliances as a means of energy savings. Newer compressors, more effective insulation, and better design of refrigerators has decreased continuing expenses substantially. In 1973, the average refrigerator used over 2000 kWh/year. By 2000, this average was reduced to 1140 kWh/year, and the most energy-efficient units (volume $20\,\mathrm{ft}^3 \sim 0.6\,\mathrm{m}^3$) used just 440 kWh/year. Several factors contributed to increases in efficiency. In the aftermath of the energy crises, legislation mandated the posting of energy guides on appliances (including refrigerators) so consumers could make rational decisions on purchases. In addition, California introduced efficiency regulations for refrigerators (and the California market is so large, it made no sense for manufacturers to make a separate California model). Finally, a \$30 million prize was offered for development of the most energy-efficient refrigerator (the prize was won by Whirlpool).

Europeans have long paid substantially more for energy than their American counterparts, and appliance manufacturers have developed many cost savings that had not been adopted in the United States. With the consolidation of appliance manufacturers worldwide, more European energy-efficient technology has made its way west. Whirlpool, for example, is now manufacturing virtually identical energy-efficient washing machines in Europe and the United States.

A uniquely American idea is the EnergyStar rating system, which is an extension of the energy guides to appliances not covered by the legislation voluntarily entered into by the appliance manufacturers. Appliances meeting EnergyStar guidelines display the EnergyStar sticker and consumers can know that they are among the most efficient available. The criteria change with time; for example, for dishwashers to be eligible for EnergyStar designation prior to January 2001, their efficiency had to be greater than 13% above federal standards, while to earn the EnergyStar after January 2001, the dishwasher had to be over 25% more energy efficient. The efficiencies are achieved by locating heater

boosters inside the dishwashers and by use of less water per cycle.

Computers have been increasingly used in many households and businesses. The use of flat screens for televisions and computer monitors saves considerable energy compared to the CRTs typically used, which is why they were originally introduced for the notebook computers, which must often run from batteries. The sleep mode of computers and computer peripherals uses much less energy than would be used if the computers were fully "awake."

Some years ago, appliances had to "warm up" before they came fully on. Consumers disliked this wait time, and manufacturers of televisions, radios, and other appliances began to manufacture instant response units. Consumers liked the feature, but didn't realize the hidden costs. The units are turned on all the time and collectively use between 10% and 25% of the electricity used in households. Such devices have been called energy vampires. The problem may be limited to developed countries, but the cost is not a necessary one. Electronic transformer use would substantially decrease this drain, and they already are used in countries where mandated by law (they cost only 0 to 20 cents more per unit, but are not installed voluntarily by cost-conscious manufacturers). Computers use much more than the 10 W or so used by VCRs and TVs in their sleep mode, though, of course, the power is much lower than when the computer is awake.

4.5 Transportation

Automobile engines have a Carnot efficiency of around 60% but are about 25% efficient in practice. As long as the internal combustion (Otto) engine continues to be used, large increases in efficiency are unlikely, but sizable incremental savings are still available. Alternatives include electric vehicles and fuel cell vehicles. The transportation sector is important because transportation accounts for 27% of total United States energy use. Most of the energy used for transportation is petroleum based. That means that importing countries depend on the exporting countries' good faith and on their continued willingness to supply oil at a relatively cheap price. While the United States pays some of the highest prices for oil, both because domestic oil is more expensive than imported oil and because the average transportation cost is large, the price of gasoline at the pump is among the lowest in the world. This is mainly due to the difference in tax structures among countries.

In Europe, automobiles are generally smaller than in the United States because of the higher energy prices consumers pay for gasoline and diesel fuel (because of the high local taxes). Smaller cars use less material to manufacture and, because the weight is smaller, cost less to run. Many drivers in the United States are reluctant to purchase small cars because they are concerned about safety (this is apparently partly responsible for the boom in sport utility vehicle, or SUV, sales). Ironically, though people in SUVs are less likely to be killed or injured in a direct front, back, or side collision, the overall death rate is higher in SUVs than in smaller cars because of the large number of fatalities in rollover accidents, which have a relatively high probability of occurrence.

American cars are much lighter than in the 1970s, a direct result of the first energy crisis. A conventional suburban car gets a mileage around 30 mi/gal. It is clear that the weight of most cars could be reduced further. A countervailing trend is for more and more SUVs and pickup trucks to be sold. These vehicles weigh more than normal cars and as a result get worse mileage. By 2000, fewer than half of all vehicles purchased for personal transportation in the United States were ordinary automobiles. A large SUV might get a mileage of just 17 mi/gal, while a small pickup gets 25 mi/gal. The reason for the better car mileage is legislative—Congress adopted Corporate Average Fuel Economy (CAFE) standards after the first energy crisis to force manufacturers to raise mileage, and it worked. The rise in SUVs and pickups have pleased the manufacturers because these vehicles were not covered by the CAFE standards. In addition, the low average energy prices of the late 1990s lulled drivers into expecting cheap imported oil would continue to be available. Political pressure for increasing CAFE standards abated, and car mileage stagnated. As a result, the fleet average for American vehicles experienced a decrease in mileage. The lowest fleet average mileage was achieved about 1989. Even imported cars' mileage has slipped. On the basis of history, only legislative mandate will be successful in increasing mileage in the absence of external threats such as giant leaps in world oil prices.

Before the 1970s, most American cars were rear-wheel drive; now most are front-wheel drive, which is more energy efficient. Most modern automobile engines are more efficient overhead cam engines. However, much more energy could be saved by continuing to pursue ways to decrease drag, and the installation of advanced automatic transmissions that are controlled electronically. Other measures, some partly introduced include improved fuel injection

systems, improved tires, improved lubricants, and reduced engine friction. All these measures are good conservation measures because they come at no or low cost (low cost means short payback times).

California's quest for less-polluting cars led to designation of quotas for lower-emission vehicles. Many ideas for automobiles that run on electricity or energy stored in high-tech epoxy-based flywheels have been proposed. The high hopes California had for so-called zero-emission vehicles were apparently unwarranted, and few total electric vehicles have been designed or produced. There have been difficulties with battery design (conventional lead-acid automobile batteries weigh quite a lot). The nickel-metal hydride battery is the apparent technology of choice for electric vehicles. In addition, battery-powered cars do not perform well at low ambient temperatures, so these cars are not common outside the southwest. Another strike against battery-powered cars is the lack of charging infrastructure. And such vehicles are not really *zero* emission, because gas, oil, or coal must be burned to produce the electricity used to recharge the batteries.

California's quest has had the effect of boosting prospects for low-emission vehicles that are hybrid (combined gasoline engines and electric systems that work together). Hybrid features that save fuel include automatic shutdown of the engine at stops and regenerative braking (converting the work done in braking into energy stored in the battery). In hybrids, the gasoline engine runs only at or near peak efficiency, and excess energy recharges the batteries. Since the fuel is conventional and the electric system recharges in use, there is no need for a special infrastructure as is the case with pure electrics. Honda introduced the first commercial hybrid, the Insight, followed quickly by Toyota with the Prius. Honda has begun to sell Civic hybrid models.

Fuel cells, which are devices that combine fuel (ideally hydrogen) with oxygen from the air without combustion, are expected to supply automobiles with energy in the near future. If the hydrogen were produced by electrolysis using solar energy, such a vehicle really would involve zero emission (outside the water made from combining hydrogen and oxygen). Fuel cells have been used in the past for transportation, but usually liquid metal fuel cells in buses because of the relatively high temperature of operation (300 to 1200°C). The development of low-temperature proton-exchange membrane fuel cells have led the auto manufacturers to engineering development. These are typically 50% efficient at transforming fuel to energy, about twice as efficient as Otto engines. (Very small fuel cells are being used as an alternative to battery packs in some electronic devices.)

The fuel cell option suffers from a lack of an infrastructure to supply the hydrogen to vehicles and the problem of how to carry sufficient hydrogen. Hydrogen is a dilute gas, and it has a very much smaller amount of energy per volume than liquid fuels. Possible solutions to the storage problem range from mixing hydrogen into borides to pressured tanks to storage as hydrides in metal containers. However, many questions still surround the storage question. Alternatively, methanol (a liquid) can be chemically transformed to produce hydrogen, and this may be a more probable choice for the short term. The disadvantage is the presence of carbon dioxide in the exhaust stream.

4.6 Industry

Together, commercial and industrial energy uses total 54.3 EJ, of which 41 EJ is industrial energy use. Industry was hardest hit by rising energy prices in the aftermath of the energy crises and had the largest incentive to reform. Indeed, the industrial sector has saved a considerable amount of energy since then (Fig. 4 shows how the industrial sector energy use breaks down). Work has been done on design of variable-speed motors and control mechanisms for machines used in industrial processes. Motors are much more efficient than those of a generation ago. Compressors are especially important to consider, as many heavy industries use compressors for many different purposes.

Many industries have the same opportunity as commercial business for reduction in energy use in offices—installation of newer, more efficient HVAC systems, replacement of ballasts for fluorescent lighting, or installation of compact fluorescents in place of incandescents, and so on. Industries often buy their electricity on a "interruptible" basis, meaning that the utility can cut them off if demand from other users is high; the industry gets concessional electricity rates in return. The processes can be designed to result in "load leveling" for the utility's demand. For example, the industry can use high demand when the utility's other customers are near the low point of demand; this helps the utility by increasing base load slightly (base load is cheapest). Many energy management control systems have been designed that automatically shuffle load on and off in response to external conditions.

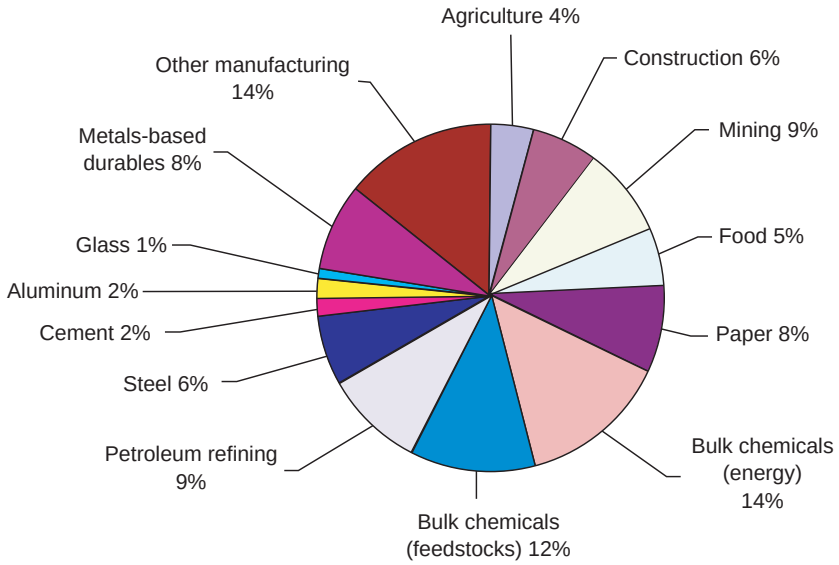

FIGURE 4 Breakdown of the energy use by industrial subsector 1992. From Interlaboratory Working Group, "Scenarios for a Clean Energy Future," Figure 5.1.

While much work has been done, opportunities remain for reducing industrial process energy use. In a 1992 study concerning reduction of carbon dioxide emissions by the United States, a National Academy expert panel identified billions of dollars in savings that would result from changing processes and materials with the aim of lowering carbon emissions (i.e., negative real cost), even in as mature an economy as was current in the United States at that time. Few of its recommendations have been adopted, mostly, it seems because of the attitude that we have not done it that way in the past (in other words, another case of inertia holding back rational change).

Opportunities remain, especially in mining technology, metals refining and working, and chemicals (large subsectors from Fig. 4). In steel processing, hot rolling of metals is being replaced by direct casting and rerolling in small hot strip mills as needed. Scrap to be melted can be preheated using furnace waste heat, reducing overall energy use. More than 50 such energy-saving measures have been identified in the steel industry alone.

Dow Chemical has been a leader in making waste streams into resource streams for other parts of the company or for other companies. This benefits society both by reducing waste emissions and reducing the impact of obtaining the resource. Dow has experienced economic returns over 100% on some programs. If such a well-managed company can find such opportunities, it is clear that practically all other companies can benefit. Experiences such as this and the success of the independent companies colocated in Kalundborg, Denmark, in exchanging materials to mutual benefit have led people to speak of a new field of study they call industrial ecology. There is a hope that bringing attention to these possibilities will result in greater savings and efficiencies in the future and that companies can learn from the best practices of other companies.

The science of chemical catalysis, originally strongest in the petroleum industry, has spread to other industrial sectors. Catalysts are chemicals that increase reaction rates without being themselves consumed in the process. Increases in reaction rates at low temperatures saves the application of thermal energy to raise the temperature (as reaction rates generally increase with temperature).

Glassmaking is an industry that uses a lot of energy per kilogram of output because of the necessity of melting the constituents of glass (or melting glass when it is recycled). New refactory materials have reduced energy use in the glass industry at no cost.

The agricultural industry is one area where penetration of ideas is slow; more energy conservation measures need to be implemented. Individual farmers are rugged individualists and apt to think in many instances that any change is for the worse. One promising avenue is for a combination of chemical and agricultural industry to grow chemical feedstocks

and to achieve ways to grow plastics in the field. For this to be entirely successful, negative attitudes held by the general public toward genetic manipulation may have to be abandoned.

4.7 The Utility Industry

Utilities are large-scale users of fossil fuels. In 2000, utilities used 42.6 EJ of mostly fossil energy, 41% of total U.S. energy use. Because they use so much energy, there is a built-in incentive to adopt the most energy-efficient equipment possible. While the average 33% efficiency in transforming thermal energy into electrical energy seems small, it is far improved from the original generators in the industry a century ago. Progress has generally been incremental, but the advent of integrated gas combined cycle power plants (known as IGCC plants) in the late 1980s and 1990s has boosted output efficiency substantially. Some combined cycle plants are operating near 60% efficiency, not far from the Carnot cycle limit. Gas turbine generators now use aircraft turbines almost unmodified and are much higher in efficiency than previous gas-fired turbines.

One way for the utility to save money is to even out its demand, as referred to briefly earlier. It is to the utility's benefit to assure that as much energy sold as possible is base load, the cheapest energy the utility can generate. The smaller the demand for high-cost peak energy, the better off the utility is. Therefore, utilities offer preferential rates to industrial users who are willing to have their electricity shut off or radically decreased when demand spikes from other users. This is known as load leveling.

Even individual users can sign up for interruptible rates if they are willing to allow the utilities to shut them (or their largest appliances such as air conditioners or water heaters) down as needed. Electronic devices can be installed that give the utility control over whether the individual interruptible appliances are on or off. The homeowner or business owner agrees to allow the utility to shut them off as needed when demand for electricity is high.

4.8 Cogeneration and Net Metering

By cogeneration, we mean generation of electricity as an incidental outcome of industrial production. For example, the paper industry uses a great deal of hot water, and produces the hot water in boilers. It could use the steam produced to run turbines and generate electricity. In the early days of electricity distribution, this occurred regularly, but with the formation of utility monopolies in the late 1800s, industrial producers were not allowed to sell their energy offsite. Given the obvious advantage (two gains for the price of one), restrictions were first loosened after the energy crises of the 1970s and 1980s, and then vanished altogether. Cogeneration has become more widespread since the 1980s. The utility typically signs a purchase agreement with the cogenerator with a contracted rate schedule. The sale of electricity contributes to the seller's bottom line.

The same dynamic is at work on the much smaller scale of the individual electric utility customer in the question of whether states have "net metering" laws. Cogeneration can occur at the scale of an individual home. Customers who install solar energy generators but remain connected to the grid for backup in states without net metering can decrease their electricity costs by using "home-generated" electricity in place of buying, but they cannot sell any excess back (the utility gets it for free). In states with net metering, the excess electricity is bought by the utility (albeit at a lower rate than the customer usually pays for electricity), in some cases leading to reverse bills—utility payments to customers for energy sold back that exceed the value of energy sold to the customer.

7. Conclusion: Rethinking Energy Consumption

Glossary

nontechnical barriers The idea that the "attitudes" of decision makers toward technology are the key determinants of innovation and that apathy, ignorance, and lack of financial interest are the major obstacles.
socially relevant actors The broad networks of individuals and organizations that may have an influence on technical change.
sociotechnical The idea that science is a sociocultural phenomenon and that the technical is always in relationship with wider social, economic, and political processes.
technical frames The sets of assumptions and culturally conditioned ways of seeing that underpin individual or organizational perspectives on technical change.
technoeconomic The idea that if technical knowledge is rigorously tested and demonstrably proved, then consumption choices will be made rationally.
universe of choice The multiple rationalities shaping technical innovation and how these relate to the contrasting contexts in which design and development actors operate.

The contribution of building science to our stock of energy efficiency knowledge is substantial. Energy-saving technologies and materials have been successfully developed and manufactured, and energy-efficient building designs have been constructed, tested, and widely publicized. In fact, for some time, designers have possessed the technical knowledge and identified the best practice design techniques necessary to construct zero-energy buildings. Moreover, extensive monitoring of local, national, and international building stocks means that more is known than ever before about the precise potential for improved energy performance. Having perfected energy efficiency technologies, the next task is to explain why apparently proved technical knowledge is often ignored in design practices, or why building occupants consistently fail to adopt energy-saving techniques. Facing the "inadequate diffusion" of apparently cost-effective energy-conserving technologies, the practice of building science is extended to consider the nontechnical processes of technology transfer and arrives at the complex question of consumption.

1. INTRODUCTION

> *Those who call ourselves energy analysts have made a mistake…we have analysed energy. We should have analysed human behaviour.*
>
> *—Lee Schipper, 1987*

> *A renewal of the social theory which informs energy consumption and conservation is called for in the face of environmental challenges.*
>
> *—Hal Wilhite, 2003*

Many researchers, like Schipper and Wilhite, are now questioning the notion that the challenge of improving the energy performance of buildings is simply a task for "building science," a term now widely used to describe the growing body of knowledge about the relevant physical science and its application to buildings. Across international boundaries and research cultures, the common aim of building science is to produce more and better

 © 2004 Elsevier Inc. All rights reserved.

knowledge about buildings and how they perform in order to identify promising solutions to the problem of energy inefficiency. The critical issue here is the definition of "better knowledge" about building performance and the subsequent identification of problems and solutions within a scientific, or techno-economic, paradigm. As with other branches of physical science, the reactions of materials and other inanimate objects are the legitimate interests of the building scientist. Like problems of rain penetration, fire safety, or structural soundness, the issue of energy efficiency in buildings becomes defined as a technical problem amenable to scientific methods and solutions. The belief is that proved technical solutions are transferable and readily applicable to other technically similar situations. Consequently, the research agenda of building science is geared toward the scientific resolution of what are taken to be physical problems. Energy is no different. As Loren Lutzenhiser points out, to date, energy management strategies have "focused almost entirely on the physical characteristics of buildings and appliances." Vast sums of money have been, and continue to be, invested in scientific research to identify and fulfill (at least experimentally) the technical potential for energy savings in buildings.

2. THEORIES OF TECHNICAL CHANGE

Acknowledgment that an actual improvement in buildings has not always matched growth in knowledge has led to the realization that building scientists must appreciate the contribution of the life sciences. Here, the most natural fit has proved to be between building science and economic theory. Economists reinterpret social processes in terms of a market arena that neatly divides the world into separate, but interlinked, domains of knowledge and action. A world of perfect information, on the one hand, and a definable logic of (utility-maximizing) rationality, on the other hand, are posited. This confidence in the capacity of individual decision makers to quantify the benefits of energy efficiency economically is central to the technoeconomic view of technology transfer. The ability of building users literally to count the costs of energy consumption will ultimately lead to more rational energy use. This approach has found eloquent expression in the field of energy economics, and the use of energy audits that enable the new user to cope with the complex conversion equations and calculation of energy costs per standard unit. As Chadderton makes clear, the link to economics is explicit:

> *An energy audit of an existing building or a new development is carried out in a similar manner to a financial audit but it is not money that is accounted. All energy use is monitored and regular statements are prepared showing final uses, costs and energy quantities consumed per unit of production or per square metre of floor area as appropriate. Weather data are used to assess the performance of heating systems. Monthly intervals between audits are most practical for building use, and in addition an annual statement can be incorporated into a company's accounts.*
>
> —*D. V. Chadderton, 1991*

This model of rational action suggests that financial and energy consumption-related decisions are comparable, and that business and domestic users alike are self-interested, knowledgeable, and economically calculative when considering energy measures. Lutzenhiser illustrates this in regard to business users in particular who, skilled at marginal cost and future calculations, would "only seem to need to see the potential competitive economic advantage of innovation to move towards energy efficiency." Following a similar logic, the development of a visible market for energy efficiency would, in turn, encourage domestic consumers to minimize their costs by substituting more efficient ways of satisfying needs for energy services such as heating, cooling, or water heating. Here, the methodological presumption of building science, that with careful monitoring and scientific control it is possible to reproduce the technical achievements of the laboratory universally, is mirrored by an economic logic that promises that technological potential will be fulfilled in any market situation that demonstrates a "static, intertemporal, and intergenerational Pareto optimality." Put simply, the view is that economically rational actors, replete with the necessary technical and economic information, will consistently put science into practice. As Hinchliffe puts it, "a rational, profit maximising man is visualised at work, at home and at play," whereas "the engineering model tends to picture humans as optimally utilising technologies after the fashion of their creators." This epistemological coalition of building science and economics has led, internationally, to a prescriptive view of technological diffusion based on the twin technical and economic logics of proved, replicable, science and idealized consumer behavior. As Lutzenhiser suggests,

> *As a result, a physical–technical–economic model (PTEM) of consumption dominates energy analysis, particularly in energy demand forecasting and policy planning. The behaviour of the human 'occupants' of buildings is seen*

as secondary to building thermodynamics and technology efficiencies in the PTEM, which assumes 'typical' consumer patterns of hardware ownership and use.

—L. Lutzenhiser, 1993

The technoeconomic view of energy efficiency suggests that if technical knowledge is rigorously tested and demonstrably proved, and if "market forces" are not "disturbed," then consumption choices should be taken rationally, with the "right decisions being taken by millions of individual consumers, both at home and in their place of work." The role of policymakers is clear, "to set the background conditions and prices such that consumers will take decisions which are both in their own and the national interest."

3. BARRIERS TO ENERGY EFFICIENCY

This way of seeing technical change is not merely a matter of the attitudes or perceptions of individual policymakers. Rather, it provides an organizational logic or operating principle on which energy research and policy proceeds. This epistemic view represents a specific social organization of technical development and diffusion. The outcome of this view in policy terms is that human and financial resources are, almost exclusively, committed to demonstrating continually the technical efficacy of energy-efficient innovation through regulation, the provision of information about technical means to reduce energy consumption, and the development of best practice demonstration schemes. That policymakers, industry, and nongovernmental organizations all find consensus in this model of technological diffusion is perhaps not surprising, given its strikingly familiarity in the wider world of environmental policy debates.

Stephen Trudgill has, approvingly, formalized the technoeconomic way of seeing innovation in his formulation of the Acknowledgment, Knowledge, Technology, Economic, Social, Political (AKTESP) barriers to the resolution of environmental problems. Trudgill presents an image of technological innovation as a path from ignorance to enlightenment, with the evils of social, political, and economic reality cast as unpredictable obstacles to an otherwise assured technical utopia. Critically, the key to overcoming AKTESP barriers is almost always located within individual motivations. As Trudgill puts it, "motivation for tackling a problem comes from our moral obligation and our self-interest in enhancing the resource base and its life—thus enhancing, rather than destroying, planetary ecosystems and plant and animal species, including ourselves." When such motivation arises, we are in a position to solve the remaining barriers to the solution and to the implementation of environmental problems. The vocabulary of solution and implementation contains similarly individualized terms: "inadequacy of knowledge," "technological complacency," "economic denial or complacency," "social morality/resistance/leadership," and "political cynicism/ideology." Within this model of technical change, individuals are consistently the linchpins of effective energy-saving action. Changes in the level of the energy demand of the built environment is seen as a process involving "thousands" of individual judgments by property owners and other decision makers. The technical, organizational, and commercial complexity of energy-related decision-making is here replaced by an image of autonomous actors, each free to commit themselves to a more sustainable urban future. As Nigel Howard has argued, "there are lots of decision-takers. There are lots of people who have to be influenced, right from government to local authorities, developers, designers, material producers, professional and trade bodies. They all have a role to play. And what we have to do is try and influence all of them." This way of seeing energy views more or less "rational" individuals as both the solution to and the cause of energy-related environmental problems. Bewildered by the apparent irrationality of the social world, government, commercial, and voluntary interests in energy efficiency have all committed to a technoeconomic view of technology transfer, whereby established, proved, scientific knowledge is impeded by lack of information and/or by other nontechnical barriers. As Kersty Hobson puts it, "the drive to provide individuals with information, either to 'create' responsibility or to affect consumption, underpins the choice of national policy mechanisms used to forward sustainable consumption issues."

We are faced here with a self-sustaining, mutually reinforcing package of beliefs spinning between the realms of technology and policy without really belonging to either. Each element of the pervasive bundle, the transferability of technical knowledge, the individualistic theory of technical change, the sequential logic of research and development, and the implicit distinction between the social and the technical, feeds into the next, creating a web of belief strong enough to encapsulate technical researchers and their project officers and elastic enough to span countries and continents.

4. LEAPING THE BARRIERS

> *By defining what is acceptable as evidence, certain privileged methods also act to exclude other sorts of data. It is in this way that certain questions remain unmasked, and certain types of evidence are ignored or dismissed as invalid.*
>
> —*M. Leach and R. Mearns, 1995*

Leach and Mearns' observations highlight how wide acceptance of the technoeconomic view of technology transfer has hitherto marginalized explanations of technical innovation concerned with the social shaping of technical change. As Thomas Hilmo suggests, the notion of barriers suggests that "problems are absolute" and that "some actors [scientists] know the truth about a problem," whereas "other actors [nonscientists] do not and obstruct the solutions in different ways." Hence, the role of social scientist is in turn reduced to that of market researchers, typically undertaking attitudinal surveys designed to identify the human barriers to good energy practice that the promotional campaigns are designed to overcome. This research has typically been described as exploring the behavioral or human dimensions of energy efficiency. While drawing on diverse intellectual sources from economic sociology to environmental psychology, such research shares a view of energy efficiency as the product of a slow cascade of more or less rational individual choices. Although Stern and Aronson usefully identify five archetypes of energy user (the "investor," "consumer," "member of a social group," "expressor of personal values," and "avoider of problems"), their narrow focus on the attitudes and motivations of individual energy consumers tends to isolate and atomize the decision-making process. Little is heard in this research about the consumption practices of organizations, or the role of the organizational actors and groups that actually design, finance, and develop buildings. As Janda points out, although this approach "usefully delineates differences in individuals' attitudes, human dimensions research does not reveal where these differences originate, how they develop, or if they can be changed." Attitudes and decisions are always shaped and framed within wider social processes. Abstraction of the opinions and outlook of energy consumers, and of design and development actors from the contexts of production and consumption, tends to isolate and freeze what are always contingent practices. This narrow, behavioral view of technical change fails to recognize the routine complexities of energy-related decision making. In particular, there is little room in this model to view technical innovations and social processes as interrelated, or to assess how energy-efficient choices may be embedded in the mundane routines of domestic life and commercial practice.

The technoeconomic way of seeing energy efficiency can be contrasted with an alternative view, the sociotechnical, which has questioned what Michael Mulkay has termed the "standard view of science," a view that exists, already formed, outside society. In its place, a broad church of sociologists have presented a revised image of science as a "sociocultural phenomenon" that questions the "authority of science," locates "knowledge-claims in their social context," and identifies the "relationship between such contexts and wider economic and political processes." This approach to understanding science and technical change can be characterized by a series of questions. Volti asks, for example, "What accounts for the emergence of particular technologies? Why do they appear when they do? What sort of forces generate them? How is the choice of technology exercised?" Rather than analyze the process of technical change internally, in terms of developments within the technology, or by reference to the ideas of famous scientists, inventors, and entrepreneurs, such research is interested in discovering to what extent, and how, does the kind of society we live in affect the kind of technology we produce. Or, as McKenzie and Wajcman ask, "What role does society play in how the refrigerator got its hum, in why the light bulb is the way it is, in why nuclear missiles are designed the way they are?"

Questioning the notion that technological change has its own logic, this way of seeing technical change recognizes the wider social contexts within which design solutions emerge and patterns of consumption evolve. Rather than viewing science and technology as asocial, nonpolitical, expert, and progressive, innovation is viewed by Andrew Webster as a "contested terrain, an arena where differences of opinion and division appear." In relation to analysis of energy problems, such research avoids individualist explanations of technological innovation (the rational energy consumer), rejects any form of technological determinism (technical innovation as handmaiden to an energy-efficient economy), and, critically, refuses to distinguish prematurely between technical, social, economic, and political aspects of energy use. As Thomas Hughes has graphically illustrated, in exploring the development of the American electricity system, "sociological, technoscientific and economic analyses are permanently

woven together in seamless web." In this world without seams, social groups and institutions are considered, alongside technological artifacts, as actors who actively fashion their world according to their own particular logic of social action. This sociotechnical analysis of energy use replaces technoeconomic descriptions of universal barriers to energy-efficient innovation (apathy, ignorance, lack of financial interest), with analysis of the ways in which the changing social organization of energy-related choices structures opportunities for more efficient energy use.

There are complementary methodological issues at stake here. Bridging the theoretical gap between the social and technical features of energy use demands a more qualitative research agenda. Rather than solely relying on positivist research tools such as surveys, opinion polls, and statistical analysis, undertaking sociotechnical research means attempting to peer over the shoulder of the actors making energy-related decisions by following actors through their professional and personal routines. In this way, research into energy efficiency finds itself on what Michel Callon has termed a new terrain: that of "society in the making." This refocuses analysis away from pure energy questions to a wider set of debates about design conventions, investment analysis, development costs, space utilization, and market value. Idealized notions of a rational energy user or best technical practice make little sense here. Instead, the social and the technical form a network of associations that serve to frame the meaning of energy efficiency, thereby encouraging or delimiting opportunities for innovation over time and space, and between organizational settings.

5. CONTEXTS OF CONSUMPTION

A significant amount of academic work has been undertaken in an attempt to put energy use into its social context. Social psychologists and sociologists have emphasized the importance of seeing energy problems and solutions in terms of "social systems rather than single causes," the need to design energy systems for "adaptability as an alternative to detailed planning," and, as Stern and Aronson argue, to treat energy policies and programs as forms of "social experiment." Reviewing this work, Lutzenhiser found "a consensus in the literature" that to understand the sociotechnical complexity of energy-saving action, policymakers must be concerned more directly with "the social contexts of individual action." As Lutzenhiser points out,

> *While the physical–technical–economic model assumes consumption to be relatively homogenous and efficiency to be driven by price, the empirical evidence points towards variation, non-economic motives, and the social contexts of consumption. Economics can supply normative guides regarding when investments would be economically desirable, but it tells us little about how persons actually make economic decisions.*
>
> —*L. Lutzenhiser, 1993*

Both Lutzenhiser and Wilhite draw attention to the social nature of energy consumption and the social dynamics of change as a form of "social load." These social loads have peaks that drive the dimensioning of peak energy loads. Wilhite provides examples from his anthropological research into lighting use in Norway. Here, home lighting is designed not simply to provide a sufficient degree of brightness to support basic human activity, but rather to provide a "cozy aesthetic." A dark house was described by Wilhite's respondents as a "sad house." Extra lighting fittings are always fitted and utilized to make sure guests feel cozy, and for social visits on a winter evening, lights are left on in every room to provide a welcoming glow as guests arrive. This, of course, means the use of extra energy. In his study sample, Wilhite discovered an average of 11.5 lights per living room. This social peak "drives the dimensioning of the material and energy system behind lighting, which based on a straightforward provision of lumens would be far smaller." As Wilhite argues elsewhere, "the things we use energy to achieve—a comfortable home, suitable lighting, clean clothes, tasty food—have also been assumed in models of consumption to be generic and physically determined." Wilhite goes on to argue that there is an "urgent need for the development of a more robust theory of consumption, one which incorporates social relations and cultural context, as well as perspectives on individual agency and social change."

6. SOCIOTECHNICAL THEORIES OF CHANGE

In Table I, the two broad positions outlined so far are contrasted. The effect of these analytical assumptions is cumulative, with a technoeconomic or sociotechnical view of buildings as an artifact leading correspondingly to a particular way of viewing energy-efficient design, energy-saving action, technical innovation, or market failure. Commitment to

TABLE I

Ways of Viewing Energy Efficiency in Buildings

	Perspective	
Aspect	**Technoeconomic**	**Sociotechnical**
Buildings	Materially similar, physical structures	Material product of competing social practices
Energy-efficient design	Replicable technical solutions	Outcome of conflicting sociocommercial priorities
Energy-saving action	Individual, rational decision-making in a social vacuum	Socially structured, collective choices
Technological innovation	Series of isolated technical choices by "key" decision makers	Technical change embedded within wider sociotechnical processes
Market failure	Existence of social barriers	Lack of perceived sociocommercial viability
Image of energy consumers	More or less rational	Creative, multirational, and strategic
Role of social science research	Evaluation of technical potential and the detection of environmental attitudes and nontechnical barriers	Identification of context-specific opportunities for technological innovation
Energy policy	Provision of information, granting of subsidies, and setting of regulations	Forging of context-specific communities of interest and promotion of socially viable pathways of innovation

either a predictable linear or socially shaped diffusion pathway for energy-efficient technologies frames the contribution of social science research to understanding innovation and the direction of energy policy-making.

These competing ways of seeing energy consumption raise a number of research dilemmas. Commitment to a technoeconomic or sociotechnical perspective on innovation focuses attention on different actors (key decision makers vs. relevant social groups), different practices (technical design vs. development strategies), and different processes (technological diffusion vs. social and commercial change). We are seemingly faced with a series of choices over how we conceptualize the problem of energy consumption in buildings. As Groak suggests, we can view buildings in terms of their physical attributes, as "essentially static objects" formed in a relatively standardized manner from an assembly of interconnecting construction materials. Seen this way, buildings appear remarkably similar. Irrespective of geographical location, ownership patterns, or operational function, the technical character of building form appears comparatively homogeneous. Alternatively, we could view buildings as material products of competing social practices. This would suggest a different analytical approach. For sociologists such as Bruno Latour, understanding "what machines are" is the same task as understanding "who the people are" that shape their use. Seen this way, technologies and technological practices are as Bijker and Law have illustrated, "built in a process of social construction and negotiation," a process driven by the shifting social, political, and commercial interests of those actors linked to technological artifacts of design and use. Although the complexity of buildings differs from the individual technologies often studied within sociological studies of science and technology, we can nevertheless develop a similar analytical approach. Thus, to understand buildings we must trace the characteristics of the "actor world" that "shapes and supports" their production. Adopting this perspective would mean relating the form, design, and specification of buildings to the social processes that underpin their development. So, although two identical buildings, standing side by side, may well appear physically and materially similar, investigation of their respective modes of production and consumption may reveal profoundly different design rationales, which in turn might help explain variations in energy performance.

This stress on the social organization of design is at odds with the technoeconomic perspective that emphasizes how a repertory of well-tried technical solutions provides reliable precedents for designers. Here, new technical challenges are seen as solvable by shifts in design emphasis, mirroring the march of scientific progress. Although the form and specification of buildings may well vary spatially with climate and culture, the objective is always viewed as the

same, i.e., the provision of the universal needs, shelter and comfort. Technical design is viewed as a process of adaptation and modification to suit changing physical circumstances. Emphasizing the social logic of design raises a different set of questions. Rather than supporting a linear model of innovation, studies in the sociology of technical change have revealed the multidirectionality of the technical design process. Rather than one preordained process of change, we are faced with competing pathways of innovation. Typically, Pinch and Bijker describe the development process of a technological artifact as "an alternation of variation and selection." For example, Wiebe Bijker's study of the development of fluorescent lighting points to a range of innovation pathways that could not be resolved by appeals to technical superiority. Instead, a standoff between lighting manufacturers (who supported a high-efficiency daylight fluorescent lamp) and electric utility companies (who, worried about the effect on electricity sales, supported an energy-intensive tint-lighting fluorescent) led to the introduction of a third design alternative, the high-intensity daylight fluorescent lamp, which combined efficiency with a high light output, thereby maintaining electricity demand. Bijker's study illustrates how a socially optimal design was established from a range of technically feasible possibilities through a process of compromise between competing social interests. In doing so, he highlights the "interpretative flexibility" of design. We might similarly ask how rival energy-efficient designs are valued by different members of the design and development process and how this process of contestation and compromise frames the resulting design strategies.

In approaching these questions, we might begin to draw attention to the idealism surrounding the technoeconomic image of enlightened, rational individuals motivated by a growing stock of technical knowledge. Although these more, or sometimes less, knowledgeable individuals are placed in a hierarchy of influence—from the key decision makers, designers, and top managers, to technicians and lower management, to domestic consumers—their social, spatial, or temporal situation appears of marginal importance. From a sociotechnical perspective, the relationship between individual and context is emphasized and made fluid. Particular technical choices are viewed as expressive of the prevailing social, political, and commercial pressures operating within spatially and temporally contingent contexts. Here, technical choices are not considered to be solely determined by knowledge or motivation, but are shaped by the existence of a more or less socially favorable context. For a variety of reasons, consumers may be unable or prefer not to use particular technologies, or may even use technologies in unpredictable ways not envisaged in the original design. To understand this social structuring of technical choice, Ruth Schwartz Cowan, in her history of home heating and cooking systems in America, treats the consumer "as a person embedded in a network of social relations that limits and controls the technological choices that she or he is capable of making." For Cowan, consumers come in "many different shapes and sizes," and operate in a variety of social contexts. Her analysis of the introduction of cast iron stoves to replace open hearth fires for cooking traces the interconnections between stove producers and merchants, fuels suppliers and merchants, and their networks of influence through production, wholesale, retail, and household domains over both urban and rural consumers. This emphasis on the embedding of the decision maker within wider social networks focuses analytical attention on the "place and time at which the consumer makes choices between competing technologies." This allows Cowan to unpack the "elements" more "determinant of choices" and the technical pathways that "seemed wise to pursue" or that appeared "too dangerous to contemplate." As Cowan points out, "today's 'mistake' may have been yesterday's 'rational' choice." Drawing on this approach, a sociotechnical perspective on energy efficiency might identify the multiple rationalities shaping innovation and how these relate to the contrasting "universe of choice" in which design and development actors operate.

If we begin to accept that the nature and direction of technical change are subject to interpretative flexibility, underpinned by multiple rationalities of context-specific choice, then we would also have to begin to alter our understanding of the process of technological innovation. As we have seen, the technoeconomic perspective views technical change as following an almost preordained pattern of design, development, and diffusion. By contrast, a sociotechnical analysis would explore why particular technical solutions emerged at a certain time and in a particular place. For example, in studying the electrification of cities, David Nye illustrates how the emergence of street lighting was less connected to the rational technical ordering of urban space, and more intimately linked to the need of utility companies to increase load and to the commercial instincts of shopkeepers keen to attract business. Nye

suggests that "shopkeepers understood lighting as a weapon in the struggle to define the business center of the city dramatizing one sector at the expense of others." Framed this way, "electric lighting could easily be sold as a commercial investment to increase the competitiveness of a business." As a result, the subsequent spread of street lighting was accelerated as "electrification of one street quickly forced other commercial areas to follow suit or else lose most of their evening customers." Following this lead, a sociotechnical analysis of energy efficiency would ask what roles were played by architects, developers, governments, investors, manufacturers, retailers, and consumers in fashioning innovation in building design and use. This approach would mean widening the nature of analytical inquiry away from explicit decisions about energy efficiency studied in isolation, to an examination of the embedding of energy-related choices in the manufacture, distribution, and retailing of the technologies, and the commercial processes framing building design and development.

Finally, asking different questions about the process of technical innovation may provide a different understanding of the market success or failure of proved energy-saving technologies. Instead of characterizing nontechnical barriers as both universal and timeless in nature, a sociotechnical approach would explore the degree to which the marketability of technical innovation can be identified as a socially, and temporally, contingent process. For example, Gail Cooper highlights how the seemingly pervasive nature of air-conditioning systems in the United States masks a more contested story about the emergence of heating, cooling, and ventilating technologies. She shows how attempts by engineers to promote the most "technically rational design," which demanded sealed buildings and passive use, was resisted by what engineers saw as "irrational users" who preferred mobile, plug-in air-conditioning systems that, although less efficient, provided greater flexibility and active control. As Cooper suggests, "the engineering culture that characterised the custom-design industry did not produce the best technology, neither did the market forces that dominated the mass production industry." The result is localized compromises that reflect the "seesawing power relations surrounding the development of air-conditioning." In particular, Cooper's study underlines the contrasting image of the energy consumer underpinning the technoeconomic and sociotechnical views. Put simply, the techno-economic "irrational user" is translated in the socio-technical literature into a "guerrilla fighter of those disenfranchised from the design process." Herein lies a key distinction. Rather than assume the intrinsic marketability of technically proved innovations, a sociotechnical approach would assess the socio-commercial viability of the artifact in varying social contexts. Instead of explaining market failure in terms of ubiquitous and timeless barriers, a socio-technical analysis would seek to explain market success or failure in situationally specific situations. Some contexts may favor innovation, others may not. Mapping what Bijker terms the "technical frames" of "socially relevant actors" is vital here, for, as Cowan points out, any one of those "groups or individuals acting within the context of their group identity…may be responsible for the success or failure of a given artefact."

7. CONCLUSION: RETHINKING ENERGY CONSUMPTION

> *The understanding of present and future energy use depends upon understanding how conventions and practices evolve over time and within and between cultures.*
>
> —*Hal Wilhite, 2003*

The aim of this new agenda is not to produce abstract social theory. Instead, a growing number of social scientists are striving to articulate a new role for social science in research and policy debates about energy consumption and environmental change. These researchers are exploring the heterogeneous and contested nature of consumption practices that shape energy use. Rather than simply assuming that people use energy, they are analyzing how energy intersects with everyday life through diverse and cultural inscribed practices such as heating and cooling, cooking, lighting, washing, working, and entertaining. To achieve this, they are drawing on methods and theories beyond science and economics, including sociology, anthropology, geography, psychology, and cultural studies, and are learning lessons from consumption debates beyond energy and the environment, including fashion, food, and shopping.

The scope of this research agenda takes us far beyond the technoeconomic analysis of energy consumption, which tends to be dedicated to identifying the potential scope and scale of energy performance improvements in different building types and in different building sectors, and to the setting of technically feasible CO_2 abatement targets. It also suggests a role for social scientists much

deeper than the forms of market research, evaluating the attitudes of what are taken to be key decision makers toward energy that typify research on human behavior and attitudes. In developing a sociotechnical approach to energy consumption, the concern is more with identifying context-specific opportunities for inserting technically proved technologies into appropriate social practices. But rather than being led by calculations of technical potential, the task is to seek to identify how specific social, spatial, and temporal configurations of energy consumption encourage, or mitigate against, effective energy-saving action. The result is stories about the circumstances in which energy efficiency and conservation practices do or do not flourish. This focus takes us far from the world of building science and the paradigmatic certainties of the technoeconomic perspective, and instead reveals the construction of energy knowledge in varying social worlds and reflects the contested nature of energy consumption practices.

Glossary

basal metabolic rate A measure of nutritional energy needed by an organism during a fasting and resting state.

bovines Large ungulate mammals belonging to genus *Bos* (cattle) and *Bubalus* (water buffalo) that were domesticated for dairy production and draft labor.

draft animals Domesticated large ungulate mammals of several families (bovines, horses, and camelids) harnessed for fieldwork or transport duties.

horses Large ungulates of the genus *Equus* that were domesticated for heavy agricultural labor and transport draft as well as for riding and warfare.

metabolic scope Multiple of the basal metabolic rate achieved during periods of maximum exertion.

The power of human and animal muscles, limited by metabolic rates and mechanical properties of working bodies, restricted the productive capacities, and hence the typical quality of life, of all preindustrial civilizations. Only the widespread adoption of inanimate energy converters replaced these animate (or somatic) energies as the most important prime movers of human society. This epochal energy transition began in parts of Western Europe and North America during the early 19th century and it was basically completed during the first half of the 20th century. In contrast, in scores of low-income countries both the subsistence agricultural production and many industrial tasks are still energized by human and animal muscles.

Human labor was the only prime mover in all subsistence foraging (gathering and hunting) societies. Simple wooden, stone, and leather tools (including digging sticks, bows and arrows, spears and knives, and scrapers) were gradually invented and adopted in order to increase and extend the inherently limited muscle power. The only extrasomatic energy conversion mastered by foraging societies was the use of fire for warmth and cooking. Even those early agricultural societies that domesticated large animals continued to rely largely on human muscles, but they increased their effectiveness by multiplying individual inputs through concentrated applications of labor and by using simple but ingenious mechanical devices.

The first approach had logistic problems. For example, only a limited number of people can grasp a small but heavy object to carry it, and merely multiplying the number of available hands makes no difference if the object is to be raised far above the people's heads. The second approach relied largely on the three simplest aids, levers, inclined planes, and pulleys, and their common variations and combinations, including wedges, screws, wheels, windlasses, treadwheels, and gearwheels. These tools and machines were used by virtually all old high cultures. They enlarged the scope of human action but their use had obvious physical limits (e.g., the maximum practical length of levers or pulleys). However, some societies that commanded just the muscle power were able to complete, aided by careful organization of complex tasks, such astounding projects as the megalithic structures at Stonehenge or on the Easter Island, the pyramids of Egypt and Mesoamerica, and

massive stone temples, walls, and fortresses on every continent except Australia.

Harnessing of large domesticated animals made the greatest difference in agricultural productivity. Depending on the soil type, a peasant working with a hoe would take 100–180 h to prepare 1 ha of land for planting cereals. A plowman guiding a single medium-sized ox pulling a primitive wooden plough could finish this task in just over 30 h. Use of a pair of horses and a steel plough reduced the time to less than 10 h and in light soil to just 3 h. Hoe-dependent farming could have never reached the scale of cultivation made possible by draft animals, and many tasks, including deep plowing of heavy soils, would have been entirely impossible without draft animals.

Draft animals harnessed to wheeled vehicles also made major contributions to land transport, construction, and industry. Wheelbarrows provided the most efficient way for an individual to transport goods, with an adult man covering approximately 10–15 km a day and moving usually less than 50 kg. Oxen were not much faster but could pull wagons up to 10 times that weight. Heavy horse-drawn wagons covered 30–40 km a day, and passenger horse carts on good roads could travel 50–70 km (galloping messengers on Roman roads could ride up to 380 km per day). Oxen and horses were deployed to transport heavy materials to building sites, such as medieval cathedrals or Renaissance villas. Horses were also used for many tedious tasks in the early stages of expanding coal extraction and incipient industrialization of the 17th and 18th centuries. Here, too, there were obvious logistic limits, no matter if the animals worked alone or in groups. Large and heavy animals could not be deployed in low and narrow mine tunnels, and smaller animals were often inadequate to perform tasks requiring hours of nonstop draft.

Harnessing of more than 20 animals to be guided as a single force is difficult, and harnessing more than 100 of them to get 100 kW of sustained power is impossible. Stabling of horses placed enormous demand on urban space, and during the late 19th century dense horse-drawn traffic often created scenes of chaos on the streets of the largest cities (Fig. 1). Even heavy animals could not demonstrate their powerful draft because of the poor preindustrial roads. Late Roman specifications restricted the loads to 326 kg for horse-drawn and up to 490 kg for slower ox-drawn carriages. By 1850, the maximum allowable load on French roads was approximately 1.4 tons, still a small fraction of today's truckloads (commonly more than 15 tons).

FIGURE 1 High density of horse-drawn traffic on a London bridge in 1872.

Maintaining larger numbers of more powerful animals also required more feed (even during periods when the animals were idle), and this was often impossible given the limited amount of land that could be taken away from food cultivation. Combustion of fossil fuels and generation of primary electricity displaced virtually all hard labor in affluent nations, but reliance on animal and human muscles remains high in most low-income countries. Unfortunately, the latter toll still includes such debilitating tasks as producing gravel by shattering rocks with hand hammers or transporting outsize loads on bent backs of porters. Indeed, this dependence on animate prime movers is one of the most obvious physical distinctions between the rich and the poor worlds.

1. MAMMALIAN METABOLISM

Basal metabolic rate (BMR) is the amount of energy needed to maintain critical body functions of any heterotrophic organism. The rate varies with sex, body size, and age, and its measurements in adults show large individual variations from expected means. To determine BMR in humans, the person must be at complete rest in a thermoneutral environment at least 12 h after consuming a meal. Neutral temperature (approximately 25°C) is required to preclude any shivering and sweating, and the wait eliminates the effects of thermogenesis caused by food digestion, which peaks approximately 1 h after the meal and can add up to 10% to the BMR. Resting energy expenditure (REE) is higher than BMR because it includes the thermic effect of meals. Mammals thermoregulate at 34–40°C (humans at approximately 37°C) and heart, kidneys,

liver, and brain are the metabolically most active organs; in humans, these four organs account for slightly more than one-half of adult BMR.

Max Kleiber pioneered the systematic study of mammalian BMR during the 1930s, and in 1961 he concluded that dependence of this rate (expressed in watts) on total body weight (mass in kilograms) is best expressed as $3.4\,m^{0.75}$ (the exponent would be 0.67 if BMR were a direct function of body surface area). Kleiber's famous mouse-to-elephant line became one of the most important and best known generalizations in bioenergetics (Fig. 2). Closer examination of available BMRs shows slightly different slopes for several mammalian orders, and individual outliers illustrate genetic peculiarities and environmental adaptation. For example, cattle have a relatively high BMR, requiring more feed per unit of body weight gain than would be expected based on their mass, whereas the relatively low BMR of pigs makes them efficient converters of feed to meat and fat. Various explanations of the three-fourths slopes have been offered in the biological literature, but the definitive solution remains elusive.

In order to obtain total energy requirements, BMRs must be increased by energy needs for growth and activity. Conversion efficiency of growth depends on the share of newly stored proteins (which are always more costly to synthesize than lipids) and on age (efficiencies range from more than 40% during postnatal growth to well below 10% for mature adults). In humans, the average food energy need is approximately 21 kJ/g of new body mass in infants, equal to a conversion efficiency of approximately 50%; adult growth efficiencies are up to 35% lower. Regarding the conversion of chemical energy of food and feed to kinetic energy of working muscles, it has been known since the late 19th century that its peak efficiency is slightly more than 20%.

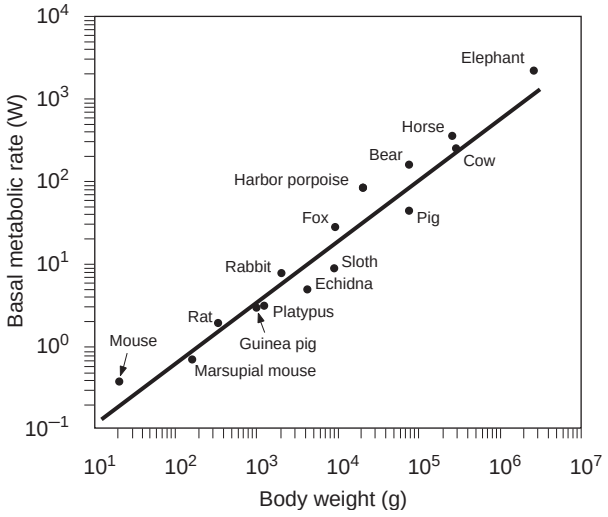

FIGURE 2 Kleiber's line showing the dependence of basal metabolic rate on body mass.

The first fairly accurate estimates of animate power were made in 1699 when Guillaume Amontons studied the effort of French glass polishers. In 1782, James Watt calculated that a mill horse works at a rate of 32,400 foot-pounds per minute, and the next year he rounded this figure to 33,000 foot-pounds, making 1 horsepower equivalent to 745.7 W. By 1800, it was known, correctly, that the power of useful human labor ranges from less than 70 to slightly more than 100 W for most steadily working adults. This means that when working at 75 W, 10 men were needed to equal the power of a good horse for tasks in which either of these animate prime movers could be used.

2. HUMAN ENERGETICS

Healthy people fed balanced diets can convert chemical energy in the three basic classes of nutrients with high efficiency: 99% for carbohydrates, 95% for lipids, and 92% for proteins (however, more than 20% of dietary protein is lost daily through urine). With the exception of people engaged in very heavy work or in strenuous and prolonged exercise, most of the digested energy is used to satisfy the basic metabolic needs. Much BMR and REE data have been acquired mostly by measuring oxygen consumption, which can be easily converted into energy equivalents: One liter of O_2 equals 21.1 kJ/g of starch, 19.6 kJ/g of lipids, and 19.3 kJ/g of protein.

The relationship between BMR and body size can be expressed by simple linear equations (Fig. 3), but these are excellent predictors of individual BMRs only for children and adolescents. More important, using these equations may lead to exaggerated estimates of energy requirements for populations outside the affluent world in general and outside of Europe in particular. For example, BMR equations favored by the Food and Agriculture Organization (FAO) overpredict BMRs of people living in tropical regions by 1.5–22.4%, with the difference being largest for adults older than age 30.

Adult BMRs vary substantially not only among individuals of the same population but also among different population groups. There are no indisputable, comprehensive explanations for these disparities.

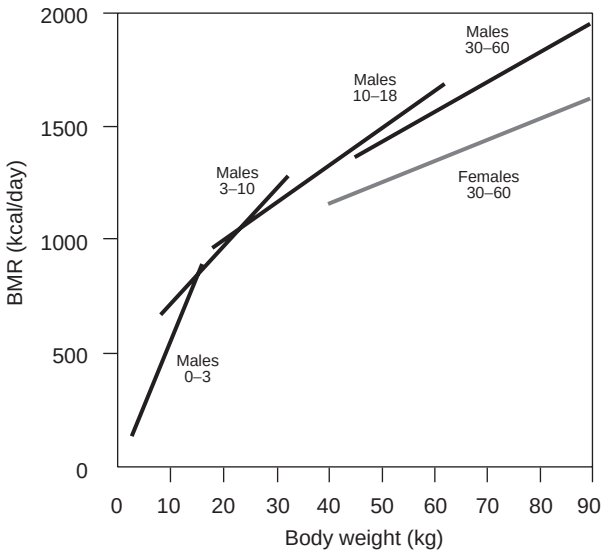

FIGURE 3 Linear predictions of basal metabolic rate (BMR) based on equations recommended by FAO/WHO/UNU.

Disparities among different populations may be due simply to different shares of metabolizing tissues (i.e., muscles and especially internal organs) in the overall body mass. Although individual BMRs vary widely, their lifetime course follows a universal trend. After peaking between 3 and 6 months of age, they decline to approximately half the peak value by late adolescence; this reduction is followed by an extended plateau. Metabolic decline, due to a steady loss of metabolizing lean tissue and increased fat deposition, resumes during the sixth decade and continues for the rest of life. By the seventh decade, fat comprises approximately one-fourth of typical male and slightly more than one-third of female body mass.

As for other mammals, human energy requirements for growth become marginal after reaching adulthood, and food intakes are accounted for almost completely by the combination of BMR and energy needed for various activities. Determination of energy costs of labor and leisure activities has a century-long tradition based on respirometry that requires masks, hoods, or mouthpieces and hoses to measure gas exchange. This is not a problem when testing a cyclist on a stationary bicycle, but it is a challenge when done in restricted workspaces and during aerobic sport activities. Nevertheless, many diverse and interesting values, including those for playing cricket in India and climbing Alpine peaks, have been obtained during decades of such research. Portable systems that can be used for continuous measurements of oxygen uptake for long periods are in widespread use, and two convenient methods allow nonintrusive measurement of energy expenditures.

The first, developed in the mid-1950s, has been used in humans since the mid-1980s: It monitors exponential losses of the doubly labeled water (marked with stable heavy isotopes of ^{2}H and ^{18}O) drunk by subjects during a period of 1 to 2 weeks. When the two heavy isotopes are washed out of the body and replaced with dominant ^{1}H and ^{16}O, loss of deuterium is a measure of water flux and the elimination of ^{18}O indicates not only the water loss but also the flux of CO_2, a key final product of metabolism, in the expired air. The difference between the washout rates of the two isotopes can be used to determine energy expenditure over a period of time by using standard indirect calorimetric calculations. The other technique involves continuous monitoring of heart rate and its conversion to energy expenditure by using calibrations predetermined by a laboratory respirometry.

3. SUSTAINED OUTPUT AND EXTREME EXERTIONS

Energy costs of individual activities, or so-called physical activity levels (PALs), are best expressed as multiples of the BMR or the REE, that is, energy flows equal to approximately 70–90 W for most adult males and 55–75 W for females. Typical averages, corresponding to the reference man of 65 kg and the reference woman of 55 kg, are 78 and 64 W, respectively. Contrary to a common belief, the high basal metabolism of the brain, which always requires approximately one-fifth of the adult food energy intake, increases only marginally when a person is engaged in the most challenging mental tasks: Typical energy increase is only 5% higher than the BMR.

Minimal survival requirements, including metabolic response to food and energy needed to maintain basic personal hygiene, require PALs between 1.15 and 1.2. Standing requires the deployment of large leg muscles, resulting in a PAL 1.3–1.5 times the BMR. Light exertions typical of numerous service and manufacturing jobs that now dominate the modern economies, such as secretarial work, truck driving, assembly line work, or car repair, require no more than 2.5 times the REE. Frequent carrying of loads, lifting of heavy burdens, deep digging, and cleaning of irrigation canals increase the exertion averages into the moderate or heavy expenditure range.

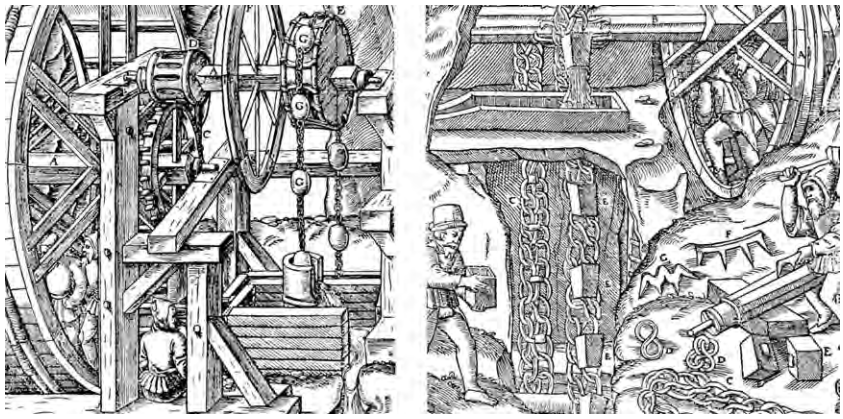

FIGURE 4 Men powering large treadwheels depicted in Agricola's famous "De re Metallica" (1556).

Activities requiring moderate (up to five times the REE), and sometimes even heavy (up to seven times the REE), exertion are now common only in traditional farming (ploughing with animals, hand weeding, and cleaning of irrigation canals are particularly taxing), forestry, and fishing. From the consensus meeting organized by the FAO, the World Health Organization, and the United Nations University PALs of 1.55 for males and 1.56 for females were determined to be the average daily energy requirements of adults whose occupations require light exertions; PALs of 1.64 for females and 1.78 for males engaged in moderately demanding work and 1.82 for females and 2.1 for males with jobs demanding heavy exertions were chosen.

A great deal of experimental work has been performed to determine the limits of human performance. Tiny amount of ATP stored in muscles (5 mmol/kg of wet tissue) can be converted to just 4.2 kJ, enough to energize contractions for less than 1 s of maximal effort. Replenishment through the breakdown of phosphocreatine can add a total of 17–38 kJ, enough to support a few seconds of intensive exertion. Maximum metabolic power achievable in such ephemeral outbursts is large—3.5–8.5 kW for a typical Western man and as much as 12.5 kW for a trained individual. Longer exertions, lasting 30 s to 3 min, can be energized by muscular glycogen. Maximum power of this anaerobic glycolysis is 1.8–3.3 kW for average men. All prolonged efforts are powered primarily by aerobic metabolism, with higher energy demands requiring linear increases in pulmonary ventilation.

Healthy adults tolerate many hours of work at 40–50% of their maximum aerobic capacity. This translates into 400–500 W for most adult men, and with typical kinetic efficiencies of approximately 20% it amounts to 80–100 W of useful work. Untrained individuals have a metabolic scope (the multiple of their BMR) no higher than 10; for active individuals and laborers habituated to hard work, metabolic scope is higher than 15, and for elite endurance athletes (none being better than Nordic skiers and African long-distance runners) the peak aerobic power can be 25 times their BMR or more than 2 kW. Among all mammals, only canids have higher metabolic scopes. Limits of human performance are variable. In total energy terms, peak aerobic capacities are l.5–3.5 MJ for healthy adults, higher than 10 MJ for good athletes, and peak at an astonishing 45 MJ. Both glycogen and fat are the substrates of oxidative metabolism, with lipids contributing up to 70% during prolonged activities.

Overall energy conversion efficiency of aerobic metabolism is 16–20%, whereas anaerobic conversion is less efficient (10–13%). The most efficient, albeit clearly demeaning and stressful, way of using people as prime movers in preindustrial societies was to put them inside (or outside of) treadwheels (Fig. 4). Their operation deployed the body's largest back and leg muscles to do tasks ranging from lifting loads at construction sites and harbors to operating textile machinery. The most efficient use of humans as modern prime movers is in cycling. Bursts of 1 kW are possible for a few seconds while pedaling, and rates of 300–400 W can be sustained for up to 10 min.

4. WORKING ANIMALS

Domesticated animals, mainly bovines (cattle and water buffalo) and equines (horses, ponies, mules, and donkeys), have been the most powerful and highly versatile providers of draft power since the

beginning of Old World sedentary farming. Horses and camels also provided the fastest means of land transport in preindustrial societies, and these and other species (including donkeys, yaks, and llamas) were also used as pack animals, whose caravans were particularly useful in mountainous or desert terrain.

Some Asian societies used working elephants (particularly in forestry operations), several Eurasian circumpolar cultures relied on reindeer as pack animals, and in preindustrial Europe dogs turned spits over kitchen fires or pulled small carts or wheelbarrows. In the Western world, the use of draft animals continued for several decades after the introduction of internal combustion engines and electric motors at the end of the 19th century, and tens of millions of them are still indispensable for fieldwork and transportation in low-income societies of Asia and Africa and in poorer regions of Latin America.

The power of working animals is approximately proportional to their weight (less than 200 kg for small donkeys and approximately 1 ton for heavy horses), but their actual field performance is also determined by a number of external variables. By far the most important are the animal's sex, age, health, and experience; soil and terrain conditions; and the kind of harness used. Only heavier animals could handle such tasks as deep plowing or extracting deep tree roots, but lighter animals were superior in muddy and dandy soils or on steep paths. Moreover, mechanical considerations favored smaller draft animals: Their line of pull is lower, and a more acute angle between this line and the direction of traction will produce a more elongated parallelogram of vectors and hence yield a greater efficiency of work.

Sustainable pulls are equal to approximately 15% of body weight for horses and only 10% for other species. Working speeds range mostly from 0.6–0.8 m/s for oxen to 0.9–1.1 m/s for horses. Thus, depending on their body mass, these draft animals can work at sustained rates of 300–500 and 500–800 W, respectively (Fig. 5). Assuming sustained human exertion at 75 W, the power of a working equine or bovine animal is typically eight times, and usually not less than six times, greater. Actual draft needed for specific fieldwork varies mainly with the soil type.

Deep plowing requires drafts of 120–170 kg, with a range of 80–120 kg for shallow plowing, heavy harrowing, and mowing. Cereal harvesting with a mechanical reaper and binder requires approximately 200 kg. Small horse (350 kg) or a good ox

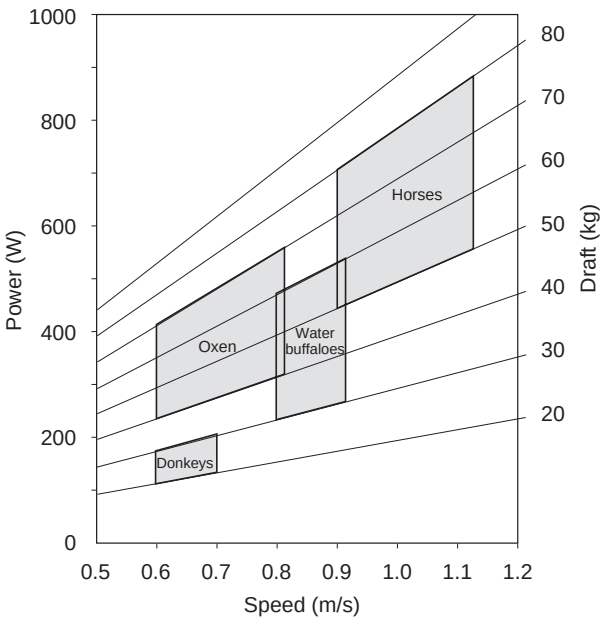

FIGURE 5 Typical performances of draft animals.

(500 kg), capable of sustained draft of approximately 50 kg, will thus not be able to adequately perform most field tasks alone. Teams of two, and later four, draft animals were common in European and American fieldwork, and efficient harnessing eventually resulted in more than 30 horses pulling the world's first combines during the 1880s.

Although the numbers of draft animals continued to increase in every country well into the 20th century, their combined power was rapidly overshadowed by new mechanical prime movers. In the United States, draft animals accounted for more than half of all prime mover power as late as 1870, but by 1950 their share was less than 0.2%. By 2000, the combined power of the world's half a billion draft animals was approximately 200 GW, less than 0.5% of the power installed in internal combustion engines.

5. BOVINES

Currently, bovines account for approximately two-thirds of the remaining draft power. More common reliance on bovines rather than on draft horses everywhere during the earlier stages of agricultural intensification, and in poorer countries and regions today, is easy to explain. Oxen (castrated males) may be difficult to train, less powerful than equally massive horses, and slower paced, but these

drawbacks are compensated by their stolidity, inexpensive harness, the lack of need for shoeing, and especially the fact that they are easy to feed. The efficient digestive system of these ruminants, with microbes (bacteria, fungi, and protists) in their rumen that are able to decompose cellulose of plant roughages that other mammals are unable to digest or can use only very inefficiently, means that during slack periods they can be kept fit only on grasses (fresh or dried) and crop residues (mostly cereal straws) that other animals find difficult or impossible to consume.

Consequently, ruminants require supplementary feeding by highly digestible concentrates (grains or milling residues) only during periods of hard work. Cattle, except for their susceptibility to trypanosomiasis, also perform better in the tropics than do horses. However, water buffaloes are unmatched in wet tropics. Their body mass ranges from 250 to 700 kg, but even the most massive buffaloes are quite nimble, moving easily on narrow dividers between rice fields. Their large hoofs and flexible pastern and fetlock joints made it easier to walk in the slippery, deep mud of rice fields. They eat many grasses, can graze on aquatic plants while completely submerged, require approximately 40% less feed energy per unit of gain than do cattle, can work reliably for at least 10–15 years, and children can take care of these docile beasts.

The energetic advantages of working bovines did not end with their draft power. After the end of their working lives, the animals became a valuable source of meat and leather, and during their lifetime they provided a great deal of organic wastes that were (usually after fermentation) returned to fields in all traditional agricultures that practiced intensive cropping. However, there were some drawbacks when working with bovines. Both the neck and head yokes used to harness draft cattle had a high traction point and required a pair of equally sized animals even when one beast would suffice for lighter work (Fig. 6). The slow pace of bovine work was another major limitation, particularly where multicropping was practiced, in which speed was essential for timely harvesting and planting of a new crop. For example, a pair of oxen working in a dry soil could plow 0.2 or 0.3 ha per day, whereas a good pair of horses could plow 0.5–0.8 ha. European experience during the 19th century was that a pair of good horses easily did 25–30% more fieldwork in a day than a team of four oxen.

In addition, oxen have neither the endurance nor the longevity of horses. The working day for many oxen was 5 h, whereas horses commonly worked twice as long. Also, although both oxen and horses started working at 3 or 4 years of age, oxen lasted usually less than 10 years, whereas horses could work for 15–20 years. Poor peasants were often forced to use their only head of cattle, a family cow, as a draft animal, compromising her milk production and getting only weak traction. More powerful oxen were, and remain, the most commonly used draft bovines: At least 250 million of them were working worldwide in 2000, mostly in Asia's two most populous countries.

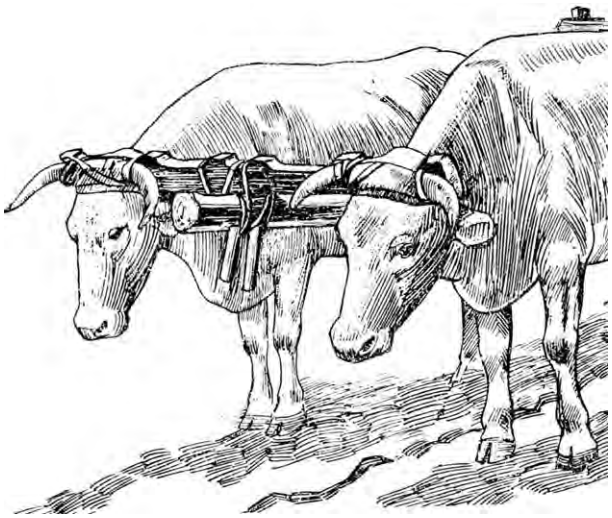

FIGURE 6 Head yoke commonly used for harnessing working oxen.

6. HORSES

There are five major reasons why horses are better draft animals than cattle. Unlike in cattle, frontal parts of horses' bodies are heavier than their rears (the ratio is approximately 3:2) and this gives them an advantage in inertial motion. Their unique arrangement of the suspensory ligament and a pair of tendons makes it possible to "lock" their legs without engaging any muscles and hence without any additional energy cost incurred during standing. Horses also grow generally larger and live longer than cattle, and they have greater work endurance. However, their superior strength was efficiently harnessed only with the widespread adoption of the collar harness and iron horseshoes, and their inherent power and endurance became readily available only with better feeding.

Fitted, and later also padded, collar harnesses provided a desirably low traction angle and allowed for the deployment of powerful breast and shoulder muscles without any restriction on the animal's breathing (Fig. 7). Its precursor was first documented in China in the 5th century of the CE, and an improved version spread to Europe just before the end of the first millennium. Another important innovation in harnessing was swingletrees attached to traces in order to equalize the strain resulting from uneven pulling: Their use made it possible to harness an even or odd number of animals. Iron horseshoes prevented excessive wear of hooves and they also improved traction.

However, collars and horseshoes alone could not guarantee the widespread use of horses: Only larger and better fed horses proved to be superior draft animals. The body mass, and hence power, of European draft horses began to increase only after the working stock benefited from several centuries of breeding heavy war animals needed to carry armored knights. However, these more powerful horses needed at least some cereal or legume grains, not just grasses fed to weaker animals and cattle. Production of concentrate feed required intensification of farming in order to provide yields high enough for both people and animals. Agricultural intensification was a slow process, and it first began in northwestern Europe during the late 18th century.

Even larger horses were taxed when pulling wooden ploughs, whose heavy soles, wheels, and moldboards generated enormous friction, particularly in wet soils. Moreover, the absence of a smooth, curved fitting between the share and the flat moldboard caused constant clogging by compressed soil and weeds. Iron moldboard ploughs were introduced

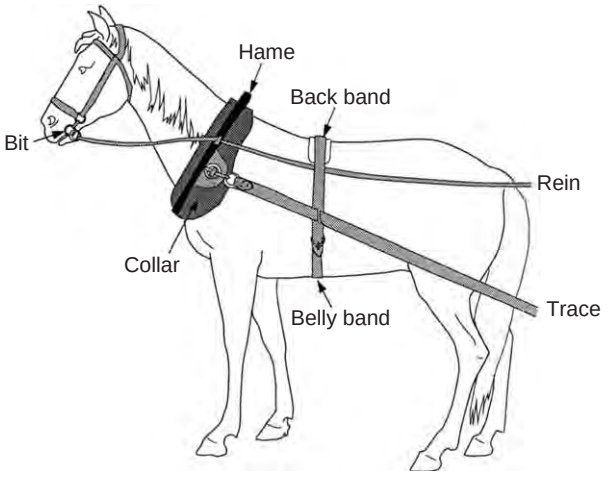

FIGURE 7 Basic parts of the collar harness.

to Europe from China during the 17th century, and cast iron shares were replaced with smooth, curved steel ploughshares by the mid-19th century during the rise of the modern steel industry. Horses then became the principal energizers of the world's largest extension of arable land that took place on the plains and prairies of North America, pampas of Argentina, and grasslands of Australia and southern Russia during the latter half of the 19th and the first half of the 20th century.

The heaviest horse breeds—French Percherons, English Shires, and German Rheinlanders—could work briefly at rates of more than 2 kW (approximately 3 horsepower), and they could steadily deliver 800–1000 W. Feed requirements of these animals were high, but their net energy benefit was indisputable: A horse eating 4 kg of oats per day preempted cultivation of food grain that would have fed approximately 6 adults, but its power could supplant that of at least 10 strong men. Larger and better fed horses also provided essential traction during the initial stages of industrialization, powering road and canal transport, turning whims in mining, and performing tasks in food processing and in numerous manufactures. In most of these tasks, they were displaced by steam engines before the mid-19th century, but even as the railways were taking over long-distance transport, horse-drawn carts, trucks, and streetcars continued to move people and goods in all rapidly growing cities of the late 19th century. Only the diffusion of internal combustion engines and electric motors ended the use of horses as urban prime movers.

However, in fieldwork, horses remained important well into the 20th century. Obviously, their largest numbers were supported where abundant farmland made it easy to produce the requisite feed. The total number of farm horses (and mules) peaked at 21 million animals in 1919 in the United States, when at least 20% of the country's farmland was needed to cultivate their feed. Subsequent mass adoption of tractors and self-propelled field machines was inevitable: Even small tractor engines could replace at least 10 horses and needed no farmland for support. The U.S. Department of Agriculture discontinued its count of draft animals in 1960, when approximately 3 million working horses were still left on American farms. However, in China, the total number of draft horses continued to increase even after 1980, when the country began its economic modernization. Horses, as well as water buffaloes, yaks, camels, and donkeys, remain important draft and pack animals in parts of Asia and Africa.

Virtually complete substitution of animate prime movers by engines and motors is one of the key attributes of modern high-energy society, in which humans act as designers and controllers of increasingly more powerful energy flows rather than as weak prime movers, and in which a rare working animal is an object of curiosity. Nothing illustrates the wide gap between the affluent and the subsistence areas of the world better than the fact that heavy, repetitive, and dangerous human exertions (including those of millions of children) and the draft of hundreds of millions of animals continue to be indispensable prime movers in large areas of the three continents on which modernity is still a promise for tomorrow.

Glossary

corporate environmental strategy (CES) A functional business slogan represented by journals by the same name, owned by Elsevier, and a set of mimic journals and books utilizing the same title and concept. In addition, it is a measured business practice, starting after the tragic accident at Bhopal, India, the Exxon *Valdez* oil spill, and other environmental catastrophes at the end of the 20th century, that allows a firm to lessen its environmental liabilities, compliance costs, and product development costs as well as pursue competitive advantage in an organized and reportable fashion.

governance and management systems The means by which the board and key advisors of a firm manage its direction and performance. After the Bhopal and *Valdez* disasters, these systems increasingly involved environmental and public liability reduction efforts.

leading change, corporate change A studied area of management whereby systems are put in place to manage change in products, leadership, and corporate direction.

market-based environmentalism A term designed to suggest that leading firms based their search for environmental performance improvements on market opportunities, not just on environmental regulation and law.

social response product development Companies restructure their operations to actively shape market desires by creating new products that bridge the gap between traditional expectations of performance, safety, and environmental responsibility.

sustainable value creation A term developed after the demise of Enron and WorldCom in the early parts of the 21st century and designed to capture in a focus phrase the need for reform in how companies position themselves and report to the investment community on the paths they are taking to make their firms more sustainable.

Corporate environmental strategy (CES) involves the tools, management programs, processes, and product development choices that allow a firm to pursue competitive advantage through environmental management strategies.

1. CORPORATE ENVIRONMENTAL STRATEGY

Management scholars such as Deming and Juran spent several decades after World War II making sure that quantity and quality processes entered the plans of corporate strategy, along with the classical concerns of price, technical quality, and distribution matters. In a similar but often more diffuse manner, the proponents of corporate environmental strategy began, in the l970s through the l990s, to alter the standard decision models of corporate strategy to include externalities that challenged the future growth of corporations, such as new environmental regulations or irregularities in energy markets and pricing.

 © 2004 Elsevier Inc. All rights reserved.

This massive set of changes in corporate behavior was first motivated by the need to extinguish both legal and public liabilities of the major multinationals, after the tragic accident at Bhopal and the highly visible oil spill of the Exxon *Valdez*. Later in the 21st century, CES took on a more "proactive" or "sustainable value creation" thrust, as described in this article.

Classic post-Bhopal examples of CES include the following:

1. Honda's and Toyota's development of the hybrid powertrain automobile that uses an electric battery recharged by braking and the conventional combustion engine.
2. British Petroleum's (BP's) and Shell's investments in solar power and their "beyond petroleum" campaigns of the late 20th century.
3. A range of high-efficiency appliances from Whirlpool and Electrolux that go beyond regulatory requirements.

By 2003, CES was a visible and stated corporate strategy and management goal for many multinational corporations. Some suggest that CES became a stated mantra of the Fortune 500; others believe it was spotty in the top companies across the globe. In either case, CES began to have clout in leadership councils and began to tie together energy conservation, materials savings in product design, and the classical environmental regulatory elements.

The core innovations in CES in the last decade of the 20th century occurred in the heavy industries, such as petroleum refining, where firms such as Shell and BP competed on lessening their environmental footprint to attract new partners and new investment capital.

CES also spilled rapidly into the chemical industry, where firms such as DuPont, Celanese AG, and Dow offered new products, such as water-based emulsions.

2. *BEYOND COMPLIANCE INITIATIVES*

Competition in domestic and international markets and legal requirements led to the rapid development of CES in the late l990s. The approaches signified by this concept are not academic in nature and were not, on the whole, developed by academia, which in the l990s spent much of its intellectual energy developing concepts in sustainable development, industrial ecology, and alternative energy.

Instead, CES is an evolving practitioner concept that is defined by corporate practice and function and has been implemented directly by thousands of companies since Bhopal.

There are at least three competing forms of CES. These are as follows: grudging compliance by companies with regulatory requirements while seeking to turn a profit; going beyond regulations and standards while developing products that have market value and demand but are also environmentally sound; a mix of the first two—namely, the combination of willing compliance with innovation in the market.

Whereas most leadership councils felt in practice that the third mix was the best, some firms pursued the purity of the first two strategies into the new century. Then, market pressures, after the Enron and WorldCom scandals, encouraged the attention of corporate leaders on governance reforms and Sarbanes Oxley laws upgrading management systems, corporate reporting, and the overall transparency of modern corporate reporting.

During the first decade of the 21st century, these corporate reforms became attached to CES in complex and still to be studied ways.

Many attempts were made in the l990s and the new century to differentiate the essential or shared ingredients of CES, but most firms found that "one size does not fit all," as CES applications range widely from the mining and extractive industries (where the cost of energy is the focus), to automotive and petrochemical firms (where efficiency is often the key), to consumer-based firms (where firms such as Avon, Coca Cola, and Nike began to compete on elements of corporate social responsibility that are based on environmental strategies). As a result, what is shared is the approach, some tools and metrics, and general direction. Yet there is tremendous variance in results.

For example, CES has become a rallying term that often appears all too inclusive. In fact, sometimes CES seems, in sloppy parlance, a surrogate for classic business strategy and simply another way to make money by serving changing customer expectations. Some view it as a tool to measure emerging issues, where Intel or Hewlett Packard may use CES tools to track how their core customers are looking at new environmental risks in the metals and plastics used in computer and information technology systems.

Some corporations view CES as a tool for new product positioning, so that Rohm and Haas and Celanese AG are building emulsions plants in Asia that bypass the usual environmental legacy questions

from traditional manufacturing of adhesives. Others see CES as a pathway whereby a firm can achieve near-term shareholder value through corporate responsibility.

It is precisely because of this significant variance of results that the history and the readiness of firms to use the term CES have been at best checkered since Bhopal.

3. MAKING THE BUSINESS CASE FOR SUSTAINABLE DEVELOPMENT

By 2003, a number of advantages to CES were being investigated and documented by the management consulting profession and by groups such as the Global Environmental Management Initiative (GEMI) and the Conference Board. These advantages serve to explain why a firm would invest in efforts to move it beyond basic legal compliance with all laws.

Competitive advantages gained by environmental strategies include the following:

1. Margin improvement—seeking cost savings at every stage of the product life cycle through more efficient use of labor, energy, and material resources.
2. Rapid cycle time—reducing time to market by considering environmental issues as part of the concurrent engineering process during the early stages of design.
3. Market access—developing global products that are environmentally "preferable" and meet international ecolabeling standards in Europe, Japan, and other regions.
4. Product differentiation—introducing distinctive environmental benefits, such as energy efficiency or ease of disassembly, that may sway a purchase decision.

CES is the blend of classical environmental regulatory compliance matters with these new strategic dimensions and elements. CES, at its best, is an integral input in the creation of business strategy, product selection, and a corporation's public affairs and reporting under Sarbanes Oxley, and related laws of disclosure both before the U.S. Securities and Exchange Commission and before the investment community.

From l985 to 2003, different firms excelled in these four highlighted attributes: margin improvement, rapid cycle time, product differentiation, and market access. Intel was motivated to pursue CES to enhance its needs for rapid cycle time reductions, and marketing-based firms such as Nike and Proctor & Gamble set up CES goals for reasons of basic product differentiation. In the end, CES began as a means of improving corporate bottom lines through cost containment and new product opportunity programs.

If one were to estimate the degree of penetration of CES into corporate boardrooms, it kept its stigma as being an added cost, or what some have referred to as a "bag on the side of corporate strategy," for many years after Bhopal. Although the diligent and deliberate attempt to lessen a firm's environmental liabilities is a prime force behind CES, the relentless thirst for profit has proven a more reliable and less distracting guide in the new thinking regarding CES. The list of four key elements and goals of CES can be thought of as the turning point from the old century thinking into the new century, where the pressures for sustainable product mixes and policies became far more palpable.

A firm can achieve CES by a sequence of related efforts, including the following:

1. Make environmental management a business issue that complements the overall business strategy.
2. Change environmental communication within the company to use traditional business terms that reflect business logic and priorities.
3. Adopt metrics to measure the real costs and business benefits of the environmental management program.
4. Embed environmental management into operations, similar to the successful design-for-environmental models (here, environmental footprint reduction elements are entered into the equation at the product design stage).
5. Radically change the job descriptions and compensation of environmental managers—and line managers—to reflect the realities of doing business.

Others answered the question of how a firm would begin to move beyond compliance by pointing to the cost and administrative inconvenience of penalties and fines. The classic and more vivid example is the demise of Union Carbide, and its eventual purchase by Dow, after Bhopal, a tragic accident that killed over 2700 people in Bhopal, India. Lessons from Union Carbide for practitioners of improving environmental management systems, under the rubric of CES, include this summary of Union Carbide's major changes after Bhopal:

1. An intricate classification scheme of standards, regulations, and audits, which allows executives more

insight into the firm's liabilities, priorities, and high-risk areas. Technical staff functions of regulatory compliance can then be linked to the legal department's liability containment measures and strategies.

2. A large database of audit findings statistically amenable to analysis. From this corporate base, executives from different divisions compete for capital resources on more exact terms. Its size and consistency make it a management tool of considerable consequence.

3. A systematic monitoring and control program, more reliable than the traditional environmental, health, and safety systems. For instance, Union Carbide's worldwide computer program prioritizes risk at its 1200 facilities worldwide and assists senior management with its growth or phase-down plans.

4. New management tools, based on the audit system, provide quality assurance and executive reassurance that the company's environmental practices do not violate the law or threaten human health or the environment. Nationwide, more than 200 executives have served jail time for environmental crimes. This executive assurance program—developed for Union Carbide by A. D. Little—helps senior management feel "in touch" with the firm's liabilities, compliance issues, and long-term viability.

Other recognized drivers in corporate behavior for corporate environmental strategy included Superfund Authorization and Reform Act (SARA) Title III, which put public pressure on companies by requiring disclosures on chemical stockpiles, warehouses, and such, and the Chemical Manufacturers Association's responsible care initiative, which outlined a code of behavior.

The disruption caused by the Union Carbide accident spurred the above regulations and conduct codes throughout the industry. The public lost faith in the industry and the negative opinion polls increased. Corporate environmental strategy is, in part, a response to the negative public image and public concerns about environmental, health, and safety performance.

4. RELATING CORPORATE ENVIRONMENTAL STRATEGY TO CORPORATE CHANGE INITIATIVES

There are several options that, ultimately, must be integrated when attempting to realize a change in corporate culture: the legal remedy, which is necessary to spur on the slow movers; the money remedy, which does not mean blindly throwing money at an environmental problem, but instead taking a more strategic approach; and finally, the regulatory remedy, which moves beyond simple regulatory compliance to a level of strategy that allows a company to stay ahead.

Some feel that without law there would be no corporate environmentalism, and yet there are those that stood at the forefront of an issue, pushing it to become law. These leaders from industry, academia, government, and the environmental movement are leading CES more than the law is, and for a company to find success through CES, it must stay well ahead with those leaders, not lagging behind with the laws. The law is functional and offers a glimpse at a company's next step, but this is not strategy.

The money remedy does not translate, as some might believe, to throwing money away, the way some companies have done. It is about information management, including audit information, environmental liability and insurance information, product selection, announcement, and positioning information, stockholder and stakeholder information, new and international market information, regulatory and government liaison information, technical information, legal information, and strategic and financial information. Without the full integration of these nine types of information, the amount of money invested in them will not matter.

Finally, there is the regulatory remedy, which can be seen in companies who have begun mass disclosure measures to create corporate transparency, well beyond simple regulatory compliance. Strategy here allows leaders to stay ahead of environmental issues and avoid the old way of constantly cleaning up past mistakes; both company executives and the public are able to see the company's liabilities and assets more easily. This also creates an environment of corporate trust for the public.

These three remedies together can create a strategic advantage for companies willing to make the effort of changing "business as usual." Table I outlines a list of five elements of success in shifting corporate culture.

Table I was based on a survey by the author's firm of over l50 companies of the Fortune 500. Whereas the five corporate change elements noted above are quite inclusive, and extend well beyond what lawyers or engineers in a firm would normally consider environmental management, they do capture the "strategic" or management and leadership council feel of CES in practice.

Without a doubt, the actual benefits of CES are most often kept quite confidential, as they are close enough to the heart of a corporation's business

strategy, when they are functional and not based on public relations, that they are kept close to the chest of the leading executives in a firm. This makes it difficult for scholars in the field to do much in their diagnostics except case studies and retrospective summaries of these elements of success.

5. HOW CES FITS INTO A NORMAL CORPORATE STRUCTURE

After Bhopal and the Exxon *Valdez* spill, it became clear that environmental management was not sufficiently integrated into normal business functions, reviews, and organizations. A l991 survey, seen in Fig. 1, revealed some interested gaps. What the study indicated, as it was replicated for different firms over subsequent years, is that there is no natural or ultimate home for CES in an organization. Depending on the firm, it might be centered in the legal, risk reduction, or regulatory divisions of a firm. But consistently, most firms feel there is a wall between these CES functions and the financial disciplines that run a firm. As a result, CES functions are often perceived as being of secondary or tertiary importance in many firms.

TABLE I

Elements of Success in Shifting Corporate Culture

1. Role for strategic recognition:
Including mission statements and performance reviews
2. Role for changes in staff:
Title and function
3. Adaptations in conventional management tools:
Such as audits or return-on-investment equations
4. Increasing role for external strategies:
Such as community relations and voluntary disclosure
5. The unexpected role for strategic alliances

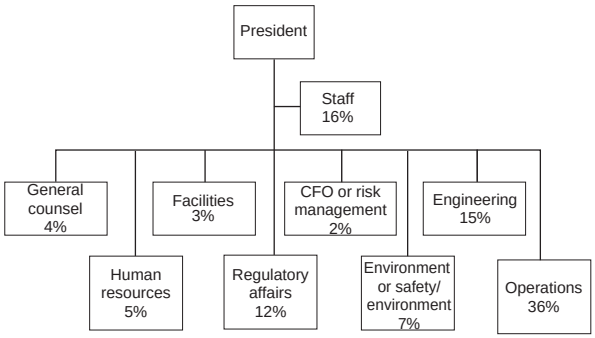

FIGURE 1 Reporting requirements in environmental management. From Coopers and Lybrant (1991), "Environmental Management in the 1990s: A Snapshot of the Profession." Reprinted from Piasecki (1995), with permission from John Wiley & Sons, NY.

6. RELATING CES TO PRODUCT INNOVATION AND STRATEGY

In the pursuit of superior cars, electronic products, and computing, several leading multinational corporations began in the last quarter of the 20th century to tie CES to their product strategy. Leaders such as Toyota and Honda are classic examples in the automotive industry, as are Shell and BP in the petroleum sector.

Those firms that had successfully integrated CES into their normal business functions by the new century shared a common set of attributes. These attributes are described below as "generic" elements of allowing CES to be elevated within a corporate setting, as they often depend on organizational dynamics or a unique set of executive interests and needs. These organizational elements of CES involve "action plans" or goals, such as the following:

1. A role for strategic recognition including mission statements and performance reviews.
2. A role for changes in staff, title, and functions where chief environmental officers and their staff become more visible and respected in corporate organizations.
3. Adaptations in conventional management tools, such as audits or return-on-investment equations.
4. An increasing role for external strategies, such as community relations and voluntary disclosure efforts.
5. In some of the more curious and interesting developments, CES also involved the unexpected role of strategic alliances, where past enemies meet.

Some individuals, such as Steve Percy, the former CEO and Chairman of BP America, have claimed that BP's purchase of Amaco was motivated by CES, since BP saw and appreciated the large natural gas holdings of Amaco and their solar research portfolio as an opportunity to advance BP's need for progress in CES as a reputation enhancer.

Other examples of these strategic alliances were found in the new century in utilities such as Exelon, chemical giants such as Dow, Celanese, and DuPont, and select automakers such as Toyota and Honda.

CES includes knowing when to play by the conventional corporate and financial rules and when

to change the game. In a small set of successful corporations, this involved the integration of "new rules" with the ever-changing game of strategy, product positioning, and product reformulation. Evidence of such "radical" or "incremental" changes became hotly debated with GEMI companies, for example. In the new century, GEMI extended its sunset clause and allowed its continued existence in order to provide a range of companies with these stated requirements in their membership rules.

GEMI companies must reach toward corporate environmental strategy:

- By sharpening existing tools and measurement systems to help managers refine and enhance their environmental performance;
- By popularizing to the press and the public the belief that corporations have a role in the search for environmental excellence, both domestically and internationally;
- By explaining how knowledge from certain business sectors can be shared, coordinated, and then adapted across different industrial sectors and nations;
- By asserting boldly that environmental strategy involves more than regulatory compliance.

7. THE NEW URGENCY FOR CES AFTER CLIMATE CHANGE

Although it is significant that many of the above four imperatives are qualitative, not quantitative, such new efforts have begun to add an elevated level of urgency to corporate environmental strategy.

Whereas the Bhopal and *Valdez* tragedies may have precipitated the birth of CES, global environmental concerns, such as water shortages in China, the energy crisis and electricity grid problems in the northeastern United States, and especially the complexities surrounding the economic impacts and costs of climate change, have begun to add a new turn-of-the-century urgency to the debates over CES.

By 2003, CES began to help firms link price, technical performance, and social response product development. In other words, conventional business tools focusing on competitive price and product strategies, in some instances, began to notice the appeal of shaping or reformulating products relative to external energy and environmental threats, such as limitations in water supply, spiking energy costs, or climate change and other carbon-related challenges. Figure 2 sums up these evolving links between CES and product development.

When multinational firms such as Toyota, Honda, Electrolux, and Whirlpool began making claims before the investment community that their efforts in corporate environmental strategy were paying off, the new emphasis on linking CES to product development and differentiation began to be in vogue.

8. SOCIAL RESPONSE PRODUCT DEVELOPMENT

Historians of business know that vogue is an element of consequence, as evidenced by the passion for Six Sigma tools that General Electric brought to firms as different as 3M, Dow, and Celanese AG. This new product-based vogue for CES enabled a more rapid embrace of CES in select companies, as illustrated in Fig. 3.

"Social response" (i.e., incorporating the sustainability dimension) product development means that instead of manufacturing products solely in response

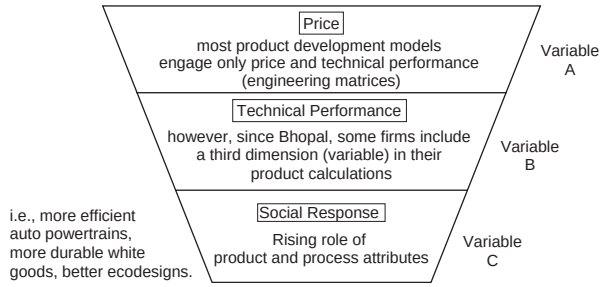

FIGURE 2 Social response product development.

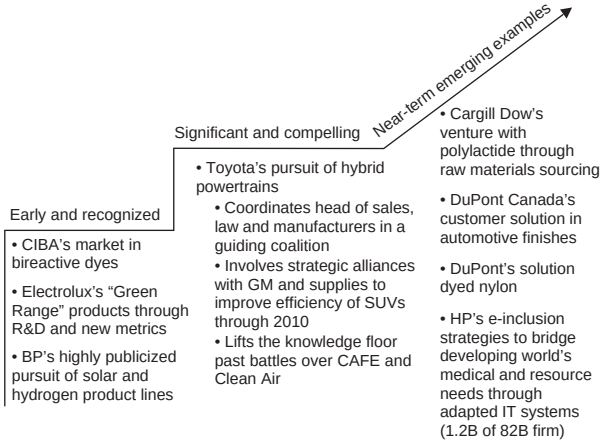

FIGURE 3 Defining social response product development through select examples.

to consumer preferences as discerned and measured by price and technical performance through market research methodologies, companies restructure their operations to actively shape market desires by creating new products such as Toyota's and Honda's hybrid cars.

Although such efforts are logically supported by new manufacturing, quality control, and resource management techniques, what is new is that they bridge the gap between traditional expectations of performance, safety, and environmental responsibility. Such expanded product development models allow a more sustainable value creation at present and through the coming decades. Social response product development also allows product differentiation in mature product lines in a fashion that attracts new capital and new forms of partnering. Examples here include Toyota, BP, Shell, and DuPont. A sustainable value approach, based on this kind of product differentiation and development, supports all other actions in the company. Examples of social response approaches include the following:

- From 1996 to 2001, Anheuser-Busch established a multiyear annual "Pledge and Promise" staff and stakeholder retreat to award eco-innovation teams. The retreat includes presidents and chief executive officers of key Anheuser-Busch stakeholder groups as external judges to select top five sustainable value leaders each year.
- From 1998 to 2002, British Petroleum established a multiyear technical task force to identify, select, and finance sustainable value product lines and plans.

Social response product development shapes how executives approach their task of accomplishing seemingly disparate goals. In chemicals, in high-performance plastics, and in new markets for cars and computers, social response product development delivers both resource efficiency and customer-demanded performance. As an example of social response product development being used as a CES strategy, Toyota's search for a superior automobile is explored.

9. CASE EXAMPLE OF CES IN PRACTICE

In this new century, there is considerable pressure on the top six automakers to reduce their environmental footprint. The automaker that wins the race to build and sell the superior car will shape consumer preferences, thereby boosting sales and profits. The winning firm will fashion a corporate strategy that drives automobile emissions to near zero while simultaneously providing high levels of performance, safety, and comfort.

The model of social response product development as a CES strategy is built on four dimensions, like the structure of a house: knowledge depth—the ever-growing basement; knowledge durability—the expanding sides; knowledge dependence—the ceiling of use; knowledge floors—the ground base. The breakthrough at Toyota was recognizing that new technologies mean that a new knowledge floor can be laid, one that makes it possible to meet all consumer expectations of performance, safety, and environment (fuel efficiency, emissions, resource efficiency, alternative fuels) without the tradeoffs previously required.

Toyota and Honda have used a new form of CES to change the rules of the game by leveraging their knowledge depth to introduce superior new cars, such as the four-door, five-passenger Prius. The Prius achieves fuel efficiency rates of 55 miles per gallon (mpg), twice the regulated corporate average fleet requirement. The move to hybrid cars—those that can run on multiple fuels, most commonly, gasoline and electricity—will be understood as truly exceptional when the realization sinks in how absolutely ordinary it will make the hundreds of millions of cars now littering the current knowledge floor. This floor—containing everything from gas-guzzling sport utility vehicles and commercial trucks to Europe's newest smart cars that are still dependent on the 100-year-old combustion engine—has been permanently superseded.

Some firsts of the Toyota Prius include the following:

1. The Prius has been designed to be recycled. Although this is most relevant to Japanese and European consumers, it does highlight how forward-thinking Toyota has become. The amount of waste avoided through this redesign is staggering, separating Toyota from General Motors, Ford, and DaimlerChrysler.
2. At 2003 gas prices, the average North American would save at least $1/day, or a total exceeding $360, at the pump by driving a Prius rather than a typical compact sedan.
3. Consumers will enjoy the convenience of driving 600 miles between fill-ups.
4. The American version of the Prius has a battery pack with 20% more power than the Japanese equivalent, yet weighs 20% less.

5. The Prius has fundamentally changed the debate over clean cars, almost eliminating the shift to all-electric cars.

6. The Prius has already become legend. It can be found at the New York Museum of Modern Art's exhibit "Different Roads." In June 1999, Toyota became the first automaker in the world to receive the United Nations Global 500 Award, not only because of the Prius, but also because of all of Toyota's environmental commitments to reduce dependence on landfills.

What is noteworthy about this case example is that much of this innovation occurred in anticipation of changes in corporate average fuel economy standards and related air pollution legislation across the globe. This represents a new form of CES as it involves aggressive product change before the regulations take final shape, as a new means of competitive advantage.

10. SUMMARY

Although it would be historically inaccurate to claim that the above-described efforts of BP, Toyota, and DuPont represent a norm, they do signify a way in which corporate environmental strategists are succeeding in the early part of the 21st century.

More and more corporate boards, after the Bhopal and *Valdez* accidents and following a second wave of reforms starting after Sarbanes Oxley required a more accurate disclosure of a firm's lasting liabilities and product assets, are taking this series of steps in linking CES to their larger corporate and social responsibility obligations and plans. Their eventual success will prove to be based on linking their mission and goals, originally compelled by a desire to meet regulations and limit a firm's liability, with products.

As in most corporations, where the product is king, this move may prove the means by which CES reinvigorates itself in the new century.

2. **History of Cost–Benefit Analysis**
3. **Rationale for Cost–Benefit Analysis Applied to Energy**
4. **Cost–Benefit Methodology**
5. **Valuation of Energy Externalities**
6. **Further Issues in the Application of Cost–Benefit Analysis to Energy**

Glossary

benefits transfer A process of taking environmental valuation estimates from existing studies and applying them outside of the site context in which they were originally undertaken.
discounting Adjusting a cost or benefit in the future so that it may be compared to costs and benefits in the present.
energy externality A cost or benefit that arises from an energy project but is not borne or appropriated by those involved in the energy project (e.g., pollution from energy generation).
environmental valuation The process of placing monetary values on environmental effects.
revealed preference methods Environmental valuation methods that use data from actual behavior to derive values for environmental assets.
sensitivity analysis A presentation of various possible outcomes of a future project or policy under conditions of uncertainty.
shadow pricing The process of adjusting a distorted market price to better reflect the true opportunity cost to society of using that resource.
stated preference methods Direct environmental valuation methods that ask people in a survey to place a value on an environmental asset.
total economic value A categorization of the various elements of value of a resource, project, or policy.
value of statistical life The translation of the value of a small reduction in the risk of death into a value for a project that would involve the equivalent of one life saved or lost.
welfare criterion The criterion in a cost–benefit analysis to assess whether a project or policy benefits society.
welfare measure A measurement tool to assess the strength of consumers' preferences for or against a project or policy in order to assess its costs and benefits.

Cost–benefit analysis applied to energy is the appraisal of all the costs and all the benefits of an energy project, policy, or activity, whether marketed or not, to whomsoever accruing, both present and future, insofar as possible in a common unit of account.

1. DEFINITION OF COST–BENEFIT ANALYSIS APPLIED TO ENERGY

Cost–benefit analysis (CBA), also known as benefit–cost analysis, is rooted in applied welfare economics. It is a way of organizing and analyzing data as an aid to thinking. It provides a set of procedures for comparing benefits and costs and is traditionally associated with government intervention and with the evaluation of government action and government projects. The underlying rationale for CBA is rational choice; that is, a rational agent will weigh the costs and benefits of any proposed activity and will only undertake the activity if the benefits exceed the costs.

A confusion that sometimes exists relates to the difference between social cost–benefit analysis and cost–benefit analysis. However, to an economist, social impacts and environmental impacts are economic impacts, so any analysis purporting to be a CBA must address social and environmental impacts.

 © 2004 Elsevier Inc. All rights reserved.

In this way, CBA differs from financial analysis in that it assesses the costs and benefits to the whole of society rather than to a portion of society. For example, a financial analysis of a proposed new power plant by a private energy supplier will not take into account the costs imposed on wider society (such as environmental impacts), whereas a CBA, by definition, will do so. In addition, there are various other subtle but important differences between financial analysis and CBA related to the fact that market prices do not always reflect the true value of goods and services to society. This provides the basis for a technique known as shadow pricing, which adjusts distorted market prices such that they may be used to value costs and benefits appropriately.

As the previous definition implies, a CBA must include all the costs and all the benefits to whomsoever accruing. Thus, the definition instructs that whether the costs or benefits are marketed or not makes no difference. In other words, even if some of the costs or benefits are not exchanged in markets at all and so do not have a price, they may still be of value. This provides the basis for the inclusion of environmental and wider social impacts in CBAs of energy projects and policies. The common unit of account in CBA is money. Therefore, insofar as is possible and reasonable, all impacts, including environmental and social, should be evaluated in monetary terms so that they can be compared with one another. This provides the basis for a technique known as nonmarket or environmental valuation—that is, placing monetary values on goods and services not exchanged in markets, such as environmental improvements and damages.

In many cases, the costs and benefits of a project or policy will arise at different times. This is the case in relation to most energy activities, where the consequences of actions may not be known until far into the future, particularly in the case of environmental impacts such as global warming. This provides the basis for a technique known as discounting, which allows future costs and benefits to be compared with those in the present.

CBA has been used *inter alia* to estimate the environmental costs of power generation, the net social benefit of different power supply options, the net benefit of the use of renewable energy sources (e.g., solar, wind, and hydroelectric power), the net benefits of alterative modes of transport, the benefits of energy efficiency programs in the commercial and domestic sectors, as well as for policy analysis of energy efficiency regulations such as energy rating and labeling.

2. HISTORY OF COST–BENEFIT ANALYSIS

Detailed histories of CBA can be found elsewhere, but the essence is as follows. In 1808, U.S. Secretary of the Treasury Albert Gallatin gave what is believed to be the first recommendation for the employment of CBA in public decision making when he suggested that the costs and benefits of water-related projects should be compared. In 1936, the U.S. Flood Control Act deemed flood control projects desirable if "the benefits to whomsoever they may accrue are in excess of the costs." In 1950, after a debate on the foundations of CBA in welfare economics, the U.S. Federal Inter-Agency River Basin Committee published a guide to CBA known as the "Green Book." From then on, there was considerable interest in CBA and the development of cost–benefit rules, with seminal contributions by a number of authors, particularly during the 1970 s. Although the distortions created by government intervention in the 1970 s provided much room for the application of CBA, the technique went through a lull in the early 1980s when structural reform replaced piecemeal intervention. However, CBA has made a comeback since then, mainly as a result of increased public awareness of environmental degradation and the associated demand that this cost be accounted for in analyses of projects and policies. However, for a number of years, the economist's view that environmental impacts could be assessed in monetary terms had little impact on policy, with many environmentalists having a particular problem with this concept. For example, in the U.S. Clean Air Act (1970), it was forbidden to use CBA, and the U.S. Clean Water Act (1972) set the objective of the elimination of all discharges into navigable waters. However, in the 1980 s, it became a requirement that the U.S. Environmental Protection Agency perform CBAs on all environmental directives to assess their economic efficiency and significant resources were devoted to researching cost–benefit techniques and methods of placing monetary values on the environment. Although it was not until the Single European Act was introduced in 1987 that a legal basis for European Union (EU) environmental policy was provided, the nature of environmental policy reflected the origins of the EU being an economic one. EU policy that "the potential benefits and costs of action or lack of action must be taken into account in the preparation of policy on the environment" provides an obvious platform for the use of CBA.

3. RATIONALE FOR COST–BENEFIT ANALYSIS APPLIED TO ENERGY

The need for CBA applied to energy results from the existence of market failure. If there were no market failure and all energy suppliers were privately owned, there would be no need for CBAs of energy projects and policies. If market signals were appropriate, those activities and projects that are in the best interests of society would be implemented automatically and financial analyses by firms would simply replace any need for CBAs. However, the market does not work perfectly. Market failure necessitates CBA of energy projects, policies, and activities as a result of the existence of externalities, the associated need for environmental policy instruments, state ownership of energy generation and supply, assessment of sustainability, and "green" national accounting.

3.1 Energy Externalities

One of the most significant areas of environmental concern today relates to the environmental impacts of energy generation from fossil fuels, particularly acidification precursors, greenhouse gases, and localized air quality impacts. Much of these emissions result from power generation and the transport sector. These environmental impacts occur at local, national, regional, and global levels.

The environment can be defined as those parts of our physical and psychological endowment that we somehow share, which are "open access." An economic analysis shows that it is precisely this shared nature of many environmental endowments that threatens their quality and character. In a market system, goods are allocated by the price mechanism. In a free market, the price of a good is determined by the demand for, and supply of, the good. Price is therefore a reflection of society's willingness to pay for, or the valuation it places on, the good in question. However, the shared nature of many environmental assets, such as air, the atmosphere, and water resources, means that they are not owned and so do not have a price. When goods are seen as free they are overused. Thus, the market fails to protect environmental assets adequately.

This failure of the market can be best demonstrated with a simple example: If a power plant produces SO_2 emissions resulting in acid rain, which causes forest damage and damage to buildings, in a free market these costs will not be reflected in the cost of power generation. Thus, the price of the energy will not reflect the true cost to society of generating it. In this case, more energy will be generated and more of the environmental asset depleted than is in the best interest of society. When a cost is imposed on those other than the person or business that produces the cost, this is known as an external cost. Of course, many energy projects will reduce such externalities, such as through renewable energy sources and improved heating and insulation systems.

When assessing the social efficiency of energy activities using CBA, it is necessary to include these externalities and other wider societal impacts. However, because by definition such costs and benefits are not traded in markets, there is no price to reflect their value. This provides the basis for the tools of environmental valuation.

3.2 Calibration of Environmental Policy Instruments

Unless some mechanism is found to internalize these externalities, they will cause a misuse of society's scarce resources. This provides the basis for government intervention in the market. The notion of externalities was addressed by economists as far back as the 1930s. Pollution was seen as the consequence of an absence of prices for scarce environmental resources and so the prescription for solving the problem was to introduce a set of surrogate prices using environmental (Pigouvian) taxes and charges. A large literature has developed on these so-called market-based instruments. One of the more controversial concepts in environmental economics is that there is an optimal level of pollution. Pollution is usually the by-product of a useful activity, such as the production of goods and services; in other words, it is an input into the production process. Reducing pollution usually involves a cost in terms of output forgone and/or the cost of the technical process of abatement. Therefore, there is a trade-off between the environmental improvement and the costs of pollution reduction. The optimal level of pollution occurs where the benefit of another unit of abatement (the marginal benefit) equals the (marginal) cost, with the (marginal) cost being higher after that point. In the case of an extremely hazardous pollutant, the optimal level of pollution will be zero or close to it, but in most cases the optimal level of pollution will be positive. CBA provides the tools to assess these trade-offs. In reality, few economic instruments are actually based on such valuations. Research on so-called target setting using

environmental valuation is still in a preliminary stage. However, it could be used to assess the optimal level of an energy tax.

3.3 State Ownership of Energy Generation and Supply/State Support of Energy Efficiency Initiatives

In some countries, energy supply companies are owned by the state. In some cases, the original rationale for such ownership was that no private company would bear the large fixed costs of developing an energy supply system. In addition, it is sometimes suggested that state companies can perform as natural monopolies and thereby exploit economies of scale while producing at minimum average cost and subsidizing energy for certain sections of society. CBA has a role to play in assessing the merits of such state initiatives and is particularly relevant when assessing the merits of government intervention to improve energy efficiency, for example, by subsidizing wind power or a domestic energy efficiency program.

3.4 Sustainability Assessment and Green National Accounting

CBA is useful in assessing sustainability; that is, what is the value of our resource stock, how is it being depleted, and is man-made capital that is replacing it of equal value? Green accounting adjusts traditional measures of economic performance such as gross national product to reflect environmental damage and the depletion of resources. In relation to energy, CBA may be used to assess the social costs and benefits of depleting energy resources such as fossil fuels.

4. COST–BENEFIT METHODOLOGY

4.1 Welfare Criterion

In using CBA to assess the costs and benefits of a project or policy to society, it is first necessary to define the social efficiency criterion. The most frequently used criterion in microeconomic theory is Pareto optimality. Using this criterion, a project would be deemed to pass a CBA if it made at least one person better off without making anybody else worse off. For an investment to pass the Pareto optimality test, compensation must be paid to those bearing the costs so as to leave them indifferent between their welfare *ex post* and *ex ante*. Most policies and investments leave somebody worse off and thus most would fail to meet the Pareto criterion. Frequently in CBA, the Kaldor–Hicks test is used. This test embodies the potential compensation principle. Kaldor categorized an action as efficient if those who gain from the action could compensate the losers and still be better off. Hicks framed the question slightly differently and labeled the action efficient if the potential losers from the action could compensate the potential beneficiaries of the action for not initiating the action. In both cases, the action is an improvement regardless of whether the compensation is actually paid. Thus, if the CBA shows the project to result in a welfare improvement under the Kaldor–Hicks test, this is essentially a potential Pareto improvement since there is the potential, in theory, to pay compensation to the losers such that nobody would be worse off. This will be the case as long as the benefits of the project outweigh the costs (i.e., the benefit:cost ratio is greater than 1).

Whether or not this potential payment is enough to show that a project is good for society has been the matter of much debate. Some authors have suggested that despite the shortcomings of the Kaldor–Hicks criterion, it is often useful to measure the effects of a change in the total value of output independently of the distribution of output; however, in judging the social efficiency of a project, equity aspects should also be considered. A two-part test may be used in which a project or policy is put to the Kaldor–Hicks test and then tested to determine if it improves (or at least does not disimprove) the distribution of income. Approaches that consider questions of equity therefore allow the possibility of acceptance of a project or policy that returns a negative figure for the sum of individual welfare changes if the gains from income distribution outweigh these losses. However, when considering equity the difficulty is in the assignment of weights to individual welfare changes. Consideration of equity issues and distributional consequences are particularly relevant in the case of projects that affect the price of energy and/or health. Energy price increases may be regressive unless poverty-proofing measures are put in place because energy is a necessity and therefore requires a larger proportion of the budget of less well-off people. On the other hand, improvements in domestic energy efficiency may bring significant health and comfort benefits to the elderly, who in some countries have been shown to be more likely to live in energy-inefficient homes and therefore more likely to be subject to winter morbidity and mortality.

4.2 Welfare Measures

In order to assess the costs and benefits of a project or policy, it is necessary to examine the strength of consumers' preferences for or against the project. The standard approach is to measure the benefit an individual obtains from a project or policy by the maximum willingness to pay on his or her part for such a benefit or the maximum willingness to accept compensation for not receiving such a benefit. Similarly, a cost can be measured by the maximum willingness to pay on the part of an individual to avoid such a cost or the maximum willingness to accept compensation for such a cost being imposed on the individual. Such welfare measures may be approximated using shadow pricing and/or direct valuation methods from surveys.

4.3 Temporal Considerations

Account must be taken of the fact that costs and benefits arise at different times. Thus, future costs and benefits must be discounted so that they can be compared with present costs and benefits. The rate of return for an investment can be strongly affected by the discount rate if there is a long time span involved. Therefore, the choice of discount rate is very important. In some estimates of damages from global warming resulting from the burning of fossil fuels, a small change in the assumed discount rate will have significant implications for climate change policy. However, despite the enormous literature on discounting, it is a difficult task to calculate the social rate of discounting. The discount rate is measured by some combination of a social rate of time preference and a measure of the opportunity cost of capital. Economists have been unable to provide a definitive figure for the social rate of discount, and so a rate tends to be chosen rather than measured.

In an application of CBA to any project or policy, a range of discount rates should be used. Often, for a government project, a published government test discount rate is used for making policy recommendations. These vary by jurisdiction. For example, UK treasury guidelines for the opportunity cost of public investment take the rate of return to marginal private sector investment as 6%. For pricing output sold commercially, public sector agencies are expected to achieve a required average rate of return of 8% to be consistent with the private sector. In the United States, recommended rates for investment projects vary. The Office of Management and Budget recommends a rate of 10%, whereas the General Accounting Office prefers a rate of 2.5% based on government bond yields. The World Bank has traditionally used an 8% rate in project analysis.

4.4 Uncertainty and Risk

In *ex ante* CBAs, investments with long time horizons are subject to uncertainty, particularly in relation to future prices. In addition, when evaluating costs and benefits *ex ante*, there may be considerable uncertainty regarding the magnitude of various parameters. This is particularly the case in relation to potential environmental impacts and their valuation. In cases in which there is a high degree of uncertainty in relation to the coefficients being used to give the monetary value of outputs of a project, lower bound estimates are sometimes used because, if the results are to be the basis for the recommendation of a change in policy, it is thought by some authors that it is better for the benefits to be underestimated rather than overestimated. It is important to note that lower bound results do not necessarily imply the lowest possible results. Rather, they denote the lower limits of a range of reasonable estimates.

Sensitivity analysis, whereby results are calculated for various scenarios, should be used in all CBAs. In addition, confidence intervals should be presented where possible. A general rule is that the more results the better while giving guidance and reasons for the particular estimates chosen by the author(s) for the purposes of recommendations based on the CBA results. Risk assessment may be incorporated by including probability estimates for various scenarios.

4.5 Shadow Prices and Wages and Community Stability

Shadow prices must be used when there are distortions within an economy that render certain prices invalid as measures of the social opportunity costs and benefits of using resources in the project in question. In the real world, market prices may not reflect the social value of goods or services because of distortions in the market, such as monopoly power (which inflates price), indirect taxes and subsidies (unless they are correcting some other distortion), and unemployment. Thus, when calculating each value of a project, it is necessary to assess the appropriateness of using the market value and, where necessary, these values should be adjusted for market distortions. This can be a problem in energy projects for which a particular piece of technology may be supplied by one

company and/or estimates must be made regarding how price would decline should such a piece of technology be widely adopted, for example, in a national domestic energy efficiency retrofit.

The approach to valuing labor is worth detailing. In reports purporting to be CBAs, labor or "employment" is sometimes treated as a benefit rather than a cost. Labor is an input into a project and, therefore, a cost even though it may have some additional benefits such as community stability, as discussed later. However, that cost may be less than the market wage would suggest. If labor markets clear, the shadow price of labor will equal the market wage. Any increase in employment in one sector of the economy will merely reduce the availability of labor to another sector. This is likely to be the case when the jobs are highly skilled and/or there is a shortage of such skills. However, for a country with a high unemployment rate, it could be argued that an increase in the demand for labor in one sector of the economy will not necessarily displace a job in another sector; that is, there may be employment additionality whereby if the new job is filled by a person who was previously unemployed, a very low cost (not zero, unless it is considered that the unemployed's spare time is totally unproductive) in terms of output forgone is imposed on society. In this case, the shadow price of labor would be close to zero. It has been the practice of some government CBAs to assume a shadow price of labor of zero. However, this is against the international practice of setting the shadow price of labor at most a fraction below the market wage. For example, in Canada, the shadow wage is usually 95% of the market wage, and in the United Kingdom they are usually considered equal. In many energy projects, specialized skills are required and so a shadow wage close to the market wage will usually be appropriate. However, in some household energy efficiency improvement schemes, long-term unemployed people have been trained how to fit various sorts of insulation, for example. In this example, a case could be made for using a lower shadow wage rate.

A related value that should be considered is whether an energy project may contribute to community stability. For example, would the provision of a new power plant in a rural area provide jobs such that depopulation of that area would halt? This value is not the value of the job per se. Rather, it is the added value of a job being in a particular place. These values are difficult to assess but are real. For example, it is often observed that employees will be willing to accept lower salaries to live in their hometown.

4.6 Valuing Changes in Energy Use

When calculating the benefits of reductions in energy use, the price of energy may be used to value such savings. However, it may be necessary to shadow price such savings. If the state supplies energy, an assessment must be made of whether there is any form of subsidy involved; if so, this should be removed. Where there is monopoly power in the energy market, either locally or, for example, through the monopolistic behavior of the Organization of Petroleum Exporting Countries, the price of energy is unlikely to reflect the true cost to society of its generation.

Energy supply is considered so essential that a premium may be placed on its supply from domestic sources if this reduces the risk of supply interruption. Most countries have assessed the importance of such supply, and this information may be used to assess any premium that should be applied. If the increase in supply that would be generated by the energy project under consideration is marginal to the total supply in a country, it is unlikely that such a premium would be significant.

In an *ex ante* analysis, a sensitivity analysis should be undertaken for alternative scenarios regarding the possible future changes in energy prices. These are difficult to predict because there are a number of offsetting effects. Possible deflationary pressures include the development of more energy-efficient machinery and technology, improved availability (and therefore reduced prices) of non-fossil fuel energy sources and systems, and any change in the regulation of the energy sector. Possible inflationary pressures include rapid economic growth and a consequent increased demand for energy, the exercising of market power in oil production, future scarcity of fossil fuels, and the introduction of carbon taxes and/or tradable permits in light of the Kyoto Protocol. However, if the price of energy is inflated by a carbon tax/emissions-trading system set to reflect the external costs of energy use, it is important to avoid summing external costs estimated by the techniques described later with the energy savings using this price because if the price already reflects the external effects, it would be inappropriate to include them a second time.

4.7 Externalities

Shadow prices adjust for one form of market failure. However, a CBA must also take into account the potential existence of externalities and public goods, as explained previously. The consideration of such

costs and benefits is extremely important in CBAs because all of the costs and all of the benefits to the whole of society are being considered. The difficulty is that these external costs and benefits are not exchanged within markets, so there is no price to reflect their value. For this reason, it is necessary to use nonmarket or environmental valuation approaches to place monetary values on these externalities.

5. VALUATION OF ENERGY EXTERNALITIES

Most energy projects have some impact on the environment that must be factored into a CBA. For example, a new coal-fired power plant will have implications for climate change, localized air pollution, and the production of acidification precursors. A cost–benefit analyst assessing the merits of a renewable energy project or an energy efficiency program will wish to factor in the value of reductions in such environmental effects.

5.1 Economic Value Concepts

A useful framework for assessing the effects of environmental impacts on humans is known as the total economic value approach. This expands the traditional concepts of economic value to include option value and existence value. In essence, an environmental asset is considered to have both use and nonuse value.

Use value can be broken down into actual use value and option value. Suppose we are estimating the value of damage caused to woodland from acid rain resulting from power generation. Actual use value is derived from the actual use of the asset and is composed of direct use value, such as timber from the woodland, and indirect use value, such as the value that would be yielded to inhabitants downstream should a forest reduce flooding.

Option value can be broken down into a number of components: the value individuals place on the preservation of an asset so that they may have the option of using it in the future (value of future options for the individual) for recreational purposes, for example; the value they attach to preserving the asset because it can be used by others (vicarious value); and the value they attach to preserving the asset so that future generations have the option of using it (bequest value). Thus, total use value is defined as

$$\begin{aligned}\text{Total use value} = {} & \text{direct use value} \\ & + \text{indirect use value} \\ & + \text{option value},\end{aligned}$$

where

$$\begin{aligned}\text{Option value} = {} & \text{value of future options for the} \\ & \quad \text{individual} \\ & + \text{vicarious value} \\ & + \text{bequest value}.\end{aligned}$$

Nonuse values are existence or passive-use values. Existence values reflect the benefit to individuals of the existence of an environmental asset, although the individuals do not actually use the asset. These values may exist due to sympathy for animals and plants and/or some human approximation of the intrinsic value of nature (i.e., this value reflects a sense of stewardship on the part of humans toward the environment). Existence value is classed as a nonuse value such that total economic value (TEV) is defined as

$$\begin{aligned}\text{TEV} = {} & \text{actual use value} + \text{option value} \\ & + \text{existence value}.\end{aligned}$$

It is important to note that the TEV approach attempts to encapsulate all aspects of a resource that enter into human's utility functions (i.e., it is anthropocentric). Thus, it does not attempt to find an intrinsic value for the environment, where intrinsic means the value that resides in something that is unrelated to humans. However, it does attempt to include the intrinsic value that humans bestow on nature. There is no agreement on the exact breakdown of the values in the TEV framework; however, the important point in CBA is to account for all these values as best as possible.

5.2 Environmental Valuation Methods

There are two broad categories of nonmarket valuation methods: revealed preference methods and stated preference methods.

5.2.1 Revealed Preference Methods

Revealed preference studies use data from actual behavior to derive values for environmental assets. Suppose the value of a marketed good depends in part on an environmental good. These methods try to isolate the value of the environmental good from the

overall value of the marketed good. Such techniques include the following:

Hedonic pricing method: The value of a house depends, in part, on its surrounding environment. This method examines the determinants of the house's value and then isolates the effect that the environmental feature (e.g., a nearby park) has on the house. This is used as an estimate of the value of the environmental asset in question.

Travel cost method: The value of the park can be estimated by the willingness to pay to attend the park in terms of costs of travel and entrance to the park.

Production function approaches: These value a decrease (increase) in environmental quality as a result of some activity by the loss of (addition to) the value of production due to that activity. For example, the cost of acid rain resulting from pollution from fossil fuel-based power plants might be measured by the lost output of timber from forests (dose–response functions), the cost of restoring the damage to buildings (replacement cost), or the cost of defensive expenditures.

The production function approaches may seem more applicable to estimating externalities of energy generation, but the hedonic pricing method and travel cost method may be used to estimate the value of an amenity such as a forest park. This value could then be used to calculate the cost of damage to the park from air pollution.

5.2.2 Stated Preference Methods

Direct valuation methods ask people in a survey to place a value on the environmental asset in question by rating (contingent valuation), ranking (contingent ranking), or choosing trade-offs between various policy alternatives (choice procedures). These direct methods via questionnaires are the only approaches that can estimate existence value. The best known and most controversial of these methods is contingent valuation.

The contingent valuation method (CVM) collects information on preferences by asking households how much they are willing to pay for some change in the provision of an environmental good or the minimum compensation they would require if the change were not carried out. Since the mid- to late 1980 s, this method has become the most widely used approach for valuing public goods and there has been an explosion in the number of CV studies.

The CVM approach is to choose a representative sample, choose an interview technique (face-to-face, telephone, or mail), and then construct a questionnaire containing:

- A detailed description of the good being valued and the hypothetical circumstance in which it is made available to the respondent.
- Questions that elicit the respondents' willingness to pay for the good being valued: open ended (How much would you pay?), bidding (Will you pay x, if not, will you pay $x-y$), payment card (Which of these amounts would you choose?), and binary choice (If it costs x, would you pay it? Yes/no).
- Questions about the respondents' characteristics (e.g., age, education, and income), their preferences relevant to the good being valued (e.g., how concerned or interested are they in the environment), and their use of the good.

The mean or median willingness to pay from the sample of households surveyed can be multiplied up to the population level to give a total valuation.

5.3 Valuing Environmental Damage and Improvements from Energy Projects

The most significant environmental effects of energy projects that are included in CBAs tend to be the contribution of such projects to global warming from changes in CO_2 emissions and acid rain resulting from the production of NO_x and SO_2. In addition, many energy projects have implications for the production of particulate matter that may have consequences for human health and visibility.

The impacts of climate change are as follows: storm and flood damage (increased in some regions, such as the Caribbean and Pacific, but not others), increased mortality and morbidity, effects on small islands (sea levels rise due to heating water and melting ice caps), increasing salinity of estuaries, damage to freshwater aquifers, and effects on agriculture and forestry. It is estimated that a substantial portion of the existing forested area of the world will undergo major changes.

There are three approaches to placing a monetary value on the benefits of greenhouse gas reductions. The damage-avoided approach values 1 ton of carbon not emitted by the cost of the damage that would have been done by global warming in the event that it had been emitted. The offset approach measures the value of not emitting 1 ton of carbon using one method compared to the next cheapest alternative method. The avoided cost of compliance

approach measures the 1 ton of saved carbon by the avoided cost of compliance with a global/regional CO_2 emissions reduction agreement. A variety of estimates have been produced regarding the benefits of reducing CO_2, including studies by the United Nations Intergovernmental Panel for Climate Change.

Several major research projects have endeavored to place monetary values on all the environmental effects related to energy. Two EU-funded projects, one on the external costs of power generation (ExternE) and the other on European environmental priorities, are very useful sources of information on such values.

The ExternE project used an "impact pathway" methodology. Under this methodology, the fuel cycle, or life cycle of the fossil fuel used for generation, is first divided into stages, such as extraction, transport, combustion, and waste disposal. The environmental burdens imposed at each stage and the likely impact of these burdens on the environment and the public are isolated. The impacts are then valued using a variety of economic valuation methods, such as contingent valuation, direct cost of damage, or cost of mitigation. These costs are then normalized to give a cost per unit energy output and a value per ton of a pollutant reduced.

The "priorities" project endeavors to derive values for various environmental externalities suitable for use in a European context. The impacts of SO_2 on acute mortality, morbidity, materials, and the fertilization effect are all included; however, some impacts are omitted, such as forest damage, adverse effects on ecosystems and cultural heritage, and the dampening effect that SO_2 has on global warming. The main areas of uncertainty relate to the value of mortality. NO_x emissions are dealt with under two headings, acidification and tropospheric ozone. The fertilization effect of NO_x is examined under acidification. For damage to health and crops, the effects of NO_x on tropospheric ozone are used. Again, the bias is toward underestimation because damage caused to forests, biodiversity, non-crop vegetation, and materials is excluded.

Care should be taken when using unit damage values such as those in the studies mentioned previously. First, the confidence intervals are large (and should always be quoted in a CBA). In addition, there is confusion about which emissions cause which adverse effects. For this reason, it is very easy to double count when using estimates derived from different studies. For example, in some studies negative health effects are included in SO_2 damage estimates, whereas in others the most significant health effects result from particulate matter emissions. Finally, the damage caused by 1 ton of most air pollutants (excluding CO_2) will vary depending on the geographical origin of the emission. However, most estimates are derived from an exercise known as benefits transfer.

5.4 Benefits Transfer

To reduce costs and where there is no alternative procedure, it is standard practice in CBAs to apply existing monetary valuation studies outside of the site context in which they were originally undertaken. This is known as benefits transfer. There are a number of rules when using this method, the most obvious being that the contexts of the studies should be very similar. In addition, appropriate statistical techniques should be used, including meta-analyses of best practice studies; the studies should have similar population characteristics; and property rights should be similarly distributed. The method is most accurate when the impacts are not affected by local characteristics (e.g., income and population size). The most comprehensive studies of energy externalities referred to previously involve significant benefits transfer.

5.5 Valuing Mortality and Morbidity

Placing monetary values on life and death is perhaps the most controversial area of economics. There are two major approaches for carrying out this task. The first values life directly through livelihood. This is known as the human capital method and is the oldest and most easily applied. It equates the value of life of an individual as the present value of future lost output of the individual, which is usually estimated using income. However, it is important to note the substantial drawbacks of this approach. Most obvious, it values livelihood rather than life per se. It is quite improbable that there would be a 1:1 relationship between individuals' earnings and their demand for risk reduction. In other words, the human capital approach makes no reference to how humans value risks to their own lives. One of the most glaring flaws of this approach, however, is the fact that it places a zero value on the retired population and those who do not "produce" marketed output (e.g., those who work in the home).

The appropriate way of valuing reductions in mortality is not to value a life per se but rather to value people's willingness to pay for a reduction in

the risk of mortality. These data derive primarily from one of three study formats: the wage risk model (also known as the hedonic wage model), the avertive behavior method, and the contingent valuation method. Although space does not permit a detailed explanation of these methods, the general approach is to value a small reduction in risk and then translate this into the equivalent of a life saved. This is the value of a statistical life (VSL).

There has been controversy regarding this approach in relation to the estimation of the costs of power generation. The VSL estimates would be expected to be considerably lower for a developing country because the willingness of people to pay to reduce risk of death is partially dependent on income. Thus, the VSL used for a developing country (e.g., for deaths from coal mining) would be expected to be lower than the VSL used for a developed area (e.g., for deaths from air emissions in Europe by the burning of such coal). It is notable that the ExternE project steered clear of controversy by using the same VSL for each area.

The value of morbidity may be assessed using a cost of illness approach. In the case of air pollution from energy generation, this would be the sum of the cost, both public and private, of hospital stays and drugs for the treatment of associated illnesses. More positively, the health benefits of improving domestic energy efficiency would be the associated avoided costs of illnesses. Other costs avoided by wider society include the loss of productivity from those who are ill and unable to work. The avoided cost to the individual beyond drugs and hospitalization direct costs (if any) is more difficult to calculate. One approach is to estimate individuals' willingness to pay to avoid "restricted-activity days." The priorities study referred to previously contains such estimates.

6. FURTHER ISSUES IN THE APPLICATION OF COST–BENEFIT ANALYSIS TO ENERGY

When undertaking or evaluating a CBA of an energy project, there are a number of additional issues that must be considered. The tool is not without its controversies. These arise because of its use of money as the common unit of measurement. First, assessing welfare changes using willingness to pay and/or willingness to accept is perfectly valid in theory if one believes that income is distributed optimally. However, care must be taken when the population(s) whose welfare is being assessed has a high income variance. Poor people will be willing to pay less, all else being equal, simply because of their budget constraint. In addition, because the values and market prices used in a CBA of an energy project or policy are in part a product of the existing income distribution, if that distribution changes, prices will change, and so will market and nonmarket values. Second, distributional effects tend to be ignored in CBAs and yet energy policies often have very different consequences for different socioeconomic groups. Because energy is a necessity, energy efficiency schemes may benefit those on lower incomes more than average. However, without poverty-proofing measures, energy taxes will comprise a much higher proportion of their income than average. Third, not all support attempts to place monetary values on environmental assets, and the value of the statistical life concept is particularly controversial. Some find it unpalatable to consider that the environment might be traded with other goods and services let alone "lives." In addition, as in all public policy or human actions, the environmental values used are by definition anthropocentric.

Finally, the environmental valuation methods are limited in their ability to assess values. Many environmental outcomes assessed by natural scientists are subject to large confidence intervals even before economists endeavor to value them. Also, the valuation methods vary in their ability to assess environmental values. Economists have identified a number of criteria by which environmental valuation methods should be evaluated: validity (the degree to which it measures the total economic value of a change in the environment), reliability (the extent to which the variability in nonmarket values is due to random sources), applicability (assesses where the techniques are best applied), and cost (the practicality and viability of carrying out the valuation study). In general, revealed preference methods (e.g., productivity loss and replacement cost) are widely accepted valuation methods that provide valid and often reliable estimates of use values. However, they are limited in that they only provide estimates of use values, and it is often difficult to find suitable and reliable links between market goods and environmental amenities. The estimated values are often sensitive with respect to modeling assumptions, reducing their reliability in such cases. In general, however, revealed preference methods are applicable for valuation of policies that primarily affect use values and can provide very reliable results. Stated

preference methods such as contingent valuation are capable of measuring both use and nonuse (existence/passive-use) values. They are applicable to a larger array of environmental issues than are revealed preference methods, and they are often the only applicable methods for benefit estimation. However, they do have a number of limitations and may be subject to a number of biases.

There are some simple rules for using cost–benefit techniques. Simpler environmental valuation methods should be used where possible (e.g., production function approaches) while recognizing these are primarily of interest when the policy changes will mainly influence use values. A high degree of reliability in stated preference methods may be achieved by adhering to sound principles for survey and questionnaire design and if the method is applied to suitable environmental goods. The methods work best for familiar environmental goods and for salient environmental issues. The methods are likely to be least reliable where the environmental good being valued is complex (e.g., in the case of biodiversity).

Finally, in CBAs of energy initiatives, it is important to note that the estimates of values are made at the margin. The plausibility of the techniques described depends in part on the fact that most things remain the same, with the implicit assumption that there is no paradigm shift in values, power, income, and the like during the time period of assessment.

Glossary

API (American Petroleum Institute) gravity A scale describing the density of an oil. Oils with gravities $>40^\circ$ are known as light oils, and those with gravities $<17^\circ$ are said to be heavy.

asphaltenes Large complex molecules in crude oils and heavy fuels, often with molecular weights in the many thousands, composed of carbon, hydrogen, oxygen, and other heteroatoms. They are responsible for most of the color of crude and heavy oils and typically are not "oily" to the touch.

bioremediation Stimulating the natural process of oil biodegradation. To date, this has been restricted to the addition of fertilizers to alleviate nutrient limitations for these organisms. Adding bacteria has not been shown to be necessary.

booms Floating devices for corralling, or sometimes absorbing, oil on water. There are many different designs for different situations, including stationary booms in rivers, towed booms for collecting oil, and fireproof booms for holding oil for combustion.

Bunker C Fuel oil used to power ships' engines. It is a very heavy, viscous fuel derived from the heaviest hydrocarbon compounds that remain after processing whole crude oil.

crude oil Natural product that is the remains of biomass that was typically alive 100 million years ago. It is a complex mixture of hydrocarbons, resins, and asphaltenes.

dispersants Concentrated solutions of surfactants that can be sprayed on floating oil to cause it to disperse into the water column, where it is naturally biodegraded.

hydrocarbons Compounds composed of only carbon and hydrocarbon; these are the most abundant molecules in most crude oils and refined fuels. They are a diverse mixture of linear, branched, and cyclic saturated compounds with 1–80 carbon atoms, together with aromatic compounds, most commonly with more than one ring and with multiple alkyl substituents.

natural attenuation The natural processes that eventually remove hydrocarbons from the atmosphere.

resins Moderately large complex molecules in crude oils and heavy fuels, often with molecular weights in the thousands, composed of carbon, hydrogen, oxygen, and other heteroatoms.

skimmers Mechanical devices to remove floating oil from water. There are many designs, including moving belts, weirs, mops, and vacuum pumps.

Crude oils and other hydrocarbons have been a part of the biosphere for millennia, so it is no surprise that a ubiquitous, diverse population of hydrocarbon-consuming microorganisms are able to exploit this resource. These organisms can be recruited to help respond to human-associated oil spills, although sometimes only after physical treatments to remove bulk oil, such as mechanical pick-up or combustion:

- If oil is floating at sea, the addition of dispersants to dramatically increase the surface area available for microbial attack will stimulate biodegradation

 © 2004 Elsevier Inc. All rights reserved.

and also inhibit the formation of troublesome tar balls and minimize the amount of oil that reaches the shore.
- If oil is on a shoreline, the addition of fertilizers to provide necessary ancillary nutrients for the degrading microorganisms will stimulate oil biodegradation.
- If oil is in surface soil, adding fertilizers and tilling the soil will provide both the nutrients and the air needed to stimulate biodegradation.
- If soluble hydrocarbons are in an underground water plume, adding a source of oxygen, whether as a gas or a soluble or slow-release peroxides, will stimulate aerobic biodegradation.

Together, these approaches exemplify modern environmentally responsible remediation activities: working with natural processes to stimulate them without causing any additional adverse environmental impact.

1. INTRODUCTION

Crude oils have been a part of the biosphere for millennia, and human use extends back thousands of years. Early uses included hafting stone axes to handles, use as an embalming agent, and use as a medical nostrum. In the Bible, Genesis implies that bitumen was used as the mortar for the Tower of Babel. It also seems likely that several religions started near natural gas seeps, either as eternal flames or as sources of hallucinogenic vapors. However, these were very minor uses, and it is only in the past century and a half that oil has come to play a truly central role in our lives. Terrestrial seeps were the first locations to be drilled when oil production began in earnest in the 19th century, such as the 1859 Drake well in Pennsylvania. Today, oil is recovered from all over the world, except the Antarctic, and from great depths, including coastal margins such as offshore West Africa and South America. The scale of oil production is staggering; global use is on the order of 10^{12} U.S. gallons per year (3.25×10^9 tonnes or 3.8×10^{12} liters/year), and much of it is transported thousands of miles before it is used. For example, the United States imported 350,000 tonnes of oil per day from the Middle East alone in 1999. Unfortunately, despite the best efforts of the oil industry, some (a relatively small fraction) of this material has been spilled at production and refinery facilities and from pipelines and vessels. Such spills generate enormous public pressure for speedy clean-up, but the obvious approach of simply sucking up the oil from the environment is rarely simple or complete. This article addresses the natural fate of oil in the environment and how understanding the underlying processes allows intervention to safely stimulate them and thereby minimize the environmental impact of spills.

2. COMPOSITION OF CRUDE OILS AND REFINED PRODUCTS

2.1 Origins

Crude oils are natural products, the result of the burial and alteration of biomass from the distant past. The alteration processes are known as diagenesis and catagenesis. The initial process of diagenesis typically occurs at temperatures at which microbes partially degrade the biomass and results in dehydration, condensation, cyclization, and polymerization of the biomass. Subsequent burial under more sediments, and thus at higher temperatures and pressures, allows catagenesis to complete the transformation of the biomass to fossil fuel by thermal cracking and decarboxylation.

It is generally accepted that most petroleum reserves are derived from aquatic algae, albeit sometimes with some terrestrial material, whereas the great coal reserves of the world arose from deposits of higher plants, typically in nonmarine environments. The generation of oil and gas invariably occurs at significant depth and under great pressure, which forcibly expels the oil and gas from the initial source rock. Commercially valuable reservoirs are formed if the migrating oil becomes trapped in a geological structure so that the oil and gas can accumulate. Most petroleum reservoirs are found in sandstones, siltstones, and carbonates with porosities of 5–30%. The traps are never completely full of oil, and there is always some water, usually containing substantial amounts of inorganic salts (brine), underlying the oil. Typical commercial oils originated from biomass that was produced on the order of 100 million years ago, although the oldest commercially valuable oils are from Ordovician biomass (486 million years ago), whereas others are as young as the late Tertiary (a few million years ago).

2.2 Hydrocarbons

Crude oils and refined products are very complex mixtures of molecules, both hydrocarbons and

compounds containing other elements, such as sulfur, oxygen, and nitrogen. The hydrocarbons, containing only hydrogen and carbon, are the best studied and understood, and they can be divided into broad classes based on their overall chemical properties. The hydrogen to carbon ratio of crude oils is between 1.5 and 2.0; the organic molecules are thus principally saturated molecules (i.e., the predominant form of carbon is $-CH_2-$). The convention in the oil industry is to call linear alkanes paraffins and cyclic alkanes naphthenes. There are also significant amounts of aromatic carbon in all crude oils and polar molecules containing the heteroatoms oxygen, nitrogen, and sulfur. These latter molecules can be fractionated by column chromatography, and the fractions have a variety of names, including resins and asphaltenes. In their classic 1984 book "Petroleum Formation and Occurrence," Tissot and Welte state that the average composition of 527 crude oils is 58.2% saturates, 28.6% aromatics, and 14.2% polar compounds, although the absolute values vary widely in different oils. On average, there is rough parity between paraffins, naphthenes, and aromatics.

The paraffins include the linear alkanes from methane to waxes with up to 80 carbons. Linear alkanes typically make up 10–20% of a crude oil, although their content can range from essentially undetectable to as high as 35% depending on source and reservoir conditions. There are also branched alkanes, usually most abundant in the C_6–C_8 range. Two branched alkanes found in almost all crude oils, pristane ($C_{19}H_{40}$) and phytane ($C_{20}H_{42}$), are molecular relics of the phytol chains of chlorophylls and perhaps other biomolecules in the original biomass that gave rise to the oil.

The naphthenes include simple compounds such as cyclopentane, cyclohexane, and decalin, together with their alkylated congeners. Tissot and Welte state that the average composition of the naphthene fraction of 299 crude oils is 54.9% one- and two-ring naphthenes, 20.4% tricyclic naphthenes, and 24.0% tetra- and pentacyclic naphthenes. These latter molecules are molecular relics of membrane components of the original biomass, and they are very useful fingerprints of individual oils.

The aromatic molecules in crude oils range from benzene to three- and four-ring structures, with traces of even larger ring systems. Because of the separation procedures used in the characterization of crude oils, any molecule containing at least one aromatic ring is included in the "aromatic" fraction, regardless of the presence of saturated rings and alkyl substituents. Crude oils typically contain aromatic molecules with up to four aromatic rings; one series contains just six-membered rings and their alkylated derivatives—benzene (one ring), naphthalene (two rings), phenanthrene (three rings), chrysene (four rings), etc. Another series includes one five-membered ring in addition to the six-membered ones—fluorene (three rings), fluoranthene (four rings), etc. Because of the operational definition based on chromatography, sulfur aromatic heterocycles, such as thiophenes, benzothiophenes, and dibenzothiophenes, are included in the aromatic category. Indoles and carbazoles, usually the most abundant nitrogen-containing species, and the less abundant basic nitrogen species such as quinolines are also included in the aromatic category. Alkylated aromatic species are usually more abundant than their parent compounds, with mono-, di-, and trimethyl derivatives usually being most abundant. Nevertheless, the median aromatic structure probably has one or two methyl substituents together with a long-chain alkyl substituent.

2.3 Nonhydrocarbons

The polar molecules of crude oils are the most difficult to characterize because they are often unamenable to gas chromatography, the usual method of choice for the molecular characterization of petroleum. All are thought to contain heteroatoms, such as nitrogen, oxygen, and/or sulfur, and the category includes the porphyrins (usually nickel or vanadium species) and naphthenic acids. Some of these molecules have molecular weights in the thousands or higher, and many are suspended in the oil rather than dissolved in it. The polar fraction of the oil contains the majority of the color centers in crude oil, and in isolation these materials are difficult to distinguish from recent biological residues, such as humic and fulvic acids.

2.4 Oil Classification

Oils are classified by several criteria, but among the most important is the specific gravity. The oil industry uses a unit known as API (American Petroleum Institute) gravity, which is defined as [141.5/(specific gravity)]−131.5 and expressed in degrees. Thus, water has an API gravity of 10°, and denser fluids have lower API gravities. Less dense fluids (e.g., most hydrocarbons) have API gravities $>10°$. For convenience, oils with API gravities $>40°$ are said to be light oils, whereas those with API gravities $<17°$ are said to be heavy (Table I). Light

TABLE I

Conversion Table for a Medium Crude Oil

1 tonne	308 U.S. gallons
	7.33 barrels
	858 liters

oils have higher proportions of small molecules; heavy oils are rich in larger molecules. Viscosity is inversely proportional to API gravity, but it is also dependent on the physical state of the polar compounds and longer alkanes in the oil, and it is highly dependent on temperature.

2.5 Refined Products

Crude oil is transported in the largest volumes, both in pipelines and in tankers, but refined products are also transported long distances, particularly in pipelines. Refining starts with distillation, and the simplest distinction of the various refined products can be related to this process. The most volatile liquid product is aviation gasoline, followed by automobile gasoline, jet fuels, diesel and heating oils, and the heavy oils that are used for fueling ships and some electrical generation. All ships contain large volumes of heavy fuel oil, often called Bunker C, that is barely liquid at ambient temperatures and must be kept warm to be pumped into engines.

Most of the molecules in gasoline have 4–10 carbons (Table II), most in diesel fuel have 9–20, and heavy fuel oils typically have very few molecules with less than 15 carbon atoms except for some added as a diluent to achieve the appropriate viscosity. It is important to recognize that fuels are not sold by their composition but by their properties, such as octane, cetane, or viscosity, and there are many chemical mixtures that meet these requirements. The chemical composition of fuels with the same name can thus be very different, even though all meet their specifications. The lightest products (i.e., those with the lowest boiling points, such as gasolines and diesels) are almost entirely hydrocarbons, whereas the heavy fuel oils are enriched in the polar constituents such as asphaltenes; this is reflected in the color of the products.

TABLE II

Number of Carbon Atoms in the Majority of Compounds in Refined Products

Product	Approximate carbon range
Aviation gasoline	C_4–C_8
Regular gasoline	C_4–C_{10}
JP4 jet fuel	C_5–C_{11}
JP8 jet fuel	C_8–C_{15}
Kerosene	C_9–C_{16}
Diesel No. 1	C_9–C_{17}
Diesel No. 2	C_9–C_{20}
Bunker C	C_8–C_{10}, C_{15}–C_{50}
Hydraulic oil	C_{18}–C_{36}
Automatic transmission fluid	C_{19}–C_{36}

TABLE III

National Research Council's Estimates of Annual Input of Oil to the Sea

Source	North America, tonnes	World, tonnes
Seeps	160,000	600,000
Consumers	90,000	480,000
Spills	12,100	160,000
Extraction	3,000	38,000
Total	260,000	1,300,000

3. RELEASES TO THE ENVIRONMENT

Crude oil has been released to the natural environment from seeps for millennia and, as mentioned previously, these have proved useful sources for humankind. Some seeps are relatively small, and the oil affects only a very small area. This was true for the seeps that gave rise to "perpetual flames" in Iraq and bitumen reserves in eastern North America. However, some are vast and have given rise to huge asphalt lakes and tarpits. The La Brea tarpits in Los Angeles are well-known, not least for the impressive bones from tigers that unwittingly became entrapped, and the large asphalt lakes in Trinidad (140 acres) were once exploited to deliver asphalt for paving in Newark, New Jersey. Clearly, a major determinant of the environmental impact is the scale of the release. Table III shows 2002 estimates of the scale of oil releases into the sea both in the United States and throughout the world.

3.1 Natural Seeps

Natural seeps are found all over the world, and the scale of their releases is quite large. In 2002, the National Research Council estimated that the total annual input of petroleum into the sea from all

sources is approximately 1.3 million tonnes, with almost 50% coming from natural seeps. For example, natural seeps in the Gulf of Mexico release an estimated 140,000 tonnes of oil per year into the sea, those offshore Southern California release 20,000 tonnes per year, and those offshore Alaska release 40,000 tonnes.

3.2 Municipal Runoff

The National Research Council estimates that releases due to the consumption of crude oil, principally municipal runoff but also including spills from nontanker ships, recreational uses, and atmospheric deposition, are the second largest input of oil into the world's oceans, far dwarfing that from catastrophic tanker spills. Again, the sheer scale of oil use is staggering; it is estimated that just the input of lubricating oil from two-stroke engine use in the U.S. coastal seas is 5300 tonnes per year.

3.3 Tanker Spills

Almost half of all oil moves by seagoing tanker at some stage between production and use, and spills from these vessels attract by far the largest amount of attention from the media. As discussed previously, their total input is relatively small compared to other inputs, and a recent estimate is that more than 99.98% of the oil in transit reaches its destination safely. The issue, of course, is that when they do occur, tanker spills are very localized, and they can have substantial localized environmental impacts that call for a cleanup response. The industry has responded to public concerns, and tanker spills are fortunately becoming rarer; for the period 1990–1999, spillage from vessels in U.S. waters was less than one-third that released in 1980–1989. Similar improvements have occurred worldwide, although there is always need for improvement.

3.4 Pipeline Spills

The Minerals Management Service estimates that there are 21,000 miles of undersea oil pipelines installed on the U.S. continental shelf delivering oil from wellheads to collection points and refineries. Spills are rare but are estimated to be approximately 1,700 tonnes per year, mainly in the Gulf of Mexico. To put this in perspective, the largest spill in the Gulf occurred in 1979, when the IXTOC-1 well "blew out" approximately 80 km off Ciudad del Carmen on the Mexican coast. The blowout lasted 9 months and spilled 476,000 tonnes of crude oil before it could be controlled.

Total U.S. liquid petroleum pipelines include a total of 114,000 miles of crude oil pipelines and 86,500 miles of pipeline for refined products, which together transport two-thirds of all U.S. petroleum. Pipeline leaks, often caused by excavation errors, lead to annual spills of approximately 19,500 tonnes, and again there has been a substantial improvement in safety during the past few decades. Because of the physical barriers around most pipeline spills, they are usually contained, and most spilled oil is collected with pumps. Unfortunately, this is not always the case; in 1997, an underwater pipeline released 940 tonnes of south Louisiana crude oil into Lake Barre in Louisiana. The spill affected 1750 ha with a light sheen, but only 0.1 ha of marsh died back. Much of the oil evaporated, some pooled oil at the edges of some marshes was recovered, and the lightly oiled areas appeared to be clean within 2 months.

3.5 Wars, Environmental Terrorism, and Vandalism

The past decade has seen a resurgence of oil spills associated with warfare, terrorism, and vandalism. Many ships were sunk in World War II, and some still contain substantial amounts of oil; an example is the USS Mississinewa, which was sunk in Ulithi Lagoon in Micronesia in 1944 and recently located. It is estimated to contain 3300–10,000 tonnes of heavy fuel oil, and this is beginning to leak from the decaying vessel. By far the largest oils spills in history were those deliberately released by Iraqi forces retreating from Kuwait in 1991. At least 10 million barrels of oil were deliberately poured into the Arabian Gulf, and 700 oil wells were ignited or otherwise destroyed. Vast lakes of oil covering approximately 49 km^2 were formed, and most remain after a decade. The volumes are so huge that the totals remain unknown.

Smaller wars also cause the release of substantial volumes of oil, although again the totals are difficult to estimate. Colombia's 780-km Cano Limon pipeline, which ships 110,000 barrels of oil per day, was bombed at least 170 times in 2001, and estimates of total oil spilled are far higher than those of well-known tanker spills. The French supertanker Limberg was apparently attacked by terrorists offshore Yemen in 2002. Even the Trans Alaska Pipeline is not immune to vandalism; 925 tonnes were spilled when a high-velocity rifle slug penetrated the pipeline in 2001.

4. NATURAL FATE OF OIL IN THE ENVIRONMENT

The description of the various inputs of oil into our environment, mainly from natural seeps and municipal runoff, makes it clear that oil has been part of the biosphere for millennia. However, we are not overwhelmed by it. This is because a variety of natural processes contribute to its removal, the most important of which is biodegradation. Crude oils and refined products provide an excellent source of carbon and energy to organisms, principally microorganisms, able to exploit it. These organisms are responsible for the consumption of most of the hydrocarbons that get into the biosphere and that are not collected or burnt. Nevertheless, this process is relatively slow, and several physical processes typically act on spilled oil before it is eventually biodegraded.

4.1 Flotation and Spreading

Almost all oils in commerce float; thus, they spread rapidly if the spill is on water. This has the effect of providing a dramatically larger surface area for evaporation and dissolution, and eventually the floating layer becomes subject to physical disruption by waves. A few very heavy oils, such as that spilled in the Delaware River from the Presidente Rivera in 1989, are sufficiently dense that they form almost solid lumps that submerge in fresh water. They do not usually sink, however, and can be collected by subsurface nets.

4.2 Evaporation

Small hydrocarbons are very volatile, and molecules smaller than those with approximately 15 carbons typically evaporate quite readily if a spill is on the surface. This can be effectively complete in a matter of days, although underground spills do not typically evaporate very rapidly. Spills are not the only source of volatile hydrocarbons in the atmosphere; trees liberate vast quantities of isoprene and other terpenes. Whatever the source, some interact with reactive nitrogen oxides in the presence of light and in high enough concentrations can contribute to photochemical smogs, The Blue Mountains got their name from this natural phenomenon long before the onset of the petroleum era. Eventually, most volatile compounds, and the reaction products of photochemical oxidations, are "rained out" and deposited on the ground, where they are biodegraded. Some biodegradation may even take place on water droplets in the atmosphere because there are many bacteria in the air.

4.3 Dissolution

A few hydrocarbons are sufficiently soluble in water that they "wash out" of floating surface or underground spills into the water phase. This phenomenon is usually only significant for the BTEX compounds (benzene, toluene, ethylbenzene, and the xylenes) and oxygenated compounds such as methyl-tertiarybutylether. Such compounds have the tendency to wash out from floating spills, whether on surface water or on the water table underground. This phenomenon is of particular concern underground because the soluble compounds have the potential to migrate and contaminate wells and surface water. Fortunately, they are biodegradable under both aerobic and anaerobic conditions.

4.4 Dispersion

Although oils do not dissolve in water, they can disperse. Wave action breaks up floating slicks and may disperse the oil so finely that it is readily biodegraded. This is what happened to most of the 85,000 tonnes of oil lost in the 1993 spill off the Shetland Islands from the Braer. Adding chemical dispersants to encourage this process is an important oil-spill response tool. If the oil is merely broken into large globs, however, these can coalesce and form tar balls that can drift for thousands of miles before eventually beaching. It is not unusual for tar balls to accumulate other debris during their travels or even to be colonized by barnacles.

4.5 Emulsification

Many oils will form very stable water-in-oil emulsions, particularly after they have weathered sufficiently to form a critical concentration of asphaltenes that can stabilize such emulsions. This can multiply the mass of the original oil by up to five times, increasing the recovery and disposal burden. Water-in-oil emulsions can achieve extremely high viscosities, making relatively light oils behave more like heavy fuel oils. This can slow the evaporative and dissolution processes so that if the emulsions are broken, the released oil's properties are more similar to those of the original material than if emulsification had not occurred.

4.6 Physical Interactions with Sediments

The formation of long-lived "pavements" is a poorly understood phenomenon that can have a significant effect on the persistence of oil in the environment. At high enough concentrations, crude oils and heavy refined products such as bunker fuels interact with sand and gravel so that the oil becomes completely saturated with sediment and vice versa. Even quite liquid oils and fine sediments can form pavements that mimic commercial asphalt, and when this occurs the inner oil is essentially entombed and protected from biodegradation. It can then last for years without significant weathering, as happened in Tierra del Fuego following the 1974 spill of 50,000 tonnes of oil and fuel from the Metula. Spill response efforts aim to minimize and prevent the formation of these pavements.

At the microscale, however, the interaction of oil with fine sediments is proving to be an important natural process that removes oil from oiled shorelines. Fine particles become associated with droplets of oil and effectively disperse into the water column, where biodegradation occurs quite rapidly. The scale and importance of this phenomenon have only been recognized during approximately the past decade.

4.7 Photooxidation

Photooxidation by sunlight is very effective at oxidizing three-, four-, and five-ring aromatics in floating slicks and stranded oil. The molecules are not completely destroyed, but they seem to be polymerized and incorporated into the resin and polar fractions of the oil, where they are probably no longer bioavailable. Photooxidation of the surface of pavements and tar balls may contribute to their longevity. Photooxidation seems to have far less of an effect on the saturated components of oil.

Photooxidation is an important phenomenon not because it removes large volumes of oil from the environment but because it removes the molecules of most toxicological concern. Crude oils and heavy fuels contain trace amounts of potentially carcinogenic polycyclic aromatic hydrocarbons such as benzo[*a*]pyrene. Fortunately, these are among the most susceptible to photooxidation, and they are readily destroyed if an oil is exposed to sunlight.

4.8 Combustion

The natural ignition of gaseous seeps is still a source of wonder whenever it occurs. All hydrocarbons are combustible, and sometimes shipwrecks catch on fire (e.g., the 144,000-tonne spill from the Haven near Genoa in 1991) or are deliberately ignited (e.g., the 1360 tonnes of fuel oil on board the New Carissa offshore Oregon in 1999). A major problem is that the oil has to maintain a high temperature to continue burning, and heat transfer to water underneath a slick usually extinguishes any fire as the slick thins. Burning spilled oil thus usually requires containment within fireproof booms, but if successful it can be very effective; combustion of $>90\%$ has been reported in several trials. Burning may be particularly useful in ice-infested waters, in which skimming is very difficult and the ice can act as an effective boom. The residue, although viscous, is not very different from oil that weathers without heat, and there is only a small increase in pyrogenic compounds in the residue. Burning oil, however, can generate a large amount of black smoke. The smoke is very low in residual hydrocarbon, but may, in certain circumstances, present a potential health concern due to fine particulate matter. If burning occurs away from population centers, the potential for environmental and health impacts of the smoke is minimal.

4.9 Biodegradation

4.1.1 Aerobic

Biodegradation is the ultimate fate of hydrocarbons released into the environment, although it is sometimes a slow process. Biodegradation under aerobic conditions has been studied for at least a century, and the variety of organisms able to consume hydrocarbons and the diverse pathways and enzymes used in the process are well understood. More than 60 genera of bacteria and 95 genera of fungi have been described that catalyze this process, along with a few species of archaea and algae. These organisms share the ability to insert one or two of the oxygen atoms of diatomic O_2 into a hydrocarbon molecule, thereby activating it and making it accessible to the central metabolism of the organism. The oxygenated hydrocarbon then serves as a source of reductant for the growth of the organism, and much more oxygen is required as the terminal oxidant.

Almost all hydrocarbons that have been studied have been shown to be biodegraded in the presence of oxygen. The small aromatics (benzene and the substituted benzenes) and alkanes are most readily consumed, followed by the larger alkanes and the two- and three-ring aromatics and their alkylated

derivatives. The branched alkanes are slightly more resistant, but they are still readily degraded. The biodegradation of alkylated three- and four-ring aromatics is slower, and some of the four- and five-ring saturated compounds, the hopanes and steranes, are among the most resistant. Indeed, they are so resistant that they can serve as conserved internal markers in the oil, and their concentration in the residual oil increases as biodegradation proceeds. They remain as "fingerprints" of the initial composition of the oil until the very last stages of biodegradation.

Estimates for the total biodegradability of the hydrocarbon fraction of different crude oils range from 70 to 97%. Less is known about the biodegradability of the resins, asphaltenes, and other polar species in crude oils, and the larger ones are not thought to be very susceptible to the process. Fortunately, these compounds lack "oiliness," are friable in small quantities, and are essentially biologically inert. Indeed, they are essentially indistinguishable from other relatively inert biomass in the environment, such as the humic and fulvic acids that make up the organic fraction of soils and sediments and are so essential for plant growth.

Aerobic oil-degrading microorganisms are ubiquitous, having been found in all natural environments in which they have been diligently pursued. Indeed, aerobic hydrocarbon-degrading organisms are the foundations of the extensive ecosystems that exploit marine oil seeps, which often include large multicellular organisms that feed on the hydrocarbon-oxidizing microbes. Oil seeps may even serve as the primary food sources for some fisheries, such as those of Atlantic Canada.

4.1.2 Anaerobic

For some time, it has been known that hydrocarbons are also biodegraded under anaerobic conditions. The hydrocarbon still acts as a reductant, and in the absence of oxygen something else must serve as a terminal electron acceptor. Sulfate (reduced to sulfide), nitrate (reduced to nitrogen), chlorate (reduced to chloride), ferric and manganic ions (reduced to ferrous and manganous ions), and carbon dioxide (reduced to methane) have all been shown to be effective oxidants for hydrocarbon degradation, at least in mixed cultures of organisms. Only a few genera of anaerobic bacteria that can catalyze these reactions have been identified, but this undoubtedly is just the tip of the iceberg and probably more an indication of the difficulty of isolating these organisms than of their scarcity in anaerobic environments. In the absence of oxygen, something else must be added to the hydrocarbon to initiate its metabolism, and at least two pathways have been identified. One adds a molecule of fumarate to the hydrocarbon, whereas the other seems to add a molecule of carbon dioxide. The anaerobic biodegradation of small hydrocarbons, especially the BTEXs, which are of most concern if they leak from storage tanks, is becoming quite well understood.

An important feature of crude oils and refined products is that although they are a rich source of carbon and energy for microbes able to consume them, they are almost uniquely unbalanced foods. Microbes typically have a carbon:nitrogen:phosphorus ratio of approximately 100:10:1, but oil contains no significant amounts of either nitrogen or phosphorus. Oil-degrading microbes must therefore obtain these elements in useful forms from elsewhere in the environment, and if there is a significant amount of hydrocarbon it is likely that the growth of the degrading organisms will be limited by the supply of these nutrients.

5. RESPONSES TO SPILLS

The first response to a spill is to stop any further release and to contain and pick up as much as possible. On land, this is relatively simple, albeit time-consuming and expensive. Indeed, most of the "oil lakes" left in Kuwait from the Gulf War are still awaiting treatment. At sea and on lakes and rivers, however, any collection requires corralling the oil with booms to stop it from spreading.

5.1 Booms, Skimming, and Combustion

Many different types of boom are available; some are inflatable, and others are rigid. Some are designed to withstand ocean waves, and others are designed to work in sheltered harbors. Often, booms are used to keep oil out of particularly sensitive areas, such as fish hatcheries and marshes. Others are designed to be towed to "sweep up" oil, and still others are fire resistant and designed to allow the oil within the boom to be ignited.

Once the oil has been corralled, it has to be collected. This is done with skimmers, which remove oil while accumulating as little water as possible. There are many different designs; mops, moving belts, and floating suction devices are all used. Each is best suited for a particular type of oil and may be

ineffective against other oils, but all attempt to collect the oil without collecting much water or debris.

Igniting oil in fireproof booms is not a trivial matter, and special igniters are usually required.

5.2 Physical Removal

If oil reaches a sandy shoreline, it can often be collected with scrapers and bulldozers. This was very effective following the 1996 spill of 72,000 tonnes of crude oil from the Sea Empress off the south coast of Wales. Sometimes, manual removal by teams of workers with shovels is appropriate, as in the case of the 2002 spill from the Prestige off the coast of Spain. If the shoreline is inappropriate for heavy equipment—such as the shorelines of Prince William Sound, Alaska, affected by the spill from the Exxon Valdez—the oil can be flushed back into the water, corralled within booms, and collected with skimmers. Recent developments include special surfactant products that help lift oil from the shoreline while allowing its retention within booms for subsequent skimming, thus allowing more oil to be released with cooler flushing. In the United Kingdom, it is permissible to use dispersants for this purpose in certain circumstances, provided that they have passed the required approval protocols. In North America, use of dispersants on shores is not permitted, and so a new generation of products have been developed that loosen the oils for removal by water stream without the unwanted effect of oil being dispersed into the near-shore water column. These products are specially formulated with amounts of surfactants sufficient to wet the surface but insufficient to foster dispersion. Some of these products have been successfully used on spills in Canada and the United States. Their main objective is to allow weathered oils to be removed by washing without having to use heated water, which could have detrimental side effects on biological communities.

5.3 Bioremediation

Although the physical removal of small near-shore spills can usually be carried out quite effectively and completely, this is rarely possible with large spills at sea. Even when physical collection or combustion are fairly effective, there is almost always some oil that escapes capture. As discussed previously, the ultimate fate of this residual oil is biodegradation, and there are several environmentally responsible ways of stimulating this process. Colloquially known as bioremediation, these can be divided into two complementary strategies. While oil is afloat at sea, the surface area available for microbial attack limits its biodegradation. Adding dispersants to disperse the oil into the water, and dramatically increase the surface area for microbial colonization, is an important option. In contrast, the biodegradation of oil remaining on a shoreline is likely limited by the supply of other necessary microbial nutrients, such as biologically available nitrogen and phosphorus, and carefully adding fertilizers is a very useful option.

5.3.1 Dispersants

Dispersants are concentrated solutions of surfactants that can be applied from the air or from ships equipped with spray booms or fire hoses. Typical application rates are approximately 5% of the oil volume, so quite large stockpiles are required, and indeed are available, in central depots. The dispersants need to be added fairly soon after a spill, but there is usually a window of several days during which they are effective. Even mild wave energy disperses the oil very effectively into the water column, and it has been demonstrated that this substantially increases the rate of biodegradation. Some dispersants also include molecules that actively stimulate oil biodegradation either by providing limiting nutrients or by adding preferred substrates. Dispersion also minimizes the beaching of spilled oils. Dispersants were used very effectively following the 1996 spill of 72,000 tonnes of a relatively light crude oil from the Sea Empress off the south coast of Wales.

5.3.2 Fertilizers

Heavily oiled sites that have been washed or otherwise physically treated to remove the bulk of the oil always retain some residual oil, and this is an ideal target for bioremediation through the addition of fertilizers. Lightly oiled beaches may also provide excellent opportunities for use of this technology without pretreatment. Aerobic oil-degrading microbes are ubiquitous, but their abundance is usually limited by the availability of oil. An oil spill removes this limitation, and there is invariably a "bloom" of oil-degrading microbes, both in terrestrial and in aquatic environments. Their growth becomes limited by the availability of something else. In marine environments, this is usually nitrogen, and although a few oil-degrading microorganisms are able to fix atmospheric nitrogen, most have to await the arrival of low levels of nitrogen with every tide. Carefully applying fertilizers to partially

overcome this limitation can substantially increase the rate of biodegradation with no adverse environmental impact. Slow-release and oleophilic fertilizers (designed to adhere to the oil) seem most effective, and they were used with significant success following the 1989 spill from the Exxon Valdez in Alaska. The oleophilic fertilizer was applied with airless sprayers, and the granular slow-release fertilizer was applied with agricultural "whirligigs." Careful monitoring revealed no adverse environmental impacts from this approach and a stimulation of the rate of oil biodegradation of between two- and fivefold. In other words, although the technique did not make the oil disappear overnight, it sufficiently stimulated a process predicted to take a decade so that it occurred in a couple of years.

Since then, bioremediation has been used on a limited site as part of the cleanup of the 1996 Sea Empress spill and has been demonstrated on experimental spills in marine or brackish environments on the Delaware Bay, a Texas wetland, a fine-sand beach in England, mangroves in Australia, and an Arctic shoreline in Spitsbergen. Experience suggests that fertilizer should be added to maintain soluble nitrogen at approximately 100 μM in the interstitial water of the oiled sediment, and this may require reapplication every few weeks. Such a level of fertilizer nutrients does not seem to cause any adverse environmental impact but stimulates the rate of oil biodegradation severalfold.

Fertilizers have also been used with success at many terrestrial spill sites after the bulk of the spilled oil has been collected. Often, biodegradation at terrestrial sites is also limited by the availability of oxygen, and this can be ameliorated by tilling of surface soils or by the addition of oxygen as air or dissolved or slow-release peroxides for subsurface plumes. One approach suspends slow-release peroxides in a series of wells that intercept flowing groundwater plumes; others sparge air into similar wells.

5.3.3 Natural Attenuation

Biodegradation is such an effective environmental process that in some cases it can be relied on to clean an oil spill without further human intervention. Sometimes this is necessary because human intervention may cause more environmental impact than the spill, such as attempts to remove small amounts of oil from marshes. Other situations in which such an approach can be appropriate include underground spills, in which soluble hydrocarbons enter the groundwater. Usually, these are degraded *in situ*, and if the source is plugged the contaminants may be degraded before the plume intercepts any sensitive receptor. In such a case, it may be best to rely on the natural biodegradation process rather than attempt to stimulate it. Clearly, it is important to have a realistic understanding of the natural processes that will remediate the spill before natural attenuation is accepted as the appropriate response.

Together, these approaches exemplify modern environmentally responsible remediation activities—working with natural processes to stimulate them without causing any additional adverse environmental impact.

Glossary

assessment An orderly process of gathering information about a system and determining the significance and causes of any observed changes following a stress on the system.

benthos The region at the sea bottom and the complex of living organisms and their specific assemblages that inhabit the bottom substrates.

biota The totality of all forms and species of living organisms within a given area or habitat.

disturbance A chemical or physical process (including stresses), often caused by humans, that may or may not lead to a response in a biological system, at the organismic, population, or community level.

ecotoxicology A discipline aimed at studying adverse effects of chemicals on biological and ecological systems.

hazards Combinations of properties and characteristics of a material, process, object, or situation that are able to harm and cause environmental, economic, or any other kind of damage.

littoral A nearshore ecological zone influenced by periodic tidal processes.

pelagial An offshore ecological zone located in open waters and inhabited by water-column organisms.

plankton The microscopic and near-microscopic plants (phytoplankton) and animals (zooplankton) that passively drift in the water column or near the sea surface.

response to stress The physiological, biochemical, reproductive, and other adaptive reactions, induced by stress, of a single organism or a whole assemblage (environmental impact).

risk The probability of realization of a particular hazard under specific conditions and within a certain period of time.

stress A chemical or physical process that leads to a response from a single organism, or at the level of a whole population or community. Acute and chronic stresses are distinguished, depending on duration of impact in situations of short-term and long-term exposure.

The largest percentage of accidental oil input into the sea is associated with oil transportation by tankers and pipelines (about 70%), whereas the contribution of drilling and production activities is minimal (less than 1%). Large and catastrophic spills belong to the category of relatively rare events and their frequency in recent decades has decreased perceptibly. Yet, such episodes can pose serious ecological risk and result in long-term environmental disturbances. Because oil spills are under particularly close scrutiny by environmentalists and strongly shape public opinion toward offshore oil development, they deserve special consideration.

1. CRUDE OIL SPILLS: CHARACTERISTICS, CAUSES, AND STATISTICS

Accidents and associated oil spills have been and continue to be inevitable events at all phases of oil and gas field development. On land, oil spills are usually localized and thus their impact can be eliminated relatively easily. In contrast, marine oil spills may result in oil pollution over large areas and present serious environmental hazards. A wealth of statistical data on accidental oil spills has been accumulated over several decades of hydrocarbon

 © 2004 Elsevier Inc. All rights reserved.

production on the continental shelves of many countries. Some of these data are presented in Fig. 1 and Tables I and II. These data as well as other corresponding materials demonstrate a number of points:

- Overall (with the exception of catastrophic spills that occurred during the Persian Gulf War in 1991), there is a trend toward lower volumes of oil spills during all maritime operations, as compared to the late 1970s.
- Particularly large oil losses result from accidental spills during tanker shipments, whereas the contribution of offshore drilling and production activities is minimal and the losses associated with oil storage and pipeline transportation occupy an intermediate position.
- Small and quickly eliminated oil spills are the most usual types of spills; because they occur frequently, they have the potential to create "stable" (long-term) oil contamination in areas of intense offshore oil production and transportation.
- Catastrophic spills (releasing more than 30,000 tons of oil) occur at a rate of zero to several incidents per year, yet these spills are responsible for the highly uneven distribution of anthropogenic input of crude oil into the sea and for its overall volume.

At least half of the oil produced offshore is transported by more than 6000 tankers. In spite of the clear tendency toward accident-free tanker operations (see Fig. 1), tanker-related accidents remain one of the major sources of ecological risk. The list of very large oil spills (tens of thousands of tons each), long as it is, may become even longer at any time. The probability of an accident involving a crude oil spill from an oil tanker is usually estimated as a function of the covered transport distance. According to one such estimate, based on many years of statistical data, the probability of an accident with more than 160 tons of oil spilled is 5.3×10^{-7} per kilometer of the tanker's route. Similar estimates can also be derived based on the total amount of transported oil.

According to a classification by the International Tanker Owners Pollution Federation (ITOPF), oil spills are categorized into three size groups: small (less than 7 tons), intermediate (7–700 tons), and large (over 700 tons). Information is now available on more than 10,000 spills, the vast majority of which (over 80%) are less than 7 tons. Analysis of causes of intermediate spills from 1974 to 2000 indicates that 35% of such spills occurred during routine operations (mainly oil loading/unloading). Accidents such as grounding and collisions gave rise to 42% of spills in this size category. The major cause of large spills relates to accidents (83%), with grounding and collisions alone making up 64%. The probability of catastrophic blowouts and large spills (more than 1000 tons) during drilling and production operations is rather small (one accident per 10,000 wells).

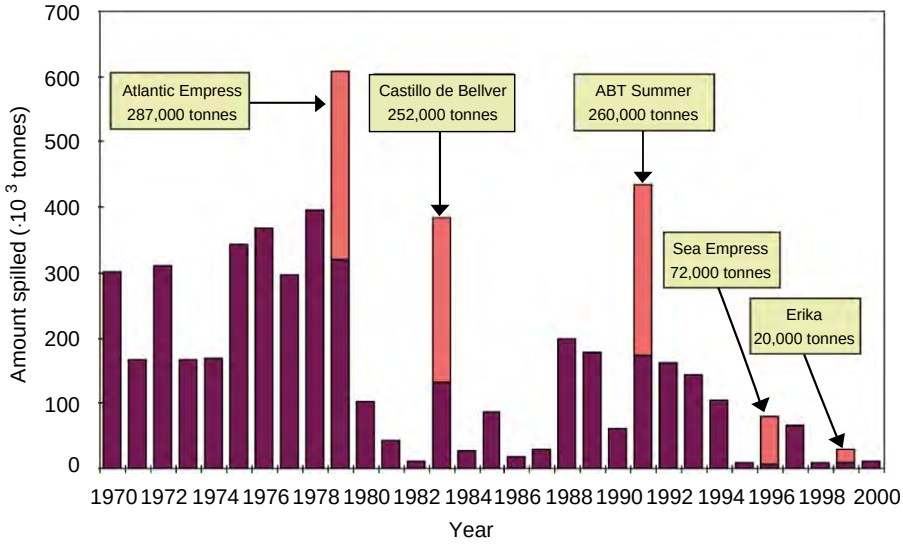

FIGURE 1 Quantities of oil spilled as a result of tanker incidents. Data from the International Tanker Owners Pollution Federation.

TABLE I

Oil Spills Associated with Different Types of Offshore Activities in 1997[a]

Activity	Number of spills	Average spill amount (tons)	Total spill amount	
			Tons	Percentage[b]
Drilling and production	4	191	764	0.5
Oil storage and handling	12	2579	30,948	19.4
Pipeline transport	63	788	49,644	31.2
Tanker transport	23	3391	77,993	48.9
Total	102	1562	159,349	100

[b] Percentage of total amount spilled in 1997.

TABLE II

Selected Major Oil Spills and Accidental Releases

Source of accident and spill	Year	Location	Oil lost (tons)
Tankers, terminals, installations, Persian Gulf War events	1991	Kuwait; off coast of Persian Gulf and in Saudi Arabia	Up to 1,000,000
Exploratory well *Ixtoc I*	1979	Mexico; Gulf of Mexico, Bahia del Campeche	480,000
Tanker *Atlantic Empress*	1979	Off Tobago, West Indies	287,000
Platform No. 3 well (Nowruz)	1983	Iran; Persian Gulf, Nowruz Field	270,000
Tanker *ABT Summer*	1991	Open water; 1300 km off Angola	260,000
Tanker *Castillo de Bellver*	1983	South Africa; 64 km off Saldanha Bay	252,000
Tanker *Amoco Cadiz*	1978	France; off Brittany	223,000
Tanker *Haven*	1991	Italy; port of Genoa	144,000
Tanker *Odyssey*	1988	Canada; 1175 km off Nova Scotia	132,000
Tanker *Torrey Canyon*	1967	United Kingdom; Scilly Isles	130,000
Pipeline, Kharyaga-Usinsk	1994	Russia; Usinsk	104,000
Tanker *Braer*	1993	United Kingdom; Shetland Islands	85,000
Tanker *Aegean Sea*	1992	Spain; La Coruna harbor port	74,000
Tanker *Sea Empress*	1996	United Kingdom; Mill Bay, Milford Haven harbor port	72,000
Tanker *Prestige*	2002	Spain; over 200 km off Spanish coast	70,000
Tanker *Exxon Valdez*	1989	United States; Alaska, Prince William Sound	37,000

Over 30 years of offshore oil operations, only a few such episodes have occurred, primarily in the early 1970s.

To date, more than 100,000 km of subsea pipelines have been laid worldwide for transporting oil and other hydrocarbons. According to different estimates, the probability of a pipeline accident accompanied by a spill is anywhere between 10^{-4} and 10^{-3} spills/km/year. The data summarized in Table I suggest that the probability of pipeline accidents can be estimated at about 6.3×10^{-4} spills/km/year, with an average spill size of about 800 tons and worldwide oil losses of about 50,000 tons/year. Regional estimates may, of course, vary widely, depending on the local conditions. Accidental spills may be caused by many factors, including pipe corrosion, mechanical damage due to tectonic shifts, and impact by ship anchors. Pipelines become less prone to accidents as their diameter increases, but in all cases the probability of damage and ecological risk increases with aging of seabed pipelines. In general, pipelines are considered to be the safest way to accomplish hydrocarbon transport at sea and on land.

2. ECOTOXICOLOGY OF OIL IN MARINE ENVIRONMENTS

Crude oil is a naturally occurring material; its influx from seabed seepage alone amounts to more than 600,000 tons/year. Additionally, more than 10 million tons/year of aliphatic and other hydrocarbons are produced by marine organisms (mainly bacteria and phytoplankton). Unlike permanent natural sources, accidental oil spills usually occur within a short period of time and produce local zones of abnormally high hydrocarbon concentrations that are hazardous to marine life.

Chemically, crude oil (petroleum) is a complex of natural (mainly organic) substances. The basic component (up to 98%) consists of saturated and unsaturated aliphatic and cyclic hydrocarbons. In seawater, the original petroleum substrate rapidly (within a few hours or days) disappears as it breaks down into fractions (forms) in different states of aggregation. The most common aggregates include surface films (slicks), dissolved and suspended forms, emulsions (oil-in-water, water-in-oil), solid and viscous fractions precipitated to the bottom, and compounds accumulated in marine organisms. Under conditions of long-term (chronic) pollution, the dominant form is usually emulsified and dissolved oil. The fate (behavior, distribution, migration) of oil substances in the marine environment is controlled by a variety of interrelated processes. The major processes, usually known as weathering, include physical transport, evaporation, dissolution, emulsification, sedimentation, biodegradation (decomposition by microorganisms), and oxidation (Fig. 2).

The background contamination levels of petroleum hydrocarbons in the marine environment vary rather widely, from 10^{-5} to 10 mg/liter in seawater and from 10^{-1} to 10^{4} mg/kg in bottom sediments, depending on a spectrum of natural and technogenic factors. Maximum concentrations tend to occur in coastal and littoral waters as a result of many types of offshore, coastal, and land-based activities (developing hydrocarbon resources, transportation, industrial discharges, wastes dumping, etc.). Bioaccumulation (i.e., intake and assimilation by living organisms) of oil substances strongly depends on their hydrophilic and lipophilic properties. The concentration of polycyclic aromatic hydrocarbons (PAHs) in marine organisms is often up to three orders of magnitude above their content in seawater. The most pronounced capacity to accumulate PAHs without noticeable metabolic degradation in tissues is exhibited by filter-feeding bivalves (e.g., mussels).

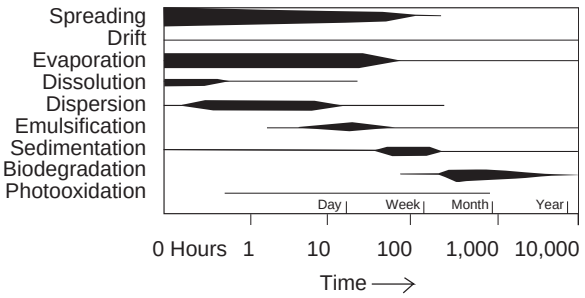

FIGURE 2 Processes acting on an oil slick as a function of time following a spill. The line thickness indicates the relative magnitude of each process. Reproduced from Swan *et al.* (1994) after Wheeler (1978).

From the ecotoxicological standpoint, oil is a complex multicomponent toxicant with nonspecific effects. Its basic component is a group of the most soluble and toxic aromatic hydrocarbons. High-molecular-weight PAHs with five and more benzene rings (e.g., benzo[*a*]pyrene) are able to produce carcinogenic effects, especially in benthic organisms, which inhabit heavily polluted bottom sediments. The primary responses of marine biota exposed to background levels of PAHs can be reliably detected by specific biochemical methods (e.g., measuring the induced activity of enzyme systems in individual marine organism tissues and organs).

For different groups of marine biota, toxic concentrations of oil (primarily aromatic hydrocarbons) in seawater and bottom sediments vary within several orders of magnitude. These differences are most pronounced in benthic communities of coastal zones polluted by oil, including those impacted by spills. Most species of the marine fauna exposed to oil are particularly vulnerable at early life stages (embryos and larvae). A simplified sequence of biological responses in marine biota, depending on oil concentrations in seawater and bottom sediments, is shown in Fig. 3.

A summary of experimental (toxicological) data and actual (measured) levels of oil content in seawater and bottom sediments of different areas of the worldwide oceans is given in Fig. 4. The upper limits of the zone in which there are "no observed effect" concentrations (NOECs), in which biological effects are either absent or manifest as primary (mostly reversible) physiological and biochemical responses, lie within the ranges of 10^{-3} to 10^{-2} mg/liter in seawater and 10–100 mg/kg in

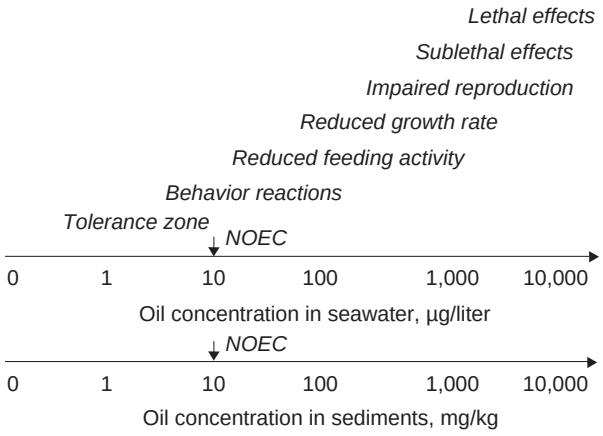

FIGURE 3 Developing characteristic effects and responses in marine biota, depending on the concentrations of oil in seawater and bottom sediments. NOEC, "No observed effect" concentration; see text for definition.

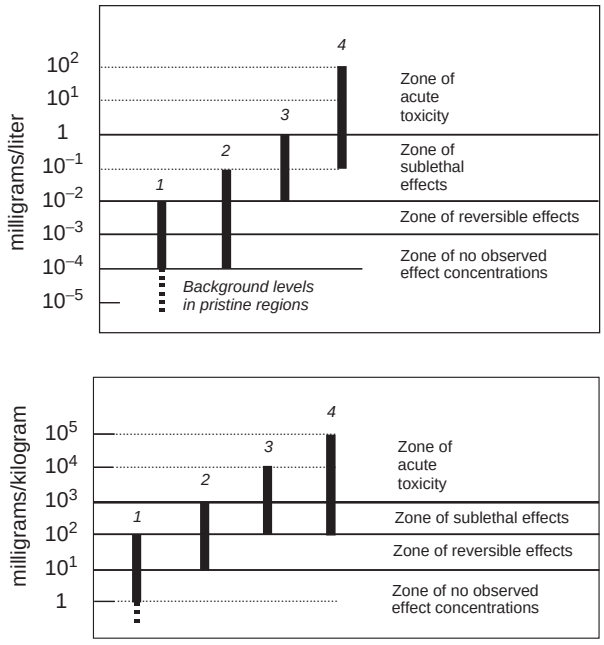

FIGURE 4 Approximate zones of biological effects and ranges of typical concentrations of oil hydrocarbons (mainly aromatic) in seawater (top) and bottom sediments (bottom). Zones: 1, pelagic areas (open waters); 2, coastal and littoral areas; 3, estuaries, bays, and other shallow semiclosed areas; 4, areas of local pollution, including oil spills.

bottom sediments. These ranges can be roughly considered as the limits of maximum permissible (safe) concentrations of oil hydrocarbons dissolved in seawater and accumulated in bottom sediments, respectively.

3. ENVIRONMENTAL IMPACTS OF OIL SPILLS

3.1 Methodology of Environmental Impact Assessment

Oil spills show one of the most complex and dynamic patterns of pollutant distribution and impact in the marine environment. In a sense, each spill is unique and unrepeatable because of the practically unlimited possible combination of natural and anthropogenic factors at a given location and at a given time. This poses a challenge that complicates the modeling of crude oil distribution, not to mention making quantitative predictions of the ecological effects of spills. At the same time, over the past several decades, a great number of special studies and field observations on oil behavior and the environmental hazards of oil spills have been conducted in a variety of ocean regions worldwide. These studies provide a good base for realistic assessment of the negative impact of oil spills on the marine environment and on living resources.

It should be noted that, to this day, no standard and widely recognized methodology of environmental impact assessment (EIA), including EIAs with respect to oil spills, actually exists. The most common methods used at different stages of EIAs include expert estimations, matrix analysis, simulations (modeling), hazards and risks theory, ecotoxicological studies, and field and laboratory experiments. Apparently, such a great diversity of methods and approaches extremely complicates standardization of the EIA procedure. At the same time, the general outlines of this procedure, including the contents and sequence of its stages, have already taken final shape in many countries.

Any system for assessing the state of environmental and human impacts has to be accompanied by a number of selected scales (classifications) for ranking spatial and temporal parameters of impact, as well as for specific evaluation of environmental hazards and risks. One of such classification used here is shown in Table III. Certainly, any scales and relative estimates of this kind will inevitably be circumstantial, but there is no other way to render the results of EIA more specific or objective. Otherwise, we are doomed to ineffective attempts to describe highly complex multifactorial natural systems with an endless number of direct and feedback relations (most often the nonlinear ones). This would leave plenty of room for subjective interpretations and uncertain estimates without any

TABLE III

Impact Scales and Gradation of Oil Spill Ecological Hazards and Consequences in Marine Environments

Impact	Definition
	Spatial scale
Point	Area under impact is less than $100\,m^2$
Local	Area under impact ranges from $100\,m^2$ to $1\,km^2$
Confined	Area under impact ranges within $1–100\,km^2$
Subregional	Area under impact is more than $100\,km^2$
Regional	Area under impact spreads over shelf region
	Temporal scale
Short term	From several minutes to several days
Temporary	From several days to one season
Long term	From one season to 1 year
Chronic	More than 1 year
	Reversibility of changes
Reversible (acute stress)	Disturbances in the state of environment and stresses in biota that can be eliminated naturally or artificially within the time span of several days to one season
Slightly reversible	Disturbances in the state of environment and stresses in biota that can be eliminated naturally or artificially within the time span of one season to 3 years
Irreversible (chronic stress)	Disturbances in the state of environment and stresses in biota that exist longer than 3 years
	General assessments
Insignificant	Changes in the state of environment and biota are absent or not discernible against the background of natural variability
Slight	Observed disturbances in the environment and short-term reversible stresses in biota (below minimum reaction threshold–0.1% of natural population reactions) are possible
Moderate	Disturbances in the environment and stresses in biota are observed without signs of degradation and loss of a system capacity for recovery; changes up to 1% of natural population reactions are possible
Severe	Stable structural and functional disturbances in biota communities (up to 10% of natural population and community parameters) are observed
Catastrophic	Irreversible and stable structural and functional degradation of a system is evident; disturbances in ecosystem parameters are more than 50% of statistical norm

assurance that the ultimate objectives of the EIA will be attained at all.

3.2 Oil Spill Types and Scenarios

From the environmental point of view, distinction should be made between two basic types (scenarios) of oil spills. One scenario includes spills that occur in open waters, without having the oil contact the shoreline and/or bottom sediments (pelagic scenarios). In this case, under the influence of wind, currents, and other hydrodynamic processes, the oil slicks are quickly (within a few hours or days) transformed and dispersed atop and under the sea surface. The dispersed and emulsified oil undergoes active biodegradation, its toxicity significantly decreases, and biological systems display attributes of acute (short-term) stress. The other type of spill, unfortunately more common and potentially more hazardous, involves influx of the oil onto the shore, its accumulation in sediments along the coast, and subsequent long-term ecological disturbances both in the littoral (intertidal) areas and on the shore. Such situations should certainly be treated as chronic stresses. The two scenarios often develop simultaneously, especially when an accidental oil spill occurs within a marine coastal zone not far from the shoreline.

According to available statistics, a majority of accidents and accompanying oil spills take place in coastal waters. In such cases, the likelihood of oil contact with the shoreline depends on many factors, including oil spill characteristics (volume and type of oil spilled, distance from the coast, etc.) and local oceanographic and meteorological conditions, particularly velocity and direction of winds and currents. In most accidents, the probability of an oil slick migration toward the coast and contact with the

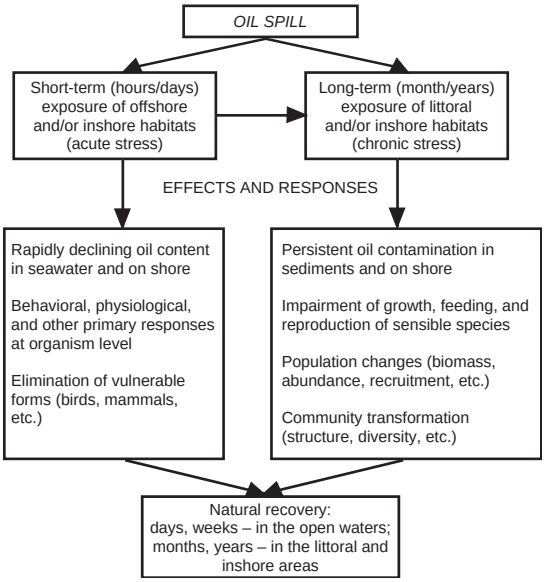

FIGURE 5 Conceptual scheme of characteristic biological effects and environmental hazards of oil spills in the sea.

shoreline is quite high (up to 50%), and the length of the coastal line impacted by oil can reach tens and even hundreds of kilometers. The conceptual scheme of developing biological effects and consequences of an oil spill under acute and chronic stresses is presented in Fig. 5. Depending on the duration, level, and scale of oil contamination, a wide range of effects may occur both in the water column and in littoral sediments—from behavioral responses of organisms at the initial phases of the spill up to long-term populational disturbances under chronic impact in the littoral zone.

3.3 Pelagic Scenarios (Oil Does Not Contact Shoreline and Bottom Sediments)

Ecological effects of oil spills in the open sea are mainly associated with short-term oil pollution of the surface water layers, where organisms such as plankton, nekton (mainly fishes), marine birds, and mammals may be affected when the situation is one of acute oil stress. Pelagic scenarios involve the formation of oil slicks in which total oil concentration ranges from 1 to 10 mg/liter in the surface seawater layers, at a depth of several meters. At horizons deeper than 10 m, oil contamination usually does not exceed background levels. After several days (sometimes weeks), surface slicks on open water are usually dispersed and eliminated under the influence of the processes and factors reflected in Fig. 2.

3.3.1 Impact on Plankton

Among all ecological forms, the hyponeuston, species that live within the most polluted surface microlayer (several centimeters deep at the atmosphere/sea interface), might be assumed to experience the heaviest toxic impact from oil spills. Nevertheless, in open waters, both hyponeuston and planktonic biota as a whole do not demonstrate any persistent structural and functional changes during pelagic oil spills. This is the result of a number of factors and processes, including a rapid decrease in the concentration of spilled oil to harmless levels, due to its dispersion and degradation in seawater; the rapid recovery of phytoplankton and zooplankton populations (within a few hours and days) due to high reproduction rates; and the influx of planktonic organisms from adjoining marine areas. There is not a single known publication in which oil spills have been shown to produce irreversible long-term impact on the planktonic populations of open waters.

3.3.2 Impact on Fish

Conclusions about the absence of any persistent long-term changes at the population level in planktonic biota after pelagic oil spills are fully valid in relation to fish populations. Due to oil localization within the surface layer of seawater, the mortality of water column organisms, including pelagic fish, is practically excluded. Fish mass mortality has never been observed even after catastrophic oil spills in the open sea. Available publications on the subject suggest that adult fish are capable of detecting and avoiding zones of heavy oil pollution.

An adverse impact of oil spills on fish is most likely to be observed in the shallow coastal areas of the sea where the water dynamics are slow. Fish in early life stages are known to be more vulnerable to oil, compared to adults, and, therefore, some younger fish may be killed by exposure to high concentrations of toxic components of crude oil. However, calculations and direct observations indicate that such losses could not be reliably detected against the natural background of high and variable mortality at embryonic and postembryonic stages of fish development.

3.3.3 Impact on Birds and Mammals

Sea birds and mammals are among the most vulnerable components of marine ecosystems in relation to oil pollution. Even short-term contact with spilled oil affects the insulating functions of hairy or feathery coats and results in quick death.

Studies of mass mortality (by tens of thousands of individuals) of birds and mammals after oil spills in coastal waters (even without oil contacting the shoreline) have been described in numerous publications.

The exact consequences of such spills depend primarily on the population traits of different species. Abundant populations with a high reproductive potential are the least susceptible to population stresses. At the same time, adverse impacts for the less abundant species with longer life spans are usually more serious and protracted. Of particular importance are the distribution and congregation patterns of birds and mammals. Even a small oil spill may severely affect a large number of birds or sea mammals that form compact colonies within a small area. In assessing such impacts, one must take into consideration the effect of natural factors, particularly natural mortality caused by extreme weather conditions, lack of food, epizootic diseases, etc. Most data suggest that populations of marine birds and mammals are able to return to their natural level (optimal for given conditions) within several years (seasons) after the oil spill impact.

3.3.4 General Assessment

Using the scales and ratings in Table III, typical oil spill impacts in pelagic scenarios can be assessed as varying from local to confined and from short term to temporary. Potential ecological hazards and biological effects in the form of acute stress for the marine pelagic biota can be assessed as predominantly reversible and varying from insignificant to moderate.

3.4 Littoral Scenarios (Oil Contacts Shoreline and Bottom Sediments)

When spilled oil reaches the shoreline, the major processes of oil accumulation, transport, and transformation occur in the littoral zone exposed to wind-induced waves, storms, surf, currents, and tides. The width of this zone may vary within tens of meters. Its potential self-cleaning capacity depends, first of all, on the geomorphology of the shoreline and characteristics of near-shore sediments and shore deposits (composition, fineness, etc.), as well as on the energy of wave and tidal processes. Numerous observations in different parts of the world indicate that oil persistence and, consequently, its adverse impact sharply increase from open rocky shores to sheltered gravel and pebble coasts (Table IV).

Some examples and characteristics of potential ecological impacts of oil spills in the littoral zone and adjoining shallow (several meters deep) sublittoral habitats are given in Table V. These assessments are based on the analysis of nearshore spill situations and describe biological effects resulting from oil pollution of both littoral sediments and seawater. Typically in such cases, local transformations of species population structures in littoral communities result in the predominance of more resistant species (e.g., some polychaetes) and rapid elimination of sensitive ones (especially crustaceans, such as amphipods, and marine birds and mammals). The time of return to environmental quality and community structure may vary widely, from a month to several years, depending on the exact combination of different natural and anthropogenic factors.

TABLE IV

Classification of Shorelines Based on Their Potential Oil Spill Recovery Capabilities

Self-cleaning capacity	Type of shoreline	Process characteristics
High (type I)	Open rocky shoreline	As a result of wave and surf action, oil is removed within several weeks; there is no need to clean inshore habitats
Medium (type II)	Accumulative coasts with fine-sand beaches	Oil does not usually penetrate deeply into fine, compact sand and can be removed by mechanical means; oil contamination persists for several months
Low (type III)	Abrasive coasts with coarse sand, pebble, and gravel stretches	Oil rapidly penetrates into deeper layers (up to 1 m) and can persist for years
Very low (type IV)	Sheltered coasts with boulder, gravel, and pebble material; wetlands (marshes, mangroves)	Favorable conditions for rapid accumulation and slow degradation of oil; tars and asphalt crusts can be formed

TABLE V

Potential Biological Effects of Oil Spills in the Littoral (Intertidal) Zone

Shoreline type[a]	Recovery capacity	Typical oil content levels in Water[b] (mg/liter)	Typical oil content levels in Bottom (mg/kg)	Characteristic biological effects
I	High	<0.1	$<10^2$	Mortality among the more sensitive species within the first days of contact; sublethal effects; primary structural changes in communities; recovery time, up to a month
II	Medium	0.1–1.0	10^2–10^3	Elimination of crustaceans (especially amphipods), predominance of polychaetes; decreasing biomass and structural changes in communities; recovery time, up to half a year
III	Low	1–10	10^3–10^4	Mass mortality among the more sensitive species (crustaceans and bivalves); steadily decreasing biomass and poorer species diversity; recovery time, up to a year
IV	Very low	>10	$>10^4$	Mass mortality among most species; pronounced declined biomass, abundance, and species diversity; recovery time, more than a year

[a] See classification in Table IV.
[b] Dissolved and emulsified forms of oil.

There are numerous records of oil spills in coastal and littoral areas in many marine regions, as well as hundreds of publications with detailed descriptions of associated environmental impacts. Besides the well-known catastrophic accident involving the tanker *Exxon Valdez* in the nearshore area of Alaska in 1989, a number of similar events have been documented, including oil spills in the coastal waters of the United States, France, United Kingdom, and Spain, among other countries (see Table II). One of the largest oil spills occurred in February 1996 when the tanker *Sea Empress* ran aground within a kilometer of the South Wales shore and 72,000 tons of crude oil were released. Despite favorable weather conditions (only 5–7% of the spilled oil reached the shore) and effective clean-up operations, the accident resulted in heavy pollution of 200 km long the coastline and littoral zone. About 7000 oily birds were collected on the shore alone. At the same time, no mass mortality of commercial fish, crustaceans, or shellfish was recorded. The time of environmental recovery in different locations was quite variable (from several months to a year and more), depending on adopted criteria and specific conditions within the affected littoral zone.

The list of this kind of accident in coastal areas is rather long. All these situations, unlike the purely pelagic spills (oil does not contact shoreline and bottom sediments), have two major phases, interpretable as acute and chronic stresses. Acute stress usually occurs within the first few days (sometimes weeks) and may result in mortality of the oil-impacted organisms (especially birds and mammals). Chronic stress lasts for several months, seasons, or even years and manifests mainly as adaptive modifications of benthic communities in response to the long-term oil contamination of littoral and coastal (inshore) sediments. In a majority of cases (excluding heavy oil pollution during very large catastrophic spills), these modifications do not exceed critical population levels and do not result in irreversible changes in structure and function of benthic populations.

3.4.1 General Assessment

In terms of ratings and definitions in Table III, typical oil spill impacts in littoral scenarios can be assessed as varying from local to subregional and from temporary to chronic. Environmental hazards and biological effects in the form of

chronic stress for the marine biota (mainly for benthic organisms) can be assessed as predominantly slightly reversible and varying from slight to severe.

4. IMPACTS ON LIVING RESOURCES AND FISHERIES

Until recently, there has been no direct evidence of any detectable impact of oil spills on the stock and biomass of commercial species. This conclusion is supported by a number of special studies, including those conducted in the situations of catastrophic accidents. Results of modeling and calculations of potential losses of commercial fish and invertebrates during oil spills lead to similar conclusion. Most estimates indicate that losses of commercial species during spills, even in the most pessimistic scenarios, usually do not exceed hundreds/thousands tons of biomass and cannot be reliably distinguished against the background of extremely high population variability (mainly due to environmental changes, natural mortality, and fishing).

Of particular concern is the possibility of the negative impact of oil spills on the anadromous fish (primarily, salmons) during their spawning migration shoreward. In this regard, it should be remembered that in the open sea, the oil concentration beneath the oil slick decreases sharply with depth, approaching background values at horizons of 5 to 10 m. Detailed studies conducted during a number of years after oil spills near the shores of Alaska and in other salmon breeding regions have shown that all basic parameters of commercial populations (abundance, structure, reproduction, migration, stock, and catches) remain within the natural ranges. Thus, there is a reasonable consensus that negative effects of oil spills on marine living resources in terms of their population parameters are negligible and could not be practically detected due to the enormous natural variability and dynamics of marine populations and communities. This conclusion does not mean, however, that oil spills do not exert any adverse impact on fisheries and the entire fishing industry. Numerous studies have shown that the actual economic losses to fisheries occur as a result of temporary restrictions on fishing activities, interference with aquaculture (i.e., growing and reproduction of marine organisms in marine farms) routines, loss of marketable values of commercial species due to petroleum taste (tainting), and oil contamination of fishing gear. The most serious economic losses for fisheries result from the limitations (bans, closures) imposed on fishing following oil spills in impacted coastal areas. Commercial fishermen are deprived of their livelihood unless they are able to exploit alternative stocks. Naturally, the exact nature and extent of such losses may vary widely, depending on a combination of diverse factors, such as oil spill size, time of year, and weather conditions. In some cases, during the catastrophic accident involving the tanker *Exxon Valdez* near Alaskan shores in the spring of 1989, for example, the losses to local fisheries were estimated at hundreds millions of dollars. This amount was eventually paid by court decisions in the United States as compensation for the restriction on fishing because of heavy oil pollution. Significant losses are known to have been sustained by aquaculturists, as was the case with many farms specializing in growing fish and shellfish during oil spills near British shores in 1993 and 1996. Similar events occurred in the winter of 2002 due to catastrophic oil pollution of the Atlantic coasts of Spain and Portugal after an incident involving the tanker *Prestige* caused release of 70,000 tons of heavy fuel oil.

Another rather common yet poorly controlled type of damage to fisheries inflicted by oil spills is associated with accumulation of petroleum hydrocarbons (especially light aromatic compounds) in marine organisms. This does not usually lead to intoxication of the organisms but results in an oily odor and taste, which inevitably means deterioration of marketable qualities of marine products and corresponding economic losses.

Legal and regulatory mechanisms of compensation for losses sustained by the fishing sector as a result of oil spills are yet to be fully elaborated, although two special international conventions are already in effect: the International Convention on Civil Liability for Oil Pollution Damage (Brussels, 1969) and the International Convention on the Establishment of an International Fund for Compensation for Oil Pollution Damage (London, 1971; amended by the 1992 Protocol). These conventions, administered by member states of the United Nations, set forth a number of measures and provisions for paying compensations to countries in cases of accidental oil spills within the bounds of their continental shelf. In the context of the conventions, fishery closures are expected to minimize or prevent economic damage that might otherwise occur.

5. OIL SPILL RESPONSE AND PREVENTION STRATEGIES

Public concern and anxiety about oil spills in the sea have been clearly augmented since the *Torry Canyon* tanker accident off the southwest coast of the United Kingdom in March 1967, when 130,000 tons of spilled oil caused heavy pollution of the French and British shores, with serious ecological and fisheries consequences. This accident was followed by a number of similar catastrophic episodes (see Table II). These events produced an acute public reaction and clearly elucidated a need for developing effective prevention and response strategies for appropriate reactions in such situations. Since the time of these spills, an impressive technical, political, and legal experience in managing the problem has been acquired in many countries and on the international level, mainly through the International Maritime Organization. In 1990, the International Convention on Oil Pollution Preparedness, Response, and Co-operation was adopted by a number of countries. The convention provided the framework for coordination of the national and international efforts to create special funds, centers, technical means, and methods for dealing with the consequences of oil spills in coastal areas. In practically all nearshore countries, specialized oil spill response centers and services have been established. Additionally, any offshore oil project is required to develop "action emergency plans." In many countries, national plans on preparedness and responses to oil spill accidents have been developed and appropriate legal rules, norms, and regulations are enforced.

An idea about the scope of economical losses and costs of oil spills may be derived from the *Exxon Valdez* incident in 1989; the clean-up operations were conducted during 2 years with about 10,000 people participating, and response costs totaled approximately $2.8 billion (total costs exceeded $9 billion). In the aftermath of this incident, the U.S. Congress adopted the 1990 Oil Pollution Act, which expanded the oil spill prevention, preparedness, and response responsibilities of both the federal government and industry.

The wide spectrum of contemporary techniques for oil spill response and clean-up operations may be divided into four major groups:

1. Mechanical means (booms, skimmers, etc.) for collection and removal of oil from both the sea surface and inshore habitats.
2. Burning of spilled oil at the site.
3. Chemical methods for dispersing surface oil slicks, aimed at accelerating oil degradation by natural factors.
4. Microbiological methods for enhancing oil degradation, usually applied in combination with mechanical and chemical methods.

The great variety of means and methods are quite relevant, taking into account the enormous variation in emergency situations as well as the extremely complex behavior of crude oil in marine environments. In the field, a combination of diverse methods is commonly used, with preference for mechanical means of oil containment and removal. Chemical and microbiological methods are applied predominantly in addition to the mechanical operations.

There are two situations when oil spill response and clean-up operations are not justified. First, oil spills in the open sea in areas with active surface water mass hydrodynamics, at great depths, and far from any shoreline need not be mitigated. As already noted, in such situations, oil slicks are relatively rapidly (usually within several days) dispersed without any significant damage to water column organisms and pelagic ecosystems. Second, shorelines are classified according to their vulnerability to oil spills. As was shown in Table IV, along open rocky shorelines, oil can be quickly dispersed and eliminated as a result of favorable natural processes (i.e., strong wave, tide, and wind activities). It is quite evident that in these situations human intervention may be senseless. Unfortunately, such situations are the exception rather than the rule. The littoral scenarios, with oil entering and accumulating in shallow coastal zones with low-energy hydrodynamic processes, are more usual. In these cases, the necessity of cleaning operations is quite evident.

Clearly, the techniques and means for alleviating the impacts of oil spills describe herein represent only a few of the armamentarium of contemporary oil spill response and prevention strategies. These strategies have been implemented worldwide and represent the development of regional systems of accident monitoring and reporting and coastal sensitivity analysis and mapping, involving adoption of detailed plans for dealing with emergencies and production of databanks and information systems for assisting spill response management. In some countries (e.g., the United Kingdom), integrated booming strategy plans (employing anchored oil-blocking booms) are being developed for protection of environmentally sensitive areas.

In conclusion, it should be emphasized that accidental oil spills are only one of a multitude of various factors of human impact on marine environments. The protection of oceans has always been and shall always be a priority task of international significance.

Glossary

circumscription theory As formulated by Robert L. Carneiro, the process whereby threats to the survival of a society stemming usually from population pressure on resources, but also from competition from other societies, and environmental constraints, lead to the increasing complexity of the sociopolitical organization.

cultural evolution (1) The process whereby human beings adapt their social and cultural behavior to deal with challenges to their survival; (2) the process whereby human societies become more complex as they adapt to deal with challenges to their survival; such challenges may be internal or external.

dissipative structure An open energy system with a form created by the constant incorporation of energy and matter as inputs and dissipation as output.

energy maximization principle As formulated by Alfred Lotka, the principle that, among living organisms, "natural selection will so operate as to increase the total flux through the system, so long as there is presented an unutilized residue of matter and available energy."

energy triggers The process whereby the dissipation of one energy flow releases dissipation from another energy source.

levels of sociocultural integration See **stages of cultural evolution.**

minimum dissipation principle As formulated by Ilya Prigogine and J. M. Waime, the principle that "when given boundary conditions prevent the system from reaching thermodynamic equilibrium (i.e., zero entropy production) the system settles down in the state of 'least dissipation'."

stages of cultural evolution Successive series of configurations of sociocultural organization that emerge as societies become increasingly complex; these various configurations are also known as levels of sociocultural integration.

Human societies, like all other living phenomena, exist by virtue of extracting energy from the environment and dissipating it in specific ways. The laws, principles, and measures applying to energy dissipation are as applicable to human society and culture as they are to the rest of nature. Theories of social and cultural evolution have developed with limited attention to this fact. The bulk of the present account is divided into three parts. The first two concern using energy dynamics in social analysis and are directed at social scientists interested in the question. The second is concerned with cultural evolution, and are directed more at those unfamiliar with the development of theory on this topic.

1. INTRODUCTION

Sociocultural evolution was first seriously explored in the 19th century by Herbert Spencer, Edward B. Tylor, and Lewis Henry Morgan, but fell under the cloud of cultural relativism in the early 20th century. The concept of sociocultural evolution was subsequently revived by Leslie White, V. Gordon Childe, and Julian Steward, and was further developed by Elman R. Service, Marvin Harris, and Robert L. Carneiro and by many of their students. Sociocultural evolution has proved to be of interest in archeology for modeling sociocultural change over extended eras of time and comparatively between different cultural traditions. It has been taken up in sociology by Gerhard Lenski and Stephen K. Sanderson and in a more Darwinian form by Donald Campbell. Also, under the influence of sociobiology, a distinctive branch of coevolutionary thinking (which will not concern us here) has been explored

by Robert Boyd and Peter J. Richarson, Charles J. Lumsden and Edward O. Wilson, and William H. Durham.

The notion that energy was relevant to understanding the social process was early described by Herbert Spencer in his *First Principles* (1863): "Based as the life of a society is on animal and vegetal products, and dependent as these are on the light and heat of the Sun, it follows that the changes wrought by men as socially organized, are effects of forces having a common origin…Whatever takes place in a society results either from the undirected physical energies around, from these energies as directed by men, or from the energies of the men themselves." Following this assessment, the connectedness of energy and cultural evolution was primarily pursued by scholars with interests other than cultural evolution. By the early 20th century, it had been seriously discussed by Wilhelm Ostwald, Patrick Geddes, and Frederick Soddy, to be followed by Alfred Lotka, T. N. Carver, and Lewis Mumford. In 1943, anthropologist Leslie White proposed it as a tool for social analysis. It was then explored in more detail by sociologist Fred Cottrell, ecologist Howard Odum, economists Nicolas Georgescu-Roegen and Herman Daly, anthropologist Richard N. Adams, and, recently, sociologists Eugene A. Rosa and Gary E. Machlis. In the latter part of 20th century, world events produced an oil crisis and with it an explosion of interest in the political economy of energy in society.

2. ENERGY AS A CONCEPTUAL TOOL FOR SOCIAL ANALYSIS

Because energy is dissipated when anything happens, it is a substantive process that provides a common denominator for all activities, human and nonhuman. The second law of thermodynamics defines the irreversibility (and therefore in an important sense, directionality) of the model and thus is a measure for everything that happens. Energy can be thought of as a material cause of everything, but in an instrumental, or agential, sense energy causes nothing; it merely requires that all events evolve so as to reduce the capacity to do work that may be available in the system. This provides a measure for the analysis of human history, one that is culture free and value free and uncolored by political or moral concerns. This permits comparison among all historically known societies of any culture.

Although not always explicit, two perspectives—the agential and holistic—have been used to describe the relationship between energy and human society. The first treats energy as a resource that is controlled by human beings to secure their survival and adaptation, i.e., to sustain their life. Seen in this way, the environment is full of energy resources—biota (including human beings), fossil fuels, water and solar radiation, subnuclear sources, etc.—that human beings harness and control to work for them. Somewhat problematic in this picture is human labor, because individuals control their own labor and may control the labor of others. Thus, when referring to the energy per capita expended by a society in a contemporary industrial nation, we are usually talking about nonhuman expenditure, but when dealing with preindustrial societies and particularly in hunting and gathering societies, human labor is the major energy source. Two phases emerge from this situation: (1) energy (including one's own energy) as controlled by individual human beings and (2) energy as controlled by society, usually by some agent for the collectivity. In complex societies (i.e., with two or more levels of social integration), leaders or authorities decide how energy resources, both nonhuman and human collectivities, are to be used. This perspective readily separates human energy expenditure as an agential process that controls and is impacted by on-going energy-based events.

In the holistic perspective, human beings and the society and the environment relevant to them are a continuing and fluctuating field of multiple energy flows. Within this field, there are islands or sectors of potential energy (materials, fuels, stored goods) held in equilibrium, the energy of which may be released for human use when an appropriate technology is applied. There are also dissipative structures (see later) wherein human labor is seen as merely one part of the flow, as simply one more energy resource. In this perspective, the triggers (see later) that release potential energy are energy flows. This perspective allows us to see social processes in terms of a series of principles, laws, and working hypotheses derived from the physical and biological sciences. If sociocultural evolution is merely one facet of general biological evolution, then these concepts and principles should be equally applicable to social evolution.

3. DYNAMICS OF ENERGY FLOW

There are a number of energetic processes useful for understanding sociocultural evolution.

3.1 Laws of Thermodynamics

The basic dynamics of energy are described in the first and second laws of thermodynamics, which require no elaboration here. The fact that energy is dissipated makes it unidirectional and measurable. What has happened can never be repeated—no matter how much new events may appear to duplicate history. The presence of historical similarities is a challenge to find out why and how they came to be.

3.2 Equilibrium and Dissipative Structures

Although it was recognized that energy was central to the social process, Ilya Prigogine's 1947 formulation of the thermodynamics of nonequilibrium structures provided a key concept—the dissipative structure—for treating human beings and human societies as dissipative energy forms within a field of both equilibrium and dissipative structures. Equilibrium structures are energy forms in relative equilibrium, in which no exchange of matter or energy is, for the moment, taking place with the environment. Dissipative structures are open energy systems that constantly incorporate energy and matter as inputs and dissipate them as output. The form they take is dissipation. They are characterized by fluctuations that are essentially indeterministic when seen in a microscopic field, but, with the operation of natural selection, may contribute to directionality over longer courses of time.

As adapted from Prigogine's model the dissipative structure provides a remarkably accurate representation of how living bodies and societies operate. It combines the inputs of matter and energy but the output also involves the discarding of waste materials that may impact and change other energy flows. Particularly significant are impacts that release potential energy of equilibrium structures and that divert or modify other dissipative processes. To use dissipative structure with sociological models requires only that we find the energy values associated with the reality being represented.

One criticism of dissipative structures as an analytical model for human societies is that it was "a nice analogy, yet while it can explain certain qualitative changes in a system by showing how order emerges from fluctuations, it cannot account for complex cultural systems with their interdependent subsystems, which influence self-organization. And it cannot explain the new structure after a phase of instability." The point is not well taken because such models are not intended to explain the specifics of historical cases. Rather, they provide a model of structural dynamics—in this case, the presence of fluctuations inherent in dissipative systems, which, when energy flow is increased, may cause the structure to become more complex. This happens at critical points where the expansion forces new structures to emerge, or the system will fragment or collapse. Such dynamics characterize Carneiro's 1970 theory of the emergence of the state. The model cannot predict the cultural details of how it occurs—things that depend on specific historical antecedents.

3.3 Energy Maximization

Treating society as a dissipative process allows us to map sociological cases on the energy model and permits the measurement of the energy dynamics at work. With this, there are some energy principles that become useful. One of the earliest of these was Alfred Lotka's 1922 principle of energy maximization: "In every instance considered, natural selection will so operate as to increase the total flux through the system, so long as there is presented an unutilized residue of matter and available energy." It is not difficult to find illustrations of this, but wars are an obvious case. Cavalry dominates over foot soldiers, firearms dominate over the bow, nuclear bombs dominate over gunpowder. In more general terms, one indication that natural selection favors societies with the greatest dissipation of energy may be seen in the reality that societies that have survived and flourished into the present day, dominating competitors, are precisely those that have dissipated the most energy. The society or species that monopolizes resources leaves none for others. The second clause of Lotka's statement, however, states that when energy is not available, maximization cannot take place. This may result from the exhaustion of resources (the path to the "the limits of growth") but may also be due to the presence of boundary conditions or technological inadequacies that prevent access or expansion.

3.4 Minimum Dissipation

Boundaries to energy systems are critical because they may be imposed from the outside, or they may be created by society. This points to a second proposition, the Prigogine–Waime principle of minimum dissipation: "When given boundary conditions prevent the system from reaching thermodynamic

equilibrium (i.e., zero entropy production) the system settles down in the state of 'least dissipation'." This states the conditions under which maximization will not take place. Adult human life is a fluctuating steady state, a homeostatic system, in which internal controls maintain a level of energy use that does not exceed the available and anticipated rate or amount of input. Boundaries may be imposed by disastrous droughts, floods, and plagues, or gradually but consistently, such as by endemic diseases or endemic warfare. Boundaries are often imposed by society through controlling life, such as infanticide, careful birth spacing practices, and putting the elderly to death. Steady-state societies are those that have found ways of controlling the consumption of energy so as to survive on the energy available.

Another way that the principle operates may be seen in the splitting off of part of a society when it is growing too large for comfort. Thus, growing hunting bands and agricultural villages, reaching a certain population size, will hive off, forming new bands or settlements. New boundaries are created because the old boundaries prove inappropriate for survival. In this way, societies follow the minimum dissipation principle because the amount of energy flow is kept to some minimum within the society; but they may succeed in doing this only by creating other societies with boundaries to separate them from the old.

Classic cases have been the peasant philosophy of the "limited good," a pattern of social control whereby those who try to surpass others in some endeavor—and thereby stretch the exploitation of available resources—are condemned and punished by their fellows and restrained from excelling. Some highland New Guinea societies sponsor periodic pig feasts, as described by Roy Rappaport: "The operation of ritual…helps to maintain an undegraded environment, limits fighting to frequencies which do not endanger the existence of the regional population, adjusts man–land ratios, facilitates trade, [and] distributes local surpluses of pig throughout the regional population…." Socially controlling for minimum dissipation is usually achieved in societies only after hard experiences with the consequences of exceeding energy resources.

The advent of capitalism and industrial exploitation of the fossil energy resources, when coupled with an era of rapid population expansion, has generally obscured the implications of the Prigogine–Waime principle. Contemporary industrial societies have sought to expand energy use rather than to limit it. Although societies differ in the degree to which they attempt to shift to more dependable sources—e.g., energy derived directly from solar radiation, river or tidal waters, wind, or hydrogen—none has as yet made a marked shift in that direction. In most industrial countries, such concerns are marginalized by commercial and political interests that promote a policy of continual expansion of dependency on traditional sources. Everywhere, however, the Prigogine–Waime principle operates as available energy resources decline.

3.5 Trigger-Flow Ratio

Energy enters society principally as solar energy but also as moving water or wind and in equilibrium or quasiequilibrium forms, as potential energy—foodstuffs, minerals, forest products, etc. The release of potential energy is literally triggered and then, depending on the technology, controlled as it dissipates into lower grades and entropy, or leaves as a residue of material artifacts and waste. Because triggers and subsequent controls require energy to operate, it is generally expected that the ratio of their energy cost to the amount of energy flow dissipated should be low. Consistent failure to achieve this can lead to the trigger energy exhausting the energy available to the system.

Energy triggers are parts of a larger process, sometimes seen as an investment of energy. It has been proposed that this energy investment is a useful analytical tool, and as such has been referred to variously as embedded energy or, as by Howard Odem, as emergy. The relationship of this investment to the energy it causes to be released is seen as a net energy gain. Odum argued that an increase in the ratio of embedded energy to the energy released constitutes an increase in energy quality. The utility of this concept of energy quality is problematic because, as Joseph A. Tainter and colleagues have noted, "Energy quality in a human system varies with context, as it may also in other living systems." Yasar Demirel prefers to see quality as "the ability of energy to be converted into mechanical work under conditions determined by the natural environment." Emergy and embedded energy are not easy to apply to real situations because they imply an infinite series of antecedent inputs; in fossil fuels alone they include "the energy that previously went into the organism from which these fuels originate as well as the energy from the chemical and geological processes that transformed dead organisms into coal, gas, or petroleum." The importance of net energy lies in economic analyses of the more immediate energy costs.

Because food is everywhere required by human beings, changes in its dynamics reveal much about the course of cultural evolution. History has seen four major kinds of trigger technologies to produce food, all of which require human input: (1) human power in hunting and gathering, (2) cultivation based solely on human energy, (3) cultivation using work animals, and (4) industrialized agriculture. The ratio of trigger energy costs to resulting dissipation changes markedly in these different phases.

Minimally, trigger costs must involve human beings, but other energy sources are also required (tools, fuel, etc.). Table I orders data comparing societies at various levels of energy consumption in terms of the relative amounts of human and nonhuman energy used in food procurement. Early human beings, like contemporary hunters and gatherers, depended almost wholly on their own human energy, as illustrated by the !Kung bushmen (Table I, column C). !Kung gatherers' energy output was almost four times as much as their food energy input (Table I, column F). The development of cultivation increased this gain from 11 to 24 times as much (column F). However, because other energy resources were also used, the output/input gain was somewhat less (column E). With the introduction of work animals, the input of nonhuman energy increases (column C). In general, however, the use of draft animals adds to the trigger costs and provides relatively less yield than can be gained by human beings alone (compare the Mexican production in Table I); the advantage lies in the saving in time it allows. Industrialization brings a major increase in yield over human energy inputs (Table I, column F). With respect to total trigger costs, however, industrialization reduces the net energy gain to a level below that of the !Kung, and much below that of any all the subsistence agriculturalists (column E). In some cases, when the caloric yield is not the object of the cultivation—as with spinach and brussels sprouts—there is a clear net energy loss in the production (column E). Human activity continues to be important in industrial situations. Comparing Japanese and U.S. rice production shows that human activity yields greater efficiency in industrial situations. The Japanese farm requires much more human labor (column C), but

TABLE I

Trigger Energy Cost and Released Flow under Different Food Production Regimes[a]

	A	B	C	D	E	F
Food production effort	Human energy input (kcal)	Total energy input (kcal)	Total energy input/human energy input	Energy output (kcal)	Energy output/ total energy input	Energy output/ human energy input
Human energy gathering						
!Kung bushmen nuts	2680	2680	1.0	10,500	3.92	3.92
Human energy cultivation						
African cassava	821,760	838,260	1.0	19,219,200	22.93	23.39
New Guinea swidden	686,300	739,160	1.1	11,384,462	15.40	16.59
Mexican corn	589,160	642,338	1.1	6,901,338	10.74	11.71
Iban Borneo rice	625,615	1,034,225	1.7	7,318,080	7.08	11.70
Work animal energy

[a] From Pimentel and Pimentel (1996).

has a higher total net yield compared to the much more energy-expensive U.S. production (column E).

Although high-energy production is costly in kilocalories, it saves time. Pimentel and Pimentel calculate that the energy required to till a hectare of land by human power alone requires 200,000 kcal in 400 hr; with oxen, energy input increases to ≈300,000 kcal in 65 hr; with a 6-hp tractor, it increases to ≈440,000 in 25 hr; with a 50-hp tractor, it increases to ≈550,000 in 4 hr. Time, of course, may be critical to survival.

Comparable changes took place in the other areas in the Industrial Revolution. Whereas human labor in fossil-fueled industry at first expanded, the fossil fuels gradually displaced human labor in most of the production process. Adams showed that in Great Britain, for example, the human population in agriculture and industry grew to over 30% of the total in 1860, then declined by 1990 to well below 20%. In Japan, between 1920 and 1990, it also declined, from 36% to, again, below 20%. All countries that have become significantly industrialized have experienced this decline. However, although human energy used in triggers has declined, total energy costs have increased profoundly, drawing on what was thought to be an unlimited availability of fossil and gravitational energy. In industrial society, the energy cost of triggers grew not only through the accessibility of fossil fuels, but through the emergence of a vast complex system of linked triggers, comprising commercial, industrial, governmental, and societal organizations. Even where consumption is relatively low, the ever-increasing need for energy is a serious challenge to the future of industrial societies.

3.6 Entropy and Energy

Some scholars of energy and society have found entropy to be useful for societal analyses. Particularly influential was Nicholas Georgescu-Roegen's work in economics, directly arguing the implications of the second law of thermodynamics against more classical views of the inevitably progressive dynamics of the market. The focus on entropy in the biological and social sciences, however, took wings when Claude Shannon and Warren Weaver used the term to characterize the statistical patterns in information processes, because they conformed to Ludwig Boltzmann's algebraic formula for thermodynamic entropy.

Scholars differ in their acceptance of the appropriateness of identifying the informational process with thermodynamics. Jeffrey Wicken argues that the former does not refer to changes in physical space but rather in complexity of structure. He argues that it is really an "entropy analogue." It is not a process for which reversibility is highly improbable because complex states may have a low or high probability of becoming more or less complex. The identity has, nevertheless, been found useful by various scholars. Daniel R. Brooks and E. O. Wiley propose a formulation of biological evolution whereby "the strictly thermodynamic entropy of the organism…increases along with the informational entropy, since increasing structural complexity requires increasing energy to maintain the steady state." Sociologist Kenneth D. Bailey tends to put aside thermodynamic questions and elaborates a macrotheory of society that focuses on entropy in terms of the probabilities of order and variation.

Students of cultural evolution have not generally taken up the challenge of the entropy formulations, although Jeremy Rifkin, in a popular account, traced the increasing use of energy as being inextricably interrelated with the creation of disorder, chaos, and waste over the course of human history. The apparent preference of scholars for the analytic utility of energy over entropy may be because the materials of social evolution and history are more easily measurable in terms of the former than the latter.

4. ENERGY IN EVOLUTION OF HUMAN SOCIETY

4.1 Culture and Evolution

Sociocultural evolution is a part of the evolution of life, a process that has been best formulated in Darwinian terms. Although some discussions differentiate biological and social evolution, in fact, the individual and the social setting are necessarily complementary parts of a single process. Human life is generated in the biology of individuals, but it survives and reproduces by virtue of the aggregate activities and interactions that take place as a part of societies. Whereas all living forms are in some way complex, social complexity is best understood as the compounding of successive levels of integration, of which the individual is one. Thus, no matter the complexity of a human cell, an individual, a family, a band, or a nation, this complexity is compounded by requiring additional interrelationships—and hence organization—among the aggregated components, thereby creating new levels of integration.

Human society grows by increasing energy flow. This is done first by biological expansion of the population. Natural selection has favored those that organized in order to reproduce, thus creating societies—what Spencer called the superorganism. It is the evolution of human superorganisms that we call social or cultural evolution. The Darwinian processes of reproduction, variation, and natural selection concern individuals, but societies exist to propagate individuals and continue to survive while individuals die. Human society is a facet of natural selection in that it organizes people to reproduce the human species.

To a degree unmatched by other species, human beings control a vast range of extrasomatic energy forms that are captured, gathered, cultivated, and mined from the environment and other societies. This extraction of energy is a cost to the environment caused by the emergence and evolution of human society. It may also be seen as a coevolution in which the human component differentially promotes and inhibits the evolution of many other species. Culture consists of the mental models people make to deal with the external world, and the behavioral and material forms that correspond to these representations. People use these mental models to manipulate the external world, to control external energy forms. In actual historical fact, the models may be the basis for creating controls, or the model may be created to describe a control that has been discovered to work; in any event, the external controls and their models develop in an interactive process. Mental models trigger energy flows. When we speak of the evolution of culture, we are speaking of both the change in the mental models and the changes in energy forms that correspond to these models. Given that both are involved, the term "cultural evolution" has been used to refer to two phases of changing human behavior: (1) the process whereby human beings adapt their mental models and social and cultural behavior to deal with challenges to their survival, and (2) the process whereby mental models, societies, and cultures become more complex as they adapt to deal with challenges to their survival.

Some treatments of cultural evolution see the first as adaptation and prefer to see the increasing complexity in terms of more complicated or compounded social organizations, or in more complicated technology that allows for the control of greater sequences of energy. The relationship between energy and cultural evolution lies in two phases of the process. One is the construction of ever longer and more complex linked trigger-flow systems. The other is the harnessing of additional energy from the environment, allowing more opportunities to tap the flow through its successive stages of dissipation. The Australian aborigines set savanna fires that release an immense amount of energy but exercise no further control over it. There is no successive system of triggers. In contrast, the fire in a steam locomotive converts water to steam that pushes a piston, that directly turns the wheels, that travels along tracks and pulls a number of railway cars, etc. The detonation of a nuclear bomb requires the careful arrangement of a chain of trigger actions before the explosion emerges.

4.2 Population Growth

The most important dynamic process in sociocultural evolution is population expansion, a thing that, in itself, entails a proportionally greater extraction of nutritional energy from the environment. That energy, however, is then further consumed by human activity that further promotes human life.

Population pressure is central to Robert L. Carneiro's circumscription theory and to Marvin Harris' depletion theory of cultural evolution; it is also at the core of Esther Boserup's concern with technological change. As such, it risks being tautological; but it need not be. Circumscription theory proposes that an expanding population pressing against an unyielding environment produces changes in social organization. Harris's depletion theory holds that societies inevitably deplete their environment and must, therefore, intensify their production to retain their living standard. The problem is that the evidence for the population pressure and for depletion lies in the fact that the social organization changes. To avoid the tautology, the problems entailed by this pressure may be specified. The amount of energy flow is central to both processes. In both hunter-gatherer and agricultural societies, changes in population density or in level of food production threaten the availability of energy inputs to the society. Land:human ratio reduction and/or environmental depletion will reduce food availability to the point that social survival is threatened. The same argument applies in defense of Boserup's thesis that farming intensified because of declining production. Specifying the connectivity avoids the tautological by showing how social organization changes due a demonstrable need to improve the food supply.

A response to such pressure in simple societies is that the society fragments, allowing the separate

segments to hive off in the search for other lands. Another response is that the society reaches out for other resources by warfare or trade, using local resources, such as mineral or aquatic resources, to trade for the inputs needed. Where no other possibility is available—or at least known within the society's cultural repertory—members may turn to warfare. This in itself, especially in complex societies, requires additional expenditures of energy. Wars may fail or may succeed in eliminating the enemy and in taking their land and resources without producing major changes in social complexity beyond those necessary for war. However, if they capture the other society and control its production, then the emergence of political subordination, slavery, etc. requires a new level of integration, i.e., greater complexity. It is only in the last case that new external sources of energy are incorporated, and it is there that the society becomes more complex.

Although there is good reason to believe that population pressure and density led to social expansion and intensification in the preindustrial eras of human history, the emergence of states decisively changed the dynamics. States often want to hold a territory, regardless of whether it has any immediate productive use, and also to hold territories that may be important for production, but may be sparsely inhabited. States therefore may occupy vast territories that have little relevance to the immediate needs of their population. Given high levels of economic control and the relative ease of international migration, relatively small states may feel population pressures that are continually eased by emigration, both temporary and permanent. Urbanization, begun with the appearance of advanced agricultural systems, continued to be a central part of the solution under the state. The consequence of these differences is that even though hunting bands combine low energy consumption with low population density, there are some states that have low energy consumption—such as Haiti, Rwanda, and Bangladesh—that have very high population density; and there are states with high-level energy consumption—Australia, Canada and the Iceland—with very low densities. Such differences would not be possible in early (i.e., low energy consumption) phases of sociocultural evolution.

R. B. Graeber has proposed a mathematical theory of cultural evolution, relating population, territorial area, societal numbers, density, and mean societal size. He concludes that density and mean societal size are "indicators of the cultural-evolutionary state attained by a population." Although suggestive for earlier phases, the argument fails to deal with the contradictory cases among contemporary states.

4.3 Stages of Sociocultural Evolution

Anthropologists have long used stages of sociocultural evolution to characterize classes of societies in evolution. Although various sequences and scales of complexity have been proposed, no systematic effort has been made to relate them to the level of energy use. In the 19th century, Morgan, Tylor, Spencer, and Karl Marx all proposed sequences that were generally progressive and argued to constitute some kind of an "advance." In the past century, Childe, Cottrell, Service, and Morton Fried have made such propositions. The formulation of stages, however, has consistently reflected an author's particular interests, and some of the proposals were not made with energy in mind. Karl Marx proposed stages concerning modes of production (tribal, ancient, feudal, and capitalist) but he evinced no interest in thermodynamic issues. His follower, Friedrich Engels, was more explicit; for him to consider energy in economics was "nothing but nonsense."

The concern for technology early appeared in Morgan's sequence of savagery, barbarism, and civilization, whereby the transition between the first two was specifically based on domestication, and therefore with energy consumption and technology. The criteria for a civilization referred not to energy changes but to the appearance of cities and the population densities that were thereby implied. Energy conversion technology implicitly came to include control of human energy by the state. On this basis, Childe proposed two major revolutions in prehistory. The first was the Neolithic Revolution that specifically increased food production. The second was the Urban Revolution that was based on the invention of the plow, but its major manifestation was the emergence of cities based on the large economic surpluses. The sequence suggested in 1971 by Service—bands, tribes, chiefdoms, and state—shifted the concern from a technology to the relative complexity of social organization.

Evolutionary stages have been useful as sequences of kinds of societies reflecting differences in, among other things, energy consumption. Otherwise, the interest shown by social anthropologists in energy has been related to interests in ecology from an ethnographic perspective. Actual measurements have been forthcoming in a few field studies, such as those by Roy A. Rappaport in New Guinea, W. B. Kemp among Eskimo, Pertti Pelto with the Skolt Lapps,

and Richard Lee and L. J. Marshall with the !Kung Bushmen.

Contemporary treatments of the stages of cultural evolution have dispensed with the notions of progress or advance that were inherent in 19th and early 20th century versions. However, there have been few major formulations that take into account the potential exhaustion of energy resources for the species as a whole and the consequent potential decline that it implies. Tainter has explored the process of decline and collapse of specific societies and civilizations, but, given the dominant role of historical contingencies, there is little basis for predicting just how cultural devolution will emerge. There is reason to suspect, however, that although the societies and cultures became more complex with increases in energy, the internal dynamics of complex organizations will lead to decreasing returns in the future. Moreover, the social life of the species has evolved as innumerable separate societies, and these will each continue to trace their own course.

4.4 Energy and Complexity

No matter how heuristically useful stages of growth have been in ordering materials, they tend to imply an unwarranted punctuated quality to the course of cultural evolution. In fact, the process has been much more gradual, fluctuating over time and space, and the central quality that reflects change in energy flow is the change in complexity.

In 1943, Leslie White formulated the first specific proposition relating energy consumption to cultural evolution:

"Culture develops when the amount of energy harnessed by man per capita per year is increased; or as the efficiency of the technological means of putting this energy to work is increased; or, as both factors are simultaneously increased." Although it has recently been claimed that "the thermodynamic conception of culture has suffused cultural evolutionism," there is little work in the anthropological literature to support this. Whereas the domestication of plants and animals was accompanied by increases in population, fluctuating increases in energy consumption, and imperial expansions over the past 5000 years, the exponential per capita growth of both population and energy flow most markedly began with the Industrial Revolution. Boserup calculates that in 1500 AD the population density in Europe was still under 8 persons/km^2, and by 1750 it was still below 16 persons/km^2; by 1900 it had reached averages as high as 128 persons/km^2.

In defining sociocultural complexity, it helps to differentiate the social from the cultural. It is useful to see social complexity as the creation or differentiation of social relationships in new configurations. Most importantly, sociocultural complexity refers to the creation of new levels of social integration, hence to stratification, centralization, inequality, and emergence of hierarchy. Service's four stages outlined a succession of compounding organizations. Cultural complexity, however, refers to the heterogeneity and multiplicity of culture, i.e., meaning systems and the corresponding material and behavioral forms—as in technology (communication, engineering), social organization (voluntary associations, networking), and mental models (intellectual and symbolic systems) allowing for mathematics and astronomy, to suggest just a few. A number of scales of complexity have been proposed for simpler societies. One by Carneiro proposed the relevance of over 600 traits in 72 societies and another by George Peter Murdock and Catarina Provost was based on 10 traits in 180 societies; the two scales correlate highly. Henri J. M. Claessen and Pieter van de Velde have proposed a specific model of evolution as a complex interaction.

The salience of comparative energy consumption has been clearly related to social complexity in the study of contemporary societies at the national level. Somewhat contrary concerns for energy shortages on the one hand, and environmental damage on the other, have stimulated a concern over the past four decades for the relation between levels of energy consumption and various aspects of living. The interests here differ from those concerning the stages of cultural evolution, not merely because they are contemporary and deal with nation states, but because they are motivated by the concern for the survival of society in the short and long terms. At this level, there is little doubt that there is a relationship between various measures of quality of living and energy consumption. In 1970, Boserup divided 130 nation-states evenly into five groups based on technology and demonstrated the consistent difference in some indices of development and welfare. The first group had an average per capita energy consumption of 50, the third had 445, and the fifth had 4910. The corresponding life expectancies were 41, 55, and 72 years. The percentage of the population that was literate was 12, 46, and 98%, respectively. However, in a much-cited 1965 study, Ali Bulent Cambel reported that in countries with over $1500 per capita, the energy consumption varied widely from below 50 to over 175 Btu per capita.

In relating the amount of energy used by a society to its complexity, there are a number of conditioning factors. First, in both the agential and holistic perspectives, the control of energy must distinguish between controls that merely release energy but do not further control it; and controls that not only release but can limit or amplify the flow, its direction, and its impact, i.e., modulate the flow. In the first case, the energy is totally an output, a degrading that removes it from the society, such as setting an uncontrolled fire, detonating a bomb, or pushing a person off a cliff; the impacts are randomized. In the second, the available energy is kept within control of the society, and the impacts are controlled, such as the adjustment of the level of electric current, the ability of a court to vary a prison sentence, or of a farmer to decide when to plant a crop. The Australian aborigines who set extensive range fires to clear out savanna litter have no control over its dissipation. According to one estimate, such fires may release up to 500 million kcal of biomass energy a year—six times that used by the average American on a per capita basis—but the fires and the dissipation cannot be controlled.

Second, the increase of societal complexity depends not merely on the total energy released, nor even that for which there is control over the dissipation, but whether the controlled energy is effective in the self-reproduction of the society. In terms of comparative societal evaluation, this is technically more difficult to ascertain. One has to judge whether ceremonial structures and performances dedicated to appeasing a rain god are in fact more cost-effective than the construction of an irrigation system, or at what point the energetic costs of imperial expansion cease to be productive for the society's reproduction. Returning to White's proposition, a revised version might be as follows: the evolution of sociocultural complexity varies directly with the amount of energy controlled per capita per year and with the efficiency of the technological means of putting this energy to work in behalf of societal reproduction.

Although there are cases in which culture appears to be devolving and to be returning to some earlier form, in fact such a return simply does not happen. If there were a vast and gradual decline of energy available for consumption, it would require cultural simplification and reduction in complexity, but this would require new adaptations. But there would be no strict reversion to the social and cultural forms that emerged during the expansive phases of the species over the past few million years, or of the human civilizations of the past 50,000 years. The so-called devolution would, among other things, be the evolution of cultures that would be formally different from their predecessors, but necessarily simpler in the diversity of traits and relationships.

4.5 Partitioning of Energy

A facet of energy flow analysis that can help clarify the nature of society is how it is differentially partitioned among different internal functions and external relations. The way that energy is channeled and how this changes throw light on what is taking place in the structure of the society. For example, the proportion of the total energy flow involved in feeding the society seems remarkably similar in both simple and complex industrial societies. John A. Whitehead compared two Australian aboriginal bands with the population in the United States. Whereas the aboriginal bands used 20–30% of their energy resources for food gathering, in the United States, household plus commercial (which included more than food) consumption was estimated at 27%. Joel Darmstadter and colleagues found in eight Euro-American countries that the household–commercial sector constituted between 24 and 32% of the output, and 19% in Japan. This suggests that there is a consistent relationship between the nutrition requirements of the human beings and the economic process that surrounds them, irrespective of the energy level of the society.

In contrast, some differences appear in human energy partitioning as the total energy flow increases. In comparing a series of nations in the past 150 years, Adams found that the proportion of the population engaged in productive activities—i.e., agriculture and industry—was as high as 40% in the 19th century, but then dropped, often below 20% by the end of the 20th century. This was true of both highly industrialized countries as well as much of the Third World that increasingly received the industrial produce of advanced countries. In contrast, the population engaged in administration and commerce was everywhere between 2 and 4% in the early censuses, but then rose to as high as 20%, varying directly with the increase in nonhuman energy. The expansion of this regulatory sector of the population was systematically more marked in the countries with high levels of energy consumption.

Changes in the partitioning of energy consumption were fundamental in the evolution of the capacity for culture. Leslie C. Aiello and Jonathan C. K. Wells write that "the emergence of *Homo* is

characterized by…an absolute increase, to greater body size [and] a shift in relative requirements of different organs, with increased energy diverted to brain metabolism at the expense of gut tissue….” The nutrition patterns changed profoundly as the range of the human diet allowed greater territorial range, and digestive efficiency increased and the relative amount of energy required decreased. This decreasing proportion of energy dedicated to food processing was accompanied by an increase in the size of the brain and the relative amount of energy contributing to it. The increased efficiency of food processing was thus related to an increase in diet quality, which is consistent with the observation that primates with higher diet quality have higher levels of social activity.

These changes occurred relatively rapidly as the hominid brain from *Australopithecus* to *Homo sapiens* grew at a rate almost three times that which characterized ungulates and carnivores in general. Part of this growth was increase in human brain size, and more particularly the appearance of fissures that Harry J. Jerison argued allowed “the evolutionary building of integrated neural circuits through which diverse sensory information could be used to create increasing complex mental images.” This suggests that the ability to create models of reality—an important component in culture—existed 50 millions years ago. The energetic dimension of this change was reflected in the changing partitioning of energy use between the brain and the gut. Today, according to Marcus E. Raichle and Debra A. Gusnard, the brain represents 2% of body weight, but accounts for 20% of calorie consumption by the body.

4.6 The Limits of Growth

Although the conveniences made possible by increasing energy use and intensifying consumption were viewed as human progress by some, the vulnerability it implied was also recognized. Soddy early devoted a number of works to this aspect of contemporary societies, arguing that energy could be a limiting factor in social growth. He recognized that the shift from renewable agricultural resources to an increasing dependence on coal and, later, petroleum posed serious problems for advanced societies. Lotka’s proposition on the maximization of energy in living systems carefully specified that the dynamics of greater energy flows exercising dominance over lesser flow could take place only “so long as there is presented an unutilized residue of matter and available energy.”

For some, the question of energy shortages was less critical than a preoccupation with the damage done to the environment by the impacts of increasing energy expenditure. Concern for this was evinced in the 19th century by George Perkins Marsh and Alexander Ivanovich Voikof; more recently, Rachel Carson’s *Silent Spring* (1962) helped trigger the environmental movement in the United States. The remainder of the 20th century saw the expansion of environmental politics and studies concerned with the destruction of natural resources over much of the world. Besides the exhaustion of nonrenewable energy resources, another major concern has been the effect of excessive combustion of fossil fuels on the atmosphere, global warming, and related deterioration of the ecology of the planet. The chemical and material pollution of oceans, lakes, and the air was coupled with the deposition of millions of tons of waste over the earth’s surface. In all this, the role of increasing energy use was fundamental, both in the despoiling of resources and in polluting the environment. The central question is shifting from simply how to get more energy to how to reduce consumption.

The concern with the availability of energy resources in the nations consuming high levels of energy, especially the United States, replays the problems of circumscription and depletion in earlier human societies. The concern has dominated both economic and political policy and action to a degree that is seldom explored to the fullest. Availability has directly affected the development of environmental concerns in areas of potential oil exploitation, pitting those concerned for the long-term environmental and human sustainability issues against those interested in the monetary yield of exploiting as many resources as fast as possible and controlling resources in other parts of the world. The response of the United States to the terrorist attacks of 2001 was not unlike those postulated for early societies facing threats to their resources created by population growth and competitive societies.

5. CONCLUDING NOTE

Spencer recognized the importance of energetic processes to the evolution of culture and society in his formulation of the modern concept of evolution in the 19th century. It was formally articulated in 1943 by Leslie White, and interest since that time has been limited mainly to archaeologists, who have found in it a useful basis for comparing societies and

for modeling the activities of prehistoric societies, and to a few ethnologists working in technologically limited societies. Independently an understanding of nonequilibrium thermodynamic systems was opened in mid-20th century by the work of Prigogine, yielding the model of the dissipative structure. This has provided the basis for the mapping of social processes onto energetic dynamics, a potential as yet little explored. The importance of energy to the organization of society and to its future has become a matter of major concern to contemporary nations because of their increasing demand for energy, and by environmentalists and globally conscious politicians and economists in their concern for ecological survival and the planet's ability to support human life. What may seem to be an arcane interest in the role of energy in cultural evolution is directly related to the imperative concern for the survival of human society.

5. Conclusion

Glossary

aggregate energy intensity The ratio of total energy use to total output measured at an aggregate level, such as industrywide and economywide.

decomposition technique The technique of decomposing variations in an aggregate over time or between two countries into components associated with some predefined factors.

Divisia index A weighted sum of growth rates, where the weights are the components' shares in total value, given in the form of a line integral.

energy intensity The amount of energy use per unit of output or activity, measured at the sectoral or activity level.

gross domestic product (GDP) A measure of the total flow of goods and services produced by the economy during a particular time period, normally 1 year.

index number A single number that gives the average value of a set of related items, expressed as a percentage of their value at some base period.

Laspeyres index An index number that measures the change in some aspect of a group of items over time, using weights based on values in some base year.

structure change A change in the shares or composition of some attribute, such as sector output in industrial production and fuel share in energy use.

This article discusses the decomposition techniques formulated using concepts similar to index numbers in economics and statistics. They have been called the index decomposition analysis. Approximately 200 energy and energy-related studies have been reported since 1978. Of these, slightly less than 20% deal with methodological or related issues and the remaining are application studies. Several other decomposition analysis methodologies have also been adopted in energy analysis, including the input–output structural decomposition analysis, which uses the input–output approach in economics to carry out decomposition. In terms of the number of studies reported, these techniques are relatively less popular compared to index decomposition analysis. The basics of index energy decomposition analysis are presented here. This is followed by a review of the methodological and application issues.

1. INTRODUCTION

Accounting for the largest share of primary energy demand in most countries, energy use in industry attracted considerable attention among policymakers, researchers, and analysts in the aftermath of the world oil crisis in 1973 and 1974. Effort was made by researchers and analysts to understand the mechanisms of change in industrial energy use through engineering process studies, energy audits, and industrywide analyses. At the industrywide level, a new research area began to emerge in approximately 1980, namely the study of the impact of changes in industry product mix, or structural change, on energy demand. It was realized that structural change could greatly influence energy demand trends, and there was a need to identify and quantify its impact to assist in policymaking. This line of research has since expanded substantially in terms of both methodology and application. It is now called decomposition analysis in the energy literature.

An important feature of decomposition analysis in the 1980s was its close linkages with the study of the

aggregate energy intensity of industry. As an aggregate for the entire spectrum of industrial sectors/activities, this indicator is defined as the total industrial energy use in a country divided by its total industrial output. A decrease in the aggregate energy intensity is generally preferred since it means that a lower level of energy requirements is needed to produce a unit of industrial output. At approximately the same time, several cross-country comparative studies of industrialized countries were conducted, and countries with comparatively low aggregate energy intensity were considered more effective in energy utilization.

Researchers and analysts then began to examine factors contributing to changes in the aggregate energy intensity of countries over time (and variations in the aggregate energy intensity between countries). In the simplest form, two contributing factors were identified, namely structural change and energy intensity change. Industry is an aggregate comprising a wide range of sectors (or activities), such as food, textiles, petrochemical, transport equipment, and electronics. Structural change is associated with the varying growth rates among these sectors, which lead to a change in the product mix. Energy intensity change is determined by changes in the energy intensities of these industrial sectors. The sectoral energy intensity, or simply energy intensity, is the ratio of energy use to output for a specific sector defined at the finest level of sector disaggregation in the data set. To determine the impacts of these two factors, the observed change in the aggregate energy intensity is decomposed using an appropriate decomposition technique. Since 1980, numerous decomposition techniques have been proposed.

Information obtained through decomposition analysis has direct policy implications. The composition of industrial activity is effectively beyond the control of the energy policymaker except through indirect measures such as energy pricing. On the other hand, many measures can be taken to influence sectoral energy intensity change, such as taxation, regulatory standards, financial incentives, and information programs. The ability to accurately quantify the relative contributions of structural change and energy intensity change provides insight into trends in industrial use of energy. The success or failure of national energy conservation programs may be evaluated. The decomposition results also provide a basis for forecasting future energy requirements and for evaluating appropriate courses of action.

2. BASICS OF DECOMPOSITION ANALYSIS

Since index decomposition analysis was first applied to analyze energy use in industry, it is appropriate to explain the underlying concept with reference to the decomposition of a change in the aggregate energy intensity of industry. To keep the discussion simple, we consider the two-factor case in which a change in the aggregate intensity is decomposed to give the impacts of structural change and sectoral energy intensity change.

2.1 Notations and Basic Formulae

Assume that total energy consumption is the sum of consumption in n different industrial sectors and define the following variables for time t. Energy consumption is measured in an energy unit and industrial output in a monetary unit.

E_t = Total energy consumption in industry
$E_{i,t}$ = Energy consumption in industrial sector i
Y_t = Total industrial production
$Y_{i,t}$ = Production of industrial sector i
$S_{i,t}$ = Production share of sector i $(= Y_{i,t}/Y_t)$
I_t = Aggregate energy intensity $(= E_t/Y_t)$
$I_{i,t}$ = Energy intensity of sector i $(= E_{i,t}/Y_{i,t})$.

Express the aggregate energy intensity as a summation of the sectoral data:

$$I_t = \sum_i S_{i,t} I_{i,t},$$

where the summation is taken over the n sectors. The aggregate energy intensity is expressed in terms of production share and sectoral energy intensity. Suppose the aggregate energy intensity varies from I_0 in Year 0 to I_T in Year T. Such a change may be expressed in two ways, $D_{\text{tot}} = I_T/I_0$ and $\Delta I_{\text{tot}} = I_T - I_0$, respectively a ratio and a difference. Accordingly, decomposition may be conducted either multiplicatively or additively, respectively expressed in the forms

$$D_{\text{tot}} = I_T/I_0 = D_{\text{str}} D_{\text{int}}$$
$$\Delta I_{\text{tot}} = I_T - I_0 = \Delta I_{\text{str}} + \Delta I_{\text{int}},$$

where D_{str} and ΔI_{str} denote the impact of structural change, and D_{int} and ΔI_{int} denote the impact of sectoral intensity change. In the multiplicative case, all the terms are given in indices, whereas in the additive case all the terms, including the aggregate being decomposed, have the same unit of measurement.

To quantify the impacts, two approaches—the Laspeyres index approach and the Divisia index approach—have been widely adopted by researchers and analysts.

2.2 Laspeyres Index Approach

The Laspeyres index approach follows the Laspeyres price and quantity indices by isolating the impact of a variable by letting that specific variable change while holding the other variables at their respective base year values (in this case, Year 0). The formulae for multiplicative decomposition are

$$D_{\text{str}} = \sum_i S_{i,T} I_{i,0} / \sum_i S_{i,0} I_{i,0}$$
$$D_{\text{int}} = \sum_i S_{i,0} I_{i,T} / \sum_i S_{i,0} I_{i,0}$$
$$D_{\text{rsd}} = D_{\text{tot}} / (D_{\text{str}} D_{\text{int}}).$$

In additive decomposition, the formulae are

$$\Delta I_{\text{str}} = \sum_i S_{i,T} I_{i,0} - \sum_i S_{i,0} I_{i,0}$$
$$\Delta I_{\text{int}} = \sum_i S_{i,0} I_{i,T} - \sum_i S_{i,0} I_{i,0}$$
$$\Delta I_{\text{rsd}} = \Delta I_{\text{tot}} - \Delta I_{\text{str}} - \Delta I_{\text{int}}.$$

The Laspeyres index approach does not give perfect decomposition. The residual terms D_{rsd} and ΔI_{str} denote the part that is left unexplained. Decomposition is considered perfect if $D_{\text{rsd}} = 1$ and $\Delta I_{\text{str}} = 0$. These are also target values of the residual terms for evaluating the performance of a decomposition technique.

2.3 Divisia Index Approach

The Divisia index is an integral index number. In this approach, first the theorem of instantaneous growth rate is applied to $I_t = \sum_i S_{i,t} I_{i,t}$, which gives

$$d\ln(I_T/dt) = \sum_i \omega_i \left[d\ln(S_{i,t})/dt + d\ln(I_{i,t})/dt \right],$$

where $\omega_i = E_{i,t}/E_t$ is the sector share of energy consumption and is known as the weight for sector i in the summation. Integrating over time from 0 to T,

$$\ln(I_T/I_0) = \int_0^T \sum_i \omega_i \left[d\ln(S_{i,t})/dt \right] + \int_0^T \sum_i \omega_i \left[d\ln(I_{i,t})/dt \right],$$

Taking the exponential, the previous equation can be expressed in the multiplicative form $D_{\text{tot}} = D_{\text{str}} D_{\text{int}}$, where

$$D_{\text{str}} = \exp\left\{ \int_0^T \sum_i \omega_i \left[d\ln(S_{i,t})/dt \right] \right\}$$
$$D_{\text{int}} = \exp\left\{ \int_0^T \sum_i \omega_i \left[d\ln(I_{i,t})/dt \right] \right\}.$$

Since in practice only discrete data are available, the weight function has to be explicitly defined in actual application. Two of the weight functions that have been proposed in energy decomposition analysis are described next.

The first is the arithmetic mean of the weights for Year 0 and Year T, where

$$D_{\text{str}} = \exp\left\{ \sum_i (\omega_{i,T} + \omega_{i,0})/2 \ln(S_{i,T}/S_{i,0}) \right\}$$
$$D_{\text{int}} = \exp\left\{ \sum_i (\omega_{i,T} + \omega_{i,0})/2 \ln(I_{i,T}/I_{i,0}) \right\}.$$

Like the Laspeyres index approach, the approach does not give perfect decomposition, and we can write $D_{\text{tot}} = D_{\text{str}} D_{\text{int}} D_{\text{rsd}}$. The additive version can be derived in the same manner, and the relevant formulae are

$$\Delta I_{\text{str}} = \sum_i (E_{i,T}/Y_T + E_{i,0}/Y_0)/2 \ln(S_{i,T}/S_{i,0})$$
$$\Delta I_{\text{int}} = \sum_i (E_{i,T}/Y_T + E_{i,0}/Y_0)/2 \ln(I_{i,T}/I_{i,0}).$$

The decomposition is also not perfect, and we have $\Delta I_{\text{tot}} = \Delta I_{\text{str}} + \Delta I_{\text{int}} + \Delta I_{\text{rsd}}$.

The second and more refined weight function is given by the logarithmic mean of the weights for Year 0 and Year T. The corresponding formulae are

$$D_{\text{str}} = \exp\left\{ \sum_i \frac{L(E_{i,T}/Y_T, E_{i,0}/Y_0)}{L(I_T, I_0)} \ln(S_{i,T}/S_{i,0}) \right\}$$
$$D_{\text{int}} = \exp\left\{ \sum_i \frac{L(E_{i,T}/Y_T, E_{i,0}/Y_0)}{L(I_T, I_0)} \ln(I_{i,T}/I_{i,0}) \right\}$$
$$\Delta I_{\text{str}} = \sum_i L(E_{i,T}/Y_T, E_{i,0}/Y_0) \ln(S_{i,T}/S_{i,0})$$
$$\Delta I_{\text{int}} = \sum_i L(E_{i,T}/Y_T, E_{i,0}/Y_0) \ln(S_{i,T}/S_{i,0}),$$

where the function $L(a, b)$ is the logarithmic mean of two positive numbers a and b given by

$$L(a,b) = (a-b)/(\ln a - \ln b), \text{ for } a \neq b$$
$$= a, \text{ for } a = b$$

The advantage of the logarithmic mean weight function is that perfect decomposition is ensured. It

can be proven that the residual term does not exist (i.e., $D_{rsd} = 1$ and $\Delta I_{str} = 0$).

2.4 An Example

Table I shows a hypothetical case in which industry comprises two sectors. The sectoral energy intensity decreases from Year 0 to Year T for both sectors. In percentage terms, it decreases by 33% in sector 1 and by 20% in sector 2. By examining the sectoral data, one would conclude that at the given sectoral level, there are significant improvements in energy efficiency. At the industrywide level, however, the aggregate energy intensity increases by 20%. This apparent contradiction arises because of structural change. Sector 1, the more energy intensive of the two sectors, expands substantially in production level and its production share increases from 20 to 50%. The achievements in energy conservation, assuming that conservation measures have been successfully implemented within sectors 1 and 2, are therefore not reflected in the industrywide aggregate indicator.

Application of appropriate decomposition techniques to give the impacts of structural change and energy intensity change helps to resolve the previous apparent contradiction. The decomposition results obtained using the Laspeyres index method and the two Divisia index methods are summarized in Table II. Based on the results for the logarithmic mean Divisia method, we conclude that in multiplicative decomposition, the contribution of structural change increases by 70%, whereas that of sectoral energy change decreases by 29%, resulting in a net 20% increase in the aggregate energy intensity as observed. In the case of additive decomposition, structural change accounts for an increase by 0.58 units, whereas sectoral energy intensity change accounts for a decrease by 0.38 units, leading to a net increase in the aggregate energy intensity of 0.20 units.

It may be seen that the impacts of structural change and energy intensity change can be conveniently estimated and the relative contributions identified. In actual application, where very fine data are available, the number of sectors can be as many as a few hundred. The decomposition results obtained are method dependent, as shown in Table II, and the choice of an appropriate technique is often an application issue. The methodology has been applied to study problems with more than two factors and in many energy-related areas.

TABLE I

An Illustrative Example (Arbitrary Units)

	Year 0				Year T			
	E_0	Y_0	S_0	I_0	E_T	Y_T	S_T	I_T
Sector 1	30	10	0.2	3.0	80	40	0.5	2.0
Sector 2	20	40	0.8	0.5	16	40	0.5	0.4
Industry	50	50	1.0	1.0	96	80	1.0	1.2

TABLE II

Decomposition Results Obtained Using the Data in Table I

		Divisia approach	
	Laspeyres approach	Arithmetic mean	Logarithmic mean
Multiplicative			
D_{tot}	1.2000	1.2000	1.2000
D_{str}	1.7500	1.6879	1.6996
D_{int}	0.7200	0.7020	0.7060
D_{rsd}	0.9524	1.0127	1[a]
Additive			
ΔI_{tot}	0.2000	0.2000	0.2000

ΔI_{rsd}	−0.2700	−0.0007	0[a]

[a] Perfect decomposition.

3. METHODOLOGY AND RELATED ISSUES

The methodological development of energy decomposition analysis since the late 1970s may be divided into three phases: the introduction phase (prior to 1985), the consolidation phase (1985–1995), and the further refinement phase (after 1995). It is a multifaceted subject, and the advances have been made due to the collective effort of researchers and analysts with backgrounds varying from science to mathematics, engineering, and economics.

3.1 The Introduction Phase (Prior to 1985)

The techniques proposed prior to the mid-1980s are intuitive and straightforward. Typically, the impact of structural change was singled out by computing the hypothetical aggregate energy intensity that

would have been in a target year had sectoral energy intensities remained unchanged at their respective values in a base year. The difference between this hypothetical target year aggregate energy intensity and the observed base year aggregate energy intensity is taken as the impact of structural change. The difference between the observed aggregate energy intensity and the hypothetical aggregate energy intensity, both of the target year, is taken as the impact of sectoral energy change. These techniques were first proposed by researchers to study trends of industrial use of energy in the United Kingdom and the United States in approximately 1980. No reference was made to index numbers in these studies, which means that the techniques were developed independent of index number theory. However, it was later found that these techniques were very similar to the Laspeyres index in concept. Methodologically, it is appropriate to refer to them as the Laspeyres index approach or the Laspeyres index-related decomposition approach.

3.2 The Consolidation Phase (1985–1995)

In this phase, several new techniques were proposed, with the realization that the Laspeyres index concept need not be the only one that could be adopted. The arithmetic mean Divisia index method was proposed in 1987 as an alternative to the Laspeyres index method. At approximately the same time, as an extension to the Laspeyres index formula that assigns the total weight to the base year, methods with equal weight assigned to Year 0 and Year T were formulated. This modification leads to formulae that possess the symmetry property.

In the early 1990s, attempts were made to consolidate the fast growing number of methods into a unified decomposition framework. A notable development was the introduction in 1992 of two general parametric Divisia index methods that allow an infinite number of decomposition methods to be specified. In these two methods, the weights for Year 0 and Year T are treated as variables whose values are explicitly defined. By choosing the weights appropriately, many earlier methods, including those based on the Laspeyres index approach and the Divisia index approach, can be shown to be special cases of these two general methods. Alternatively, the weights can be determined in an adaptive manner based on energy consumption and output growth patterns in the data set. In chaining decomposition, the weights would be updated automatically over time. By the mid-1990s, this technique, called the adaptive weighting parametric Divisia index method, was the most sophisticated decomposition technique. It was later adopted by some researchers and analysts.

3.3 Further Refinement Phase (after 1995)

Until the mid-1990s, all the proposed energy decomposition techniques left an unexplained residual term. Studies found that in some situations the residual term could be large, especially for the Laspeyres index approach. This issue became a concern because if a large part of the change in the aggregate is left unexplained, the interpretation of decomposition results would become difficult if not impossible, and the objective of decomposition analysis would be defeated.

Researchers began to search for more refined decomposition techniques, and the first perfect decomposition technique for energy decomposition analysis was proposed in 1997. This technique is similar to the logarithmic mean Divisia index method. In addition to having the property of perfect decomposition, the logarithmic mean Divisia index methods are also superior to the arithmetic mean Divisia method in that they can handle data with zero values. After the application of decomposition analysis was extended to include the effect of fuel mix in the early 1990s, the existence of zero values in the data set became a problem for some decomposition techniques. Zero values will appear in the data set when an energy source, such as nuclear energy or natural gas, begins or ceases to be used in a sector in the study period.

In the Laspeyres index approach, the residual terms, such as those shown in Table II, are known to researchers to consist of interactions among the factors considered in decomposition. A scheme to distribute the interaction terms, whereby perfect decomposition is achieved, was proposed in 1998. It has been referred to as the refined Laspeyres index method because it may be considered a refinement to the Laspeyres approach. In 2002, researchers introduced the Shapley decomposition, a perfect decomposition technique that has long been used in cost-allocation problems, to energy decomposition analysis. It has been determined that the refined Laspeyres index technique introduced in 1998 and the Shapley decomposition technique are exactly the same. Several other techniques that give perfect decomposition have been reported, including one that uses the concept of the Fisher ideal index.

3.4 Other Methodological Issues

In addition to method formulation, the following methodological issues are relevant to the application of decomposition analysis: multiplicative decomposition versus additive decomposition, disaggregation level of the data, and decomposition on a chaining basis versus a nonchaining basis. Each of these issues is briefly described.

For a given data set, the analyst may use either the multiplicative scheme or the additive decomposition scheme, and generally only one will be chosen by the analyst. The decomposition formulae for the two schemes are different, as are the numerical results obtained. However, the main conclusions are generally the same. As previously mentioned, the numerical results of the estimated effects are given in indices in multiplicative decomposition, but they are given in a physical unit in additive decomposition. Preference of the analyst and ease of result interpretation are the main considerations in the choice between the two decomposition schemes. Methodologically, the logarithmic mean Divisia index method has an advantage over other methods because the results obtained from the multiplicative and the additive schemes are linked by a very simple and straightforward formula. This unique property allows the estimate of an effect given by one of the two schemes to be readily converted to that of the other, and the choice between the multiplicative and additive schemes made by the analyst before decomposition becomes inconsequential.

The disaggregation level of the data defines the level or degree of structural change to be estimated. In the case of energy use in industry, past decomposition studies used levels varying from 2 sectors, which is the minimum, to approximately 500 sectors. The choice of disaggregation level dictates the results since structural change and energy efficiency change are dependent on the level chosen. Hence, result interpretation must be done with reference to the level defined and generalization should be avoided. A fine level of sector disaggregation is normally preferred. For instance, energy efficiency change is often taken as the inverse of the estimated energy intensity change. Derived in this manner, a good estimate of the real energy efficiency change requires that industry be broken down into a sufficiently large number of sectors. The quality of the estimate improves as the number of sectors increase.

When year 0 and year T are not consecutive years but two points in time separated by 1 year or more, nonchaining decomposition simply uses the data of the two years in the analysis without considering the data of all the intervening years. In contrast, decomposition on a chaining basis involves yearly decomposition using the data of every two consecutive years starting from year 0 and ending at year T, with the decomposition results computed on a cumulative basis over time. Chaining decomposition has also been referred to as time-series decomposition and rolling base year decomposition. In nonchaining decomposition, the year-to-year evolution of factors over time between year 0 and year T is not considered. It has been shown that there is less variation between the results given by different decomposition techniques when decomposition is performed on a chaining basis. This consistency, which arises because decomposition is "path dependent," is a distinct advantage. As such, the chaining procedure should be preferred when time-series data are available. However, nonchaining decomposition is the only choice in some situations, such as in studies that involve a very large number of sectors for which energy and production data are not collected annually.

3.5 Further Remarks

The methodological development of energy decomposition analysis has also been driven by the need of energy researchers to study an increasingly wider range of problems. In the simplest form and with only two factors, many decomposition techniques have a strong affinity with index numbers (i.e., product mix and energy intensity as equivalent to commodity quantity and price on an aggregate commodity value in economics). However, the problems studied after 1990 seldom have two factors. A typical decomposition problem on energy-related national carbon dioxide (CO_2) emissions, for instance, involves five factors—total energy demand per unit of gross domestic product (GDP), per capita GDP, population, energy demand by fuel type, and the CO_2 emission coefficient by fuel type.

There is a good collection of decomposition techniques that can cater to almost every possible decomposition situation or suit the varied needs of the analyst. Each of these techniques has its strengths and weaknesses. Perfect decomposition has been widely accepted as a very desirable property of a decomposition technique in energy analysis. In some situations, especially in cross-country decomposition, some of the techniques that do not give perfect decomposition could have a residual term many times larger than the estimated main effects. In addition, there are techniques that fail when the data set contains zero values or

negative values. Some techniques, such as those based on the Divisia index, have the advantage of ease of formulation and use, whereas others, including those based on the Laspeyres index, have complex formulae when more than three factors are considered.

In general, whether a specific technique is applicable or the "best" among all depends on the following: (i) the properties of the technique, which are related to the index number with which the technique is associated with; (ii) ease of understanding and use; (iii) the problem being analyzed, such as whether it is a temporal or cross-country problem; and (iv) the data structure, such as whether zero or negative values exist in the data set. A good understanding of the strengths and weaknesses of the various decomposition techniques would allow analysts to make sound judgments as to which technique to use. These issues are addressed in some publications.

4. APPLICATION AND RELATED ISSUES

The origin of energy decomposition analysis is closely linked to the study of energy use in industry. Not surprisingly, this application area accounted for most of the publications on the subject until 1990. Since then, the application of decomposition analysis has expanded greatly in scope. The main reasons are the growing concern about the environment and the increased emphasis on sustainable development globally. Moreover, decomposition analysis can be conveniently adopted as long as structural change can be meaningfully defined and data are available at the chosen disaggregation level. Indeed, its simplicity and flexibility opens up many possible application areas. Some of these, such as the development of national energy efficiency indicators to monitor national energy efficiency trends, are unique to index decomposition analysis as a decomposition methodology. In terms of application by country, decomposition analysis has been adopted to study energy and energy-related issues in a large number of countries, including all major industrialized countries, most Eastern European countries including Russia, and many developing countries. The following sections focus on developments in several key application areas.

4.1 Energy

With the successful application to study trends of energy use in industry, extensions to decomposition analysis were made to study energy use in the economy as a whole, in energy-consuming sectors other than industry, and in the energy supply sector. In the case of national energy demand, the aggregate to be decomposed is generally energy use per unit of GDP, commonly known as the energy-output ratio in the energy literature, where energy use covers all sectors of the economy and structural change refers to changes in GDP product mix. However, such studies often have difficulty matching energy consumption with economic output. This is due to the fact that energy uses in some sectors, such as private transportation and residential, have no direct match with output sectors/activities in the GDP, and as such some adjustments to sector definition and data are often needed.

Regarding energy consumption in major sectors other than industry, studies have been performed on energy use in passenger transportation and in freight transportation. For passenger transportation, aggregate energy use per passenger-kilometer has been decomposed to give the impacts of transportation modal mix and modal energy intensity given by modal energy requirement per passenger-kilometer. Similarly, for freight transportation, aggregate energy use per tonne-kilometer of freight moved has been decomposed. For residential energy use, decomposition has been conducted to quantify the impact of changes in the mix of residential energy services consumed. For electricity production, aggregate generation efficiency has been decomposed to give the impacts of generation mix and the generation efficiency of each fuel type.

4.2 Energy-Related Gas Emissions

Since the early 1990s, due to the growing concern about global warming and air pollution, an increasing number of studies on the decomposition of energy-induced emissions of CO_2 have been performed. The extension of the methodology presented in Section 2 to decompose an aggregate CO_2 indicator is fairly straightforward. Assume that the ratio of industrial energy-related CO_2 emissions to industrial output is the aggregate of interest. A declining trend for the indicator is generally preferred, and the motivation is to study the underlying factors contributing to changes in the aggregate. This would normally be formulated as a four-factor problem with the following factors: industrial output structure change, sectoral energy intensity change, sectoral fuel share change, and fuel CO_2 emission coefficient change. Similar decomposition procedures have been applied to study energy-related CO_2

emissions for the economy as a whole, other major energy-consuming sectors, and the energy supply sector. Although the focus among researchers and analysts has been on CO_2 emissions, some studies have dealt with emissions of other gases, such as sulfur dioxide and nitrogen oxides. The number of decomposition studies dealing with energy-related gas emissions equaled that of studies on energy demand by the late 1990s and exceeded the latter in 2000.

4.3 Material Flows and Dematerialization

Another extension of decomposition analysis is the study of the use of materials in an economy. The materials of interest to researchers include a wide range of metals and nonmetallic minerals, timber, paper, water, cotton, etc. The list also includes oil, coal, and natural gas, which are treated as materials rather than energy sources. The aggregate of interest would be the consumption of a material divided by GDP or some other meaningful output measure. In material flows studies, dematerialization refers to the absolute or relative reduction in the quantity of material to serve economic functions, and its concept is similar to reduction of aggregate energy intensity. The technique of energy decomposition analysis can be easily extended to material decomposition analysis to study trends of material use. Indeed, a number of such studies have been performed, and it has been found that decomposition analysis is a useful means of analyzing the development of the materials basis of an economy.

4.4 National Energy Efficiency Trend Monitoring

Increasingly more countries see the need to have appropriate national energy efficiency indicators or indices to measure national energy efficiency trends and progress toward national energy efficiency targets. The energy efficiency indicators may be defined at the national level or at the sectoral level of energy consumption, such as industrial, transportation, commercial, and residential. Here, the primary focus of decomposition analysis is not to study the impact of structural change. Rather, it is the elimination of the impacts of structural change and other factors from changes in an aggregate such as the ratio of national energy consumption to GDP, whereby the impact of energy intensity change computed is sufficiently refined to be taken as inversely proportional to real energy efficiency change. Advances in the decomposition analysis methodology, including the use of physical indicators to measure output or activity level, have allowed the development and use of more meaningful and robust energy efficiency indicators or indices. A related methodological framework that would more accurately track trends in energy efficiency has been developed by many countries and international organizations, including the Energy Efficiency and Conservation Authority of New Zealand, the U.S. Department of Energy, the Office of Energy Efficiency of Canada, the International Energy Agency, and the European Project and Database on Energy Efficiency Indicators.

4.5 Cross-Country Comparisons

Cross-country comparisons involve the quantification of factors contributing to differences in an aggregate, such as aggregate energy intensity or the ratio of energy-related CO_2 emissions to GDP, between two countries. The factors considered are similar to those in the study of changes in the indicator over time in a country. In decomposition analysis, the data for the two countries are taken to be the same as those for two different years in a single-country study. Such studies have been carried out for a number of countries. Studies have also compared CO_2 emissions between world regions, such as between North America and the developing world. For the factors considered, because the variations tend to be larger between two countries/regions than between two years for a country, the decomposition tends to give a large residual term if nonperfect decomposition techniques are applied. In general, the use of a perfect decomposition technique is recommended for cross-country decomposition analysis.

5. CONCLUSION

The methodology development and application of index decomposition analysis have been driven by energy researchers since the 1970s, immediately after the 1973 and 1974 world oil crisis. In the case of the basic two-factor decomposition problems, the tool has a strong affinity with index number problems. Nevertheless, over the years, energy researchers and analysts have continuously refined and extended the methodology for the unique situations and requirements in the energy field. As a result, decomposition analysis has reached a reasonable level of sophistication and its usefulness in energy studies has been firmly established.

A well-defined set of decomposition approaches/methods is now available to accommodate an arbitrary number of factors to be decomposed. Decomposition can be conducted multiplicatively or additively, on a chaining or nonchaining basis, and on a temporal or cross-sectional basis. Due to its simplicity and flexibility, the index decomposition analysis has been adopted in a wide range of application areas. The number of application studies has increased rapidly over time, particularly since the early 1990s, and interest among energy researchers in the methodology has been growing.

The previously mentioned developments were driven by the concern about world energy supply that began in the 1970s and were reinforced by concern about global warming and the need to reduce the growth or cut emissions of CO_2 and other greenhouse gases since the late 1980s. Because energy and the environment will remain important global issues and sustainable development will become increasingly more important in the following years, it is expected that index decomposition analysis will continue to play a useful role in providing information for policymakers to address energy, environmental, and resource depletion problems that mankind will continue to face.

Glossary

backstop A substitute supply that is expected to become active when current supplies are exhausted. This is taken as a "renewable" supply available indefinitely at a constant unit cost. The "price of the backstop" would be this "high" unit cost. Commercially viable fusion reactors have been taken as the backstop energy source.

hotelling rent The rent per unit extracted that exists because of the finiteness (exhaustibility) of the stock being extracted from.

marginal cost of extraction Given an equilibrium, the cost of extracting one more unit

Nordhaus (Herfindahl) model A linked sequence of "Hotelling models," each with a higher unit cost of extraction. The demand schedule is unchanging in the Herfindahl version.

rent The positive gap between market price per unit and marginal cost for supplying an additional unit.

Ricardian rent The rent per unit that exists because of a quality advantage of the unit in question.

royalty A payment to the owner of a deposit by the extractor, who in effect is renting or borrowing the deposit.

In the early years of the 21st century, industrialized nations exist in a world of cheap energy. Direct outlays by households for electricity, household heating, and fuel for transportation occupy small fractions of almost all family budgets. Canada and the United States, with 5% of the world's population, consume 25% of global energy. In per capita terms, the United States consumes 354 million Btu/year, Western Europe consumes 170 million Btu/year, and India consumes 12 million Btu/year. A Btu is the amount of heat required to raise the temperature of 1 lb of water 1°F. Energy use in North America grew 31% between 1972 and 1997. Is an era of high energy costs just around the corner? Is there a signal of a higher priced era to be read out there today? In the period following oil price hikes in 1973–1974, the U.S. Department of Energy predicted $150 a barrel for oil in the year 2000 in year 2000 prices. Exxon predicted a price of $100. What has abundant energy accomplished for us? Since approximately 1800, the four most revolutionary changes in a person's life in industrialized countries are (1) the substitution of machine power for animal and manpower, (2) the more than doubling of life expectancy, (3) the arrival of relatively low-cost transportation for persons and commodities, and (4) the arrival of global and low-cost communication. Clearly (1) and (3) are outcomes of new forms of energy use. The dramatic increase in longevity is probably mostly a consequence of improvements in the processing of water, food, and wastes—that is, improvements in the public health milieu, broadly conceived rather than a result of low-cost power, directly. But the impact of reduced demands on humans and animals for power on a person's life expectancy should not be dismissed. Improved, low-cost communication is related to the arrival of electricity and electronics, not power per se. The words labor, from Latin, and work, from Greek, both capture the idea of an expenditure of painful physical or mental effort, of energy expenditure. People who do no labor or work then are those expending little energy. Revolutionary in human history is the substitution of machine power for human and animal power. Hoists (pulleys) and levers

 © 2004 Elsevier Inc. All rights reserved.

were early simple machines that magnified human and animal power considerably. Watermills and windmills arrived and showed what could be accomplished with new energy sources captured by machines and new types of power output—namely, steady and continuous rather than episodic. But it was the arrival of steam engines (heat machines) that revolutionized the concept of usable power. The concept of transporting goods and people changed dramatically and powering a factory was freed from ties to watermills and windmills.

1. DEPLETION PRESSURE

It is easy to make the case that depletion pressures induced invention and innovation in energy use. Since at least the time of Great Britain's Elizabeth I, say 1600, conservation of forests for future fuel and timber supply was prominent on the public agenda. In the early 1700s, English iron production was using up approximately 1100 km^2 of forest annually. The notion that forest depletion drove the development of British coal fields is a popular one. But causality is tricky here — did the arrival of cheap coal lead to a liquidation of remaining forests or did the depletion of forests induce innovation in coal supply? This really has no ready answer. Fuel scarcity apparently led to the importation of iron by England in the mid-18th century. Around 1775, coal became viable in smelting iron and England's importing ceased. Coinciding with the coalification of the British economy was the development of the steam engine, first as a water pump and later as a source of power in factories, such as cotton mills. Jevons (1865, p. 113) opined that "there can be no doubt that an urgent need was felt at the beginning of the 17th century for a more powerful means of draining mines." Savery's steam pump was operating in 1698 and Smeaton made Newcomen's engine, with a piston, sufficiently efficient to be commercially viable. In 1775, the new steam engine of James Watt was developed.

Given the documented concern in Great Britain about timber supply, say, before 1700, one should observe a rise in the price of wood for fuel, house-building, and ship-building at some point. The year 1700 seems like a reasonable year to select as having recorded an increase in wood price. Firewood prices grew three times faster than the general price level in England between 1500 and 1630 and the 17th century was one of "energy crisis." Over one-half of the total tonnage entering British ports in the 1750s was timber, and fir imports grew 700% from 1752 to 1792. France also experienced rapid increases in fuel wood prices over this latter period. The prevailing "high" price in 1700 should, of course, spur the search for substitute energy sources. Importation is one form of substitution and coal development would be another. Given flooding problems with new coal deposits, an investment in reasonable-quality pumps was a low-risk strategy. The deposits were known to exist and the demand for coal seemed certain. The Saverys and Newcomens rose to the occasion. This is a possible explanation for the invention and introduction of steam pumps after 1700. It shifts the emphasis from spontaneous invention to profit-driven invention and innovation. A wood supply crisis is the ultimate impetus in this scenario. Current or anticipated fuel scarcity raises fuel costs and induces a search for substitutes. Coal is the obvious substitute but mine-draining looms up as a serious constraint on coal production—hence, the pressure to invent and to make use of steam pumps. Cheap coal transformed the British economy. In 1969, Landes estimated coal consumption in Great Britain at 11 million tons in 1800, 22 million tons in 1830, and 100 million tons in 1870. The British appear to have been sensitive to energy use over the long run. The Domesday Book, published in 1086, records over 5000 water-wheels in use in England—one mill for every 50 households.

Attractive in this scenario is the low-risk nature of investment in pumping activity. The coal was there, the demand was there, and one simply had to keep the water level in the mines low. Recall that a Newcomen engine was part of a multistory structure and thus represented a serious outlay. However, the technology had been proven in small-scale engines and the minerals were there for the taking. The second watershed moment in the history of steam power, associated with James Watt, was its development for powering whole factories. It can be argued that it was the depletion of good watermill sites, well documented for the Birmingham region by Pelham in 1963, that spurred invention. Richard Arkwright's invention of the cotton-spinning machine and mill and James Watt's invention of the improved steam engine compete in the literature on the industrial revolution for the label, "the key events." Spinning mills required a power source and water-wheels were the standard at the time. But convenient sites for water-wheels had mostly been taken up by the 1770s. The price of those sites would have exhibited a significant rise in, say, 1775, the year Watt was

granted his special patent for his engine with a separate condenser, an engine vastly more efficient than the Newcomen type. The climate was right for invention in the power supply field. Depletion of good water-wheel sites drove up their prices and the resulting umbrella of profitability made invention in this area attractive. At approximately this time, serious research of water-wheels was undertaken by Smeaton with a view, of course, to obtain more power from the waterflow. Obviously, a profit-driven view of events is not the only plausible one, but there is no doubt that profits accrued to Watt and his partner, Boulton.

Coal and oil compete as bulk fuels in many parts of the world for powering electricity-generating plants but steam engines for motive power have been displaced by gasoline, diesel, and electric engines in most areas of the world. Steam locomotives were common in industrialized countries as late as the 1950s. This is the classic case of a low-cost, clean energy source (e.g., a diesel engine for a locomotive) being substituted for a dirtier and, presumably, higher cost source. The conspicuous aspect of energy use is the capital goods that come with the energy flow. For example, wind is the energy source and the mill transforms the energy flow into usable power in, for example, grinding wheat. Similarly, the rushing stream is the energy source and the wheel and mount are the capital goods that allow for the production of usable power. What Savery, Newcomen, Watt, and others did was to invent a capital good that turned a heat flow into usable power. The role of the inventor is to envisage a capital good, a machine, that allows for the transformation of an energy flow into a power flow. From this perspective, it is difficult to conceive of an energy supply crisis. One looks forward to larger and better machines harnessing old energy flows better and new flows well. An oil supply crisis in the early years of the 21st century would translate into a transportation cost crisis but not an end-of-civilization crisis. Approximately one-fifth of electricity in the United States was generated with petroleum in 1970. In 2002, that figure is one one-hundredth. Coal burning produces approximately one-third more carbon dioxide than oil burning and approximately twice as much as the burning of natural gas, per unit of heat. Transportation fuel can be synthesized from coal and methane, but only at relatively high costs, given today's technology. The Germans used the Fischer-Tropsch process to produce gasoline from coal during World War II and the search for a catalyst to produce gasoline from methane is under way.

The appropriate aggregate production function to consider for an economy takes the form of output flow, $Q = F[N, K, E(K^E, R)]$, where $E(\cdot)$ is power derived from an energy flow R, say, oil, and capital equipment, K^E, K is other capital, and N is labor services. Before 1800, K^E was windmills and water-wheels for the most part and R was wind and water flow. In the 21st century, food is cooked in and on electric stoves rather than in hearths, light is provided by electric units rather than candles or lanterns, and heat is provided by furnaces and distribution devices rather than by fires, fireplaces, and stoves. $E(K^E, R)$ is dramatically different even though basic houses are similar in concept and shape and eating styles and habits are not hugely different. What would the world be like with steam power but no electricity? There was an interval of approximately 75 years during which this state existed. Steam power was decisive in liberating people from much heavy labor. Steam power could drive hoists, diggers, and pumps. It could also power tractors, locomotives, and even automobiles. Factories could be well mechanized with steam engines. In 1969, Landes suggested that the 4 million hp of installed steam engines in Britain in 1870 was equivalent to 80 million men, allowing for rest, or 12 million horses. A worker with steam power was like a boss with, say, 16 healthy workers at his bidding. In 1994, Smil estimated that a worker can put out 800 kJ net per hour. From this, he inferred that the Roman empire's 85,000 km of trunk roads required 20,000 workers, full time, working 600 years for construction and maintenance. The gain in bulk power production from the use of electric motors rather than steam motors seems marginal when history is viewed on a large time-scale. Electricity rather created new activities such as listening to the radio, watching television, and talking on the telephone. These are large gains in the range of consumer goods, essentially new attractive commodities, but they are on a different order from innovations relieving humans of great and steady physical exertion. Electric stoves and washers have undeniably made housework easier, and air-conditioning (room cooling) has the lessened the discomfort of labor for many as well as altered the geographical distribution of settlement.

With regard to personal travel, steam power might have been revolutionary enough. Steamships were quite different from sailing ships and trains were quite different from stagecoaches. Steam-powered automobiles and trucks are technically feasible. The internal combustion engine, drawing on gasoline and

diesel fuel, is not a crucial technology, though steam power for vehicles was quickly displaced. Steam power revolutionized the concept of daily work and of personal travel. Huge numbers of people ceased to be beasts of burden. Huge numbers of people were able to visit relatively distant places quite rapidly. Diets changed significantly when new foods could be transported from distant growing places. Crucial to modernization, however, was the substitution of machine power for human and animal power, which steam engines effected, and the spread of reasonable living standards to low-income families. Steam power brought about this latter effect only indirectly, by making mass production techniques widespread. Mechanization brought down the prices of many goods (e.g., cotton) but displaced workers in the handicraft, labor-intensive sectors. Wages rose in Great Britain some 50 years after the industrial revolution was well rooted. Machine-intensive production relieves workers of much grinding physical exertion but usually eliminates many traditional jobs as well. A large virtue of market-oriented (capitalistic) development is that entrepreneurs create and often invent new jobs for the workers displaced by mechanization. Wages and living standards have risen, particularly with a decline in family size.

2. DEPLETION ECONOMICS

Though in 1914 Gray first formalized the idea that impending natural stock (say, oil) scarcity would show up in current price as a rent, a "surplus" above extraction cost, Hotelling presented the idea most clearly in 1931. A royalty charged by an owner of a deposit to a user of the deposit is, in fact, "Hotelling rent." Thus, the idea of "depletion" being a component of current mineral price is ancient. Competing, however, with the Gray–Hotelling theory is a theory that has current oil price rising up the market demand schedule because each subsequent ton is becoming more expensive to extract. Deeper is more costly. This approach was adopted by the great W. S. Jevons in his monograph on coal use in Great Britain: "…the growing difficulties of management and extraction of coal in a very deep mine must greatly enhance its price. It is by this rise of price that gradual exhaustion will be manifested …" (Jevons, 1865, p. 8) Jevons' son, also a professor of economics, reflected on his father's work, pointing out that the price of coal had indeed risen over the 50 years since his father's book was written, by, however, just 12% relative to an index of prices. And reflecting on his father's analogy of high energy prices being like a tax, Jevons recommended accumulating alternative forms of capital to compensate future generations for their shrunken coal capital. A standard modern view has the current rent in oil price, a reflection of the profit or rent derivable from currently discovered new deposits. Hotelling theory sees current oil price as a reflection of (1) how long current stocks will carry society until users are forced to switch to substitute sources and (2) what price those substitute sources will "come in at." It was then the value of remaining stocks that held current price up, rather than pressure from currently steadily worsening qualities. As Nordhaus has made clear, in Hotelling's theory of depletion or "resource rent," current price turns crucially on the cost of supply from the future substitute source (the backstop) and on the interval that current stock will continue to provide for demand. See Fig. 1 for an illustration of Hotelling theory.

r is the interest rate in the market and Hotelling's approach is often referred to as the r percent theory of resource rent because profit-maximizing extraction by competitive suppliers implies that rent rises over time at r percent. Hence, the quantity sequence in an equilibrium extraction program is the one displaying rent rising at r percent per period. Current rent (price minus current unit extraction cost) turns out to be simply discounted terminal rent, with this latter term being defined by the unit cost of energy from the backstop or substitute source. To say that the price of oil is high today could mean that remaining stock is not abundant and substitutes will

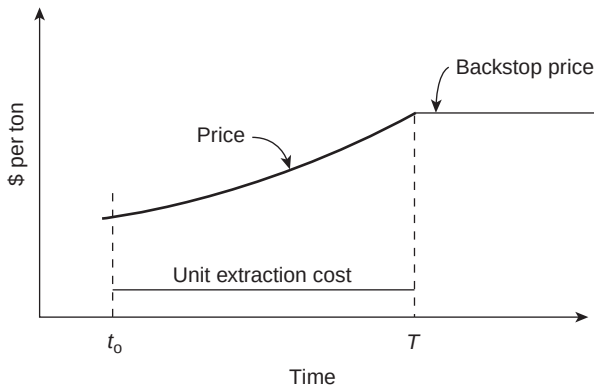

FIGURE 1 Hotelling model. In this competitive case, rent (price less unit extraction cost) rises r% until the stock is exhausted, at date T. Price "fed into" a market demand schedule yields current quantity supplied at each date. Unit cost, backstop price, stock size, and the demand schedule are parameters. Interval (t_0, T) is endogenous.

be available at high prices (Hotelling theory) or that future supplies will come from lower quality, high-cost deposits (Jevons theory). These two theories have been brought together in one model in a simple version by Herfindahl (see Fig. 2) and in a more complicated version in 1977 by Levhari and Leviatan and many others. The Herfindahl version has scarcity or depletion rent rising at r percent and, although unit extraction costs are constant, then jumping down as the next deposit or source is switched to. For the case of many deposits, Fig. 2 depicts a combination of intervals with rising rent linked by jumps down in rent. Quality decline causes rent to jump down. The Hotelling or depletion effect moves counter to the quality-decline effect. Thus, even in this simple world of no uncertainty or oligopoly in supply, one cannot be accurate in saying that exhaustibility is showing up in current price movement as an increasing rent or depletion effect (Fig. 2).

Hotelling provided a systematic theory of how depletion would show up in current price and how finiteness of the stock would show up in the pace of stock drawdown. In the simplest terms, exhaustibility is represented by a wedge between current unit cost and price. Thus, if world oil stocks were dwindling rapidly, one would expect oil prices to be high, well above unit extraction costs. And in fact, episodes of high world oil prices have been observed in recent decades, times when average world oil prices were well above unit extraction costs. Such wedges are labeled "rents" in standard economics and, with something like oil, the wedge might be referred to as scarcity rent or Hotelling rent. The world demand schedule does not shift in these episodes but current extracted output does shift back

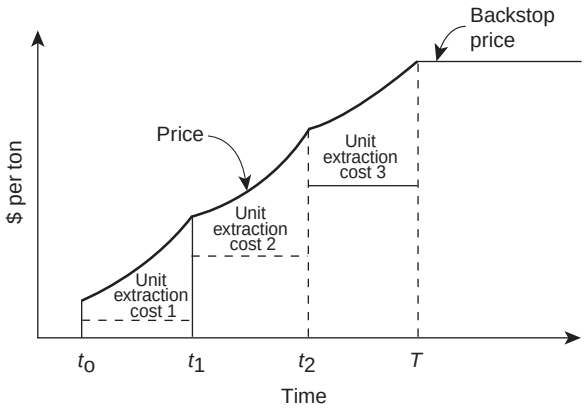

FIGURE 2 Nordhaus (Herfindahl) model. A three-source, linked Hotelling model. Low-cost supplies are exhausted first. Rent rises r% except at source switch. Rent jumps down across source switch. Intervals of source use are endogenous.

for some reason. It is these fairly sudden contractions in current production that cause current prices to jump up and "create" extra rent. The first large jump was in the fall of 1973. Another occurred in 1979, with the collapse of the Palhevi monarchy in Iran, and a large drop in price occurred over mid-1985 to mid-1986. Here the argument is that discipline among a cartel of oil suppliers broke down and world supply increased fairly quickly.

Price changes are largely driven by changes in current production flow or supply and current production is a complicated function of parameters, including estimated remaining stock or cumulative supply. Hotelling theory is an intertemporal theory of discounted profit maximization by competitive producers that links current production to remaining stock, extraction costs, demand conditions, and backstop price. It makes precise the exhaustibility effect or depletion in current resource price. Hotelling theory obtains a "depletion effect" in current price relatively simply in part because it makes use of the traditional assumption of perfect foresight by profit-maximizing agents. Economic theory relies on this assumption because it becomes an essential component of intertemporal profit maximization. The real world is, of course, replete with events that are very difficult to anticipate, such as wars, government regime switches, and technical changes. For example, research suggests that oil may be generated deep in the earth by unexpected geothermal processes. Uncertainty makes simple calculation of a depletion effect in current price a dubious course.

In its original form, Hotelling theory abstracted from uncertainty completely. And Hotelling did not take up quality variation in current deposits or stocks. This has, fact, led many observers to argue that Hotelling theory is fundamentally flawed as an explanation of rent or price paths for, say, oil. Also, Hotelling did not address oligopoly in supply and such market structures have been considered to be crucial in explaining oil price movements in recent decades. In the face of those well-known difficulties in arriving at a theory of oil price determination, in 1985 Miller and Upton tested "Hotelling's valuation principle" for a sample of oil-producing companies whose shares were being traded on the New York Stock Exchange. Employing heroic simplifying assumptions, they derived an equation to estimate in a sequence of straightforward steps and fitted their equation to the data, with positive results. It seems undeniable that extraction to maximize discounted profit is the reasonable maintained hypothesis and in a sense Miller and Upton confirm this position. But

profit maximization by an extractive firm in an oligopoly setting, for instance, yields a quite different extraction program than that for a firm in a competitive setting. Miller and Upton provide weak evidence in favor of competitive extractive behavior by oil extraction companies. Implicit in their work is an argument that Hotelling rent is positive and present in the price of oil. However, the plausible "crowding" of such rent by stock quality decline cannot be evaluated from their analysis. In 1990, Adelman argued that current oil rent reflects the marginal cost of discovering new supply and most rent earned by producers is a Ricardian rent, one attributable to a quality advantage possessed by current suppliers lucky enough to be currently working a low-cost deposit.

Consider the reality of a backstop source of energy. Suppose the world does have a 20-year supply of "cheap" oil available, as Deffeyes suggested in 2001. (The Edison Electric Institute estimates that proven reserves of oil will last 37 years, those of natural gas will last 61 years, and those of coal will last 211 years.) In 2001, Kaufmann and Cleveland presented a careful, empirically based critique of Hubbert's bell-shaped supply schedule. Why is a foreseeable energy supply crisis not showing up in markets today? The answer appears to be that backstop supplies are fairly abundant, in the form of large deposits of coal, natural gas, tar sands oil, shale oil, and uranium. None of these supplies is as attractive and as low-cost as oil but it would not be complicated to power a modern economy with a combination of these energy feedstocks. Directly difficult would be fuel for transportation, given current engine technology and driving habits. Whatever transpires with long-term oil supplies, the era of low-cost individualistic transportation will likely end. The century 1920–2020 may well go down in history as the curious low-cost, automobile period, an era of individuals dashing about the surface of continents in big cocoons of steel on expensive roadways, while seriously polluting the atmosphere.

In 1974, Nordhaus brought his combination of Hotelling and backstop economics together in an ingenious empirical exercise. Given a backstop supply price and a sequence of world demands for energy into the distant future, and given world stocks of oil, coal, and uranium and unit extraction costs, he let his computer solve for the Hotelling transition path from his base period, 1973, to the era of constant cost fusion power. Naturally, stocks with lower unit extraction costs provide energy early on. See Fig. 2. Thus, one observes an oil supply era of endogenous length, a coal era, a uranium era, and then the fusion power era with constant unit cost into the indefinite future. A critic can easily dismiss this investigation as computer-aided, crystal-ball gazing. However, the Nordhaus model was subjected to sensitivity testing at low cost, and the empirical output appeared to be fairly robust. Central to this is, of course, discounting. Events beyond 30 years register little today, given discounting. Hence, fusion power costs largely fade out in the current price of energy, as do many other parameters of the model. It remains, nonetheless, a very good framework for organizing one's thinking about the future of energy. When the oil runs out, modern life does not end, just the curious era of abundant, low-cost energy, especially for personal transportation.

Nordhaus's "simulation" yielded a current price (1973) of energy somewhat below the observed market price. He inferred that this occurred because his model was "competitive," *a priori*, whereas the real world contained much oligopoly in energy production—hence, an obvious need to refine the computer formulation. However, the introduction of oligopoly to extraction models is tricky, if only for reasons of incorporating the dynamic consistency of agents' strategies. There must be no obvious possibilities for profit-taking simply by reneging on one's "original" strategy selected at time zero. To rule out such possibilities for profits, problems must be analyzed and solved backward, from tail to head, and this turns out to be much more complicated than, for example, Nordhaus's essentially competitive formulation. There is an important lesson here. If one believes that current energy prices reflect noncompetitive behavior among suppliers, which seems most reasonable, then quantifying such capitalizations is known to be difficult. One can rule out simple explanations for current energy price levels. The combination of Hotelling theory and backstop theory indicates that traditional supply and demand analysis is an inadequate way to think about current energy price formation. The addition of oligopoly considerations complicates an already complicated process of current price determination.

In the simplest case of current price shift, as for, say, October 1973, suppliers revise estimates of remaining stock downward and current price jumps up. "Mediating" this price shift is a process of agents discounting back from "the terminal date" to the present, discounting along a Hotelling extraction path. Current quantity extracted jumps down and current price jumps up. If demand is inelastic in the region, aggregate revenue will jump up. Thus, the

motivation to raise current price could be for reasons of revenue. With some coordination of quantities in, say, a cartel, the current price jump may be an oligopoly or cartel phenomenon rather than an outcome of stock size revision. Somewhat analogous is a revision by suppliers of the anticipated backstop supply price. A revision of expectations upward would lead to a current price jump upward and vice versa. A price drop occurred briefly when University of Utah researchers announced "cold fusion." And the popular interpretation of the large drop in world oil prices during 1985–1986 is that cartel discipline broke down Organization of Petroleum Exporting Countries (OPEC) and key members raised their outputs above their quota levels.

It is undeniable that the current interaction of the world supply curve for oil and the world demand curve yield the current price. At issue is how depletion rent and oligopoly rent are capitalized in the current costs of production, costs that determine the characteristics of the effective supply schedule. In the mid-1970s, reasonable observers debated whether the 1973 jump in world oil price was the result of production restraint by OPEC, an oligopoly effect, or a reckoning that future oil stocks would be rather smaller than had been anticipated. In any case, current production was cut back and world prices leapt up. A popular view of the poor performance of the U.S. economy in the later 1970s was that it had to accommodate unanticipated supply-side shocks in the energy sector. The notion of cost-push inflation became popular and an extensive literature emerged on this issue.

Since impending exhaustibility is predicted to manifest itself in currently high price, which is reflecting a large scarcity rent, a standard view is that the current and anticipated high prices should induce a search for substitute supply. How tight is this link between, say, rising current oil price and a spurt of invention to develop an alternative supply? It was argued above that this link is relevant for explaining two of the most significant events in human history—the effect of timber scarcity in Great Britain on the timing and intensity of the invention of mine-draining machinery (the steam engine) and the effect of watermill site scarcity on the timing and intensity of invention in steam engine efficiency (Watt's separate condenser). It may be the anticipated high price rather than the current actual high price per se that induces inventors to perform, to come up with substitute supply. Simply anticipating that, say, oil will be exhausted soon while current price is not yet high may be sufficient to get invention going. Inventors can have foresight. They need a process or invention that brings in a competitive supply of energy when the oil runs out. In 2003, Mann argued that recent low oil prices have slowed innovation in the alternative energy sector.

Interesting models in which the substitute supply is, in fact, invented or perfected today in the public sector in order to force current oil suppliers to lower current prices have been developed. The invention is annouced and mothballed until the oil is exhausted. In such a scenario, it is not high prices today that speed up invention, rather it is the anticipation of the high prices in the future that induces inventors to perfect the substitute today.

3. THE SCARCITY OF CLEAN ENERGY SUPPLIES

Attention has shifted from energy sources with low cost, per se, to sources that can provide energy cleanly, at low costs. Smog in Los Angeles seems to have spurred policymakers to move toward designs for a future with cleaner air and with low-emission vehicles, homes, and factories. Eighty-five percent of world energy supply is currently derived from fossil fuels and 1% is renewable (excluding hydropower). The recent DICE model of global warming of Nordhaus and Boyer has unlimited energy produced at constant unit extraction cost from hydrocarbons but energy production contributes directly to an atmospheric temperature increase, via carbon dioxide emissions. The temperature increase shows up in explicit current economic damage. This is a large departure from the Hotelling view because Nordhaus and Boyer have no stock size limitation for, say, oil. Price, inclusive of an atmospheric degradation charge (a Pigovian tax on energy use), rises along the industry demand schedules because, essentially, of the increasing scarcity of moderate atmospheric temperatures. It is "moderate temperature" that is being "depleted" in this view and a "depletion charge" in the form of a marginal damage term (a carbon tax) is required for full cost pricing of energy. A world without carbon taxes is, of course, one of "low" energy prices, one in which the atmosphere is a carbon sink, with carbon dioxide dumped in at zero charge. User fees for dumping? "If U.S. consumers pay $1 billion a year, would that be enough to cover the problem? How about $10 billion? The level of economic damage that might be inflicted by greenhouse gas abatement is so

uncertain that even the Kyoto treaty on global warming … says not a word about what the "right" level of emissions should be." (Mann, 2002, p. 38) In 2002, Sarmiento and Gruber reported that atmospheric carbon dioxide levels have increased by more than 30% since the industrial revolution (the mid-18th century).

A formal statement of the world energy industry along Nordhaus–Boyer lines looks much like the Hotelling variant of Levhari and Leviatan amended to incorporate a continuous quality decline of the oil stock. Aggregate benefits (the area under the industry demand schedule) from current energy use, q, are $B(q)$. Temperature interval, T, above "normal," increases with q in $dT/dt = \alpha q$. Energy users (everyone) suffer current economic damage, $D(T)$. Thus, the only way to stop the full cost price of energy from rising is to switch to a source that does not drive up global temperatures. Here, the current price is $[dB(q)]/(dt)$ and the carbon tax in price is the discounted sum of marginal damages from temperature increments. (A constant unit extraction cost changes the formulation very little.) This price needs the right Pigovian tax on carbon emissions, a dumping fee, to be the full market price for energy.

Will the current, dirty, energy-generating technologies be invented around? Would they be invented around if current energy prices were higher? Mann thinks so. How abundant will fuel cells, solar generation installations, "pebble bed" nuclear reactors, windmill farms, synthetic fuels, and more sophisticated electric power transmission grids be 20 years from now? Are carbon taxes and attendant high current energy prices the best prescription for a cleaner energy future? Many policymakers have not espoused this approach, particularly in the United States and Canada.

4. SUMMARY

Depletion theory is the attempt to explain price formation for commodities such as oil, those with current flows being drawn from finite stocks. Price rises above unit extraction cost because of a depletion effect and one analyzes the nature of this effect in order to try to predict future price paths. Until recently, attention was focused on how the progressive scarcity of an oil stock was translating into the current high price for oil in use. In the past decade, attention has shifted from how the limitation on future supply is showing up in, say, oil price to how the effects of pollution from fossil fuel burning should be incorporated into current price. The depletion effect on the clean environment becomes a component (a pollution tax) in current full price. The hope is that full pricing of energy will signal to users how best to use energy currently and will signal to suppliers the potential profitability of innovating in the energy supply process.

Glossary

derivative The term used in finance to describe a financial product with value dependent on the value of another instrument, commodity, or product.

forward Forward contract is a transaction that provides for delivery of the underlying commodity at a future date, at the price determined at the inception of the contract, with cash being paid at or after an agreed number of days following the delivery.

NYMEX Commodity exchange located in New York City, offers a number of listed energy contracts.

option A contract that gives the holder the right, but not the obligation, to buy (sell) a financial instrument or commodity (the underlying) at a predetermined price (a strike or exercise price) by or on certain day.

real options In the energy markets, flexibilities or rigidities embedded in bilateral transactions or physical assets that can be valued using option pricing technology developed for the financial markets instruments.

swap An exchange of streams of cash flows over time between two counterparties. The level of the cash flows depends on prices of financial instruments or commodities referenced in the swap agreement. In a typical commodity swap, one side pays a fixed price; the second side pays a floating (varying) price that corresponds to the market price of the underlying commodity.

volatility The most important input to the option pricing models. Volatility is typically defined as the annualized standard deviation of price returns.

A derivative is a financial instrument with a value based on, or derived from, the value of another stock, bond, or a commodity (the underlying). In the case of energy derivatives, the underlying is an energy commodity, energy-related derivative or a physical asset used to produce or distribute energy.

1. CLASSIFICATION OF ENERGY DERIVATIVES

Energy derivatives can be classified based on (1) the contract definition specifying the rules by which the instrument derives its value from the price of another traded instrument, (2) the market or platform on which they are traded, or (3) the underlying commodity or commodities. Most energy derivatives can be classified as forward (futures) contracts or options. Both types of instruments can be negotiated as physical contracts that require actual delivery of the underlying commodity as financial contracts that are cash settled, based on the prices of the underlying observed in the marketplace or published by an industry newsletter or a specialized business.

Energy derivatives are traded and valued as stand-alone contracts or may embedded in bilateral transactions and physical assets. Such options existed for a long time and only recently they have become a subject of rigorous analysis directed at their valuation and risk management of the exposures they create.

2. FORWARDS AND FUTURES

A forward contract is a bilateral transaction that provides for delivery of the underlying commodity at a future date, at the price determined at the inception of the contract, with cash being paid at or after an agreed number of days following the delivery. In many markets, the fair price of a forward contract

 © 2004 Elsevier Inc. All rights reserved.

can be derived from the spot commodity price, interest rate, and the storage cost, using the so-called arbitrage principle. Specifically, the forward price (F) is equal to the spot price (S) adjusted for the financing and storage cost (r – annualized interest rate, s – unit storage cost), or $F = S^*(1 + r + s)^{(T-t)}$ where $T-t$ represents the life of the contract (t is today's date, T is the delivery date, and both are measured in years). The logic behind this equation is based on the arbitrage argument that defines the upper and lower bounds on the forward price; one can prove that both bounds are equal giving the unique forward price. The buyer of the forward contract can lock in the economic outcome of the transaction by borrowing funds at rate r, buying the commodity at spot (S) and storing the commodity and taking a short position in the forward contract (selling). At contract expiration, the transaction is reversed: the commodity is delivered into the forward contract at price F and the financing and storage costs are recovered. The arbitrageurs will engage in such transactions, as long as $F > S^*(1 + r + s)^{(T-t)}$. Alternatively, the lower bound can be established by recognizing that one can borrow the commodity, sell it in the spot market, and invest the funds at rate r, taking a long position in the forward contract. This argument breaks down often in the case of commodity-related forward contracts for two reasons. Some energy commodities may be unstorable (like electricity) or the supply of storage may be limited at times. In some cases, the existing market framework does not allow for shorting of the underlying physical commodity, eliminating one of the arbitrage bounds.

Given that both the storage cost and interest rate are positive, the arbitrage argument implies that the forward price is always greater than the spot price and that the forward price curve (a collection of forward prices for different contract horizons) is an increasing function of time to expiration (the curve is always in contango). In reality, forward price curves for many commodities, including natural gas and crude, are often backwardated (the forward prices in front of the curve exceed the prices in the back). This arises from the fact that for many market participants holding physical commodity has a higher value than controlling a forward contract. The stream of benefits that accrue to the owner of physical commodity is called a convenience yield. Assuming that the convenience yield can be stated per unit of commodity, δ, the full cost-of-carry formula for an energy forward contract is given by the following equation:

$$F = S^*(1 + r + s - \delta)^{(T-t)}.$$

Futures are forward contracts traded on an organized exchange that provides credit guarantees of counterparty performance, provides trading infrastructure (typically an open outcry system or screen trading), and provides the definition of a standardized contract. Credit protection is provided by margining and by the capital contributed by the exchange members and ultimately their credit. At inception, each counterparty posts the so-called initial margin that is followed by the so-called maintenance margin deposited if the original margin is eroded by losses on the contract. The practice of marking to market the contract and providing (receiving) additional margin is the most important difference between the futures and forward contracts. The most important exchanges offering energy contracts (crude, natural gas, heating oil, gasoline, and electricity) are the New York Mercantile Exchange (NYMEX), International Petroleum Exchange (IPE) in London, Nordpool in Norway. The Intercontinental Exchange offers many energy-related contracts but should be treated more as a trading platform, not as an organized exchange.

Under some fairly restrictive conditions, the futures and forwards have the same value. Potential differences arise from the practice of margining the contract that results in stochastic financing cost (one has to borrow/invest the funds paid/received) and from the differences in default risk. An organized exchange offers more layers of credit protection than bilateral arrangements. In practice, the differences between futures and forwards have been found to be rather small in most empirical studies. The energy industry typically ignores this distinction in routine transactions.

The distinction between the forward and futures contracts has become more ambiguous in many markets. The practice of requiring and posting periodically collateral to provide guarantee of performance under a bilateral forward contract, which has become a standard practice in the United States and many other countries, has obliterated one major difference between forwards and futures. Classical forwards, unlike futures, did not trigger cash flows before contract maturity.

3. ENERGY COMMODITY SWAPS

Swaps can be looked at as a basket of forwards that has to be executed as one contract (no cherry picking is allowed). In the general sense, a swap is the exchange of two streams of cash flows: one of them is based on a fixed (predetermined) price and the

second on a floating (variable) price. At inception, the fixed price is determined by finding the fixed price that makes the fixed and floating legs of the swap equal. The fixed leg is equal to the sum of the periodically exchanged volumes of the underlying commodity multiplied by the fixed price, discounted back to the starting date. The floating leg is equal to the sum of the volumes multiplied by the floating price, discounted back to the starting date. The floating price is obtained from the forward price curve, a collection of forward prices for contracts with different maturities. In other words, the fixed price of the swap is derived from the following equality:

$$\sum_{t=1}^{n} \frac{F_f \times v_t}{(1+r_t)^t} = \sum_{t=1}^{n} \frac{F_t \times v_t}{(1+r_t)^t}, \qquad (1)$$

where F_f denotes the fixed price of the swap, F_t – the floating price, r the applicable discount rate, and v_t – periodic deliverable volumes.

In practice, a swap may be physical or financial. A sale of an energy commodity at a fixed price, with deliveries distributed over time, is referred to and priced as a swap. A swap may be a purely financial transaction, with one counterparty sending periodically to another the check for the fixed-floating price difference (multiplied by the underlying volume), with the direction of the cash flow dependent on the sign of the difference.

4. OPTIONS

An option is a contract that gives the holder the right, but not the obligation, to buy (sell) a financial instrument or commodity (the underlying) at a predetermined price (a strike or exercise price, usually denoted by K), by or on certain day. The option to buy is referred to as a call, the option to sell as a put. An option that can be exercised only at maturity is known as a European option, an option that can be exercised at any point during its entire lifetime is known as an American option. In the case of an energy-related option, the underlying is an energy commodity or another energy derivative (a forward, a swap, a futures contract, or even another option). Some popular energy options are defined in terms of a number of several different commodity prices (have multiple underlying commodities or instruments).

Most energy options traded in bilateral transactions have a forward contract as the underlying and this has important implications for the valuation procedures. Through the rest of this article, we are assuming that the underlying is a forward or a futures contract. Most options transacted in the energy markets are plain vanilla European calls and puts. Certain features of energy markets created the need for more specialized structures, addressing specialized needs of commercial hedgers, with complicated payoff definitions. Most popular options with complex payoff definitions and many practical applications are Asian and spread options.

Asian options are defined in terms of an average price. The payoff of an Asian option at maturity is defined as max (avg (F)-K, 0) for a call option and max (K-avg (F), 0) for a put option, where F stands for the forward price of the underlying and K for the strike price. The term avg (F) corresponds to the average price calculated over a predefined time window. The rationale for Asian options arises in most energy markets from the fear of price manipulation on or near option expiration date, given relatively low trading volumes and the relative ease to affect the price through targeted buying or selling. Averaging mitigates this risk, reducing the impact of any single day price on the option payoff. In many cases, the exposures facing commercial energy hedgers are defined in terms of average prices. For example, an electric utility buying natural gas as a fuel is exposed to an average cost over time, given its ability to pass on its average costs to the end users. Asian options tend to be cheaper than corresponding European options, as price averaging reduces price volatility, an important input to the option pricing models (discussed later).

Spread options are defined in terms of a price difference. The payoff of a call spread option is defined as max (F_1-F_2-K, 0) and the payoff of the put as max (K-F_1-F_2, 0). The price difference may correspond to the location spread (for example, the difference between Brent crude produced in the North Sea and West Texas Intermediate, WTI) or time difference (calendar spread between price of natural gas corresponding to December natural gas and July natural gas contracts with delivery at Henry Hub location in Louisiana). Quality spread corresponds to the price difference of different grades of the same commodity (for example, sweet and sour crude oil). The rationale for spread options arises from the exposures that many commercial operations face in the energy markets: exposures to price differentials as opposed to exposures to a single price level. A refinery is exposed to the spread between the composite price of the basket of refined products and the price of crude. A power plant is exposed to the

difference between price of electricity and the price of fuel. An oil company buying gasoline in Europe and shipping it to the United States faces combined location and calendar spread risks when the cargo is in transit.

The importance of price differential related exposures created specialized terminology describing different types of spreads. The difference between the price of heating oil and the price of crude is referred to as a heat spread; the difference between the price of gasoline and crude in referred to as the gas crack spread. The difference between natural gas prices at one of many trading hubs in the United States and the price at Henry Hub (the delivery point for the NYMEX natural gas futures contracts) is routinely referred to as *basis* in the U.S. natural gas markets (in more general sense, basis denotes price difference). The difference between price of electricity and the price of natural gas is known as the spark spread. In the case of the spark spread, the price of natural gas, denominated typically in $/MMBTU, has to be converted into $/MWh. This is accomplished in practice by multiplying natural gas price by the heat rate (MMBTU/MWh) that corresponds to the thermal efficiency of a specific (or notional) power plant (the energy input required to produce one MWh of electricity).

Spread options are used to value many transactions in the energy markets. One example is the contract for transmission, known as a firm or fixed transmission right (FTR). The FTR protects a provider of electricity against basis risk. This type of exposure happens when a supplier offers delivery at one point but owns generation at another point in a power pool. If no transmission capacity is available between these two points (i.e., congestion develops on the transmission grid), the prices at two locations may decouple and the supplier may be unable to deliver into his contractual obligation. The supplier would have to buy electricity at the point where his or her load is located, running the risk that he will incur a loss. To hedge against this risk he may buy FTRs offered by many power pools through special auctions. An FTR contract may be structured as a swap or an option. A swap pays the difference between the two locational prices and allows lock-in the economic outcome of the original power supply transaction, irrespective of the potential congestion. An FTR contract that is structured like an option may be priced as a spread option.

A special type of energy related option was invented to offer protection against combination of volumetric and price risks. Many energy producers and buyers (especially utilities and local distribution companies) are exposed to both uncertain prices and quantities. This risk is addressed through the so-called swing option that has a number of unique characteristics. It is typically structured as a forward start option: the strike price is set equal to the market price of the underlying on some future date. In the U.S. natural gas markets, this price is typically equal to the first of the month price for base load deliveries over the entire calendar month, published by one of the industry newsletters (like, for example, Inside FERC Natural Gas Market Report). Some swing options use a strike price that is fixed in a bilateral contract. The holder of the option is entitled to buy the commodity at the strike price n times over the defined period (typically one calendar month) within certain volumetric limits, referred to as a minimum and maximum daily quantity. The option definition may be complicated further by ratchets that allow the holder to reduce or increase the purchased volumes in certain increments. The contract may provide also for minimum and maximum takes over certain time periods (for example, months, quarters, and years) and for penalties if the periodic bounds are exceeded. The swing options are popular in the U.S. natural gas and electricity markets as a form of protection against a jump in prices combined with an increase in consumption requirements. Pricing such options is quite complicated due to the need to keep track of both types of optionality (with respect to price and volume).

Basket options are defined as contracts on a composite commodity like, for example, a package of natural gas and crude oil. The price of the underlying in this case is a (weighted) sum of prices of commodities included in the basket. Such options are typically used by producers who have exposure to multiple commodity prices and want to hedge the overall exposure, as the price fluctuations of the basket components may be mutually offsetting, providing a natural hedge. The value of a basket option, like the value of a spread option, is heavily influenced by the correlations between basket components.

5. MAIN ENERGY DERIVATIVES MARKETS

An alternative classification of energy derivatives is based on the market at which they are transacted. The most transparent and liquid markets are those

provided by the organized or electronic exchanges. An organized exchange may be based on the principle of open outcry or may be based on screen-based trading. The most important exchanges in the United States are the New York Mercantile Exchange (NYMEX) and the Intercontinental Exchange. The latter provides an electronic trading platform and other services such as netting and settlements (with London Clearing House and Merchant Exchange). NYMEX offers both futures and options on futures (options that have a futures contract as the underlying and are exercised into a futures contract that has to be taken into delivery or closed in a separate transaction). NYMEX trading is based on the principle of the open outcry but electronic trading is available as well for certain contracts or after regular trading hours. Table I provides the summary of the contract available on NYMEX (only contracts with significant volumes are listed, as opposed to all listed contracts that may have no significant activity).

Other exchanges important in the energy markets are International Petroleum Exchange of London (futures and options on futures for Brent oil and gas oil, futures contracts for natural gas), Powernext in Paris (day-ahead electricity contracts), European Energy Exchange (EEX) in Leipzig, Germany (electricity), and Nordpool in Scandinavia (electricity).

The exchange-based transactions are supplemented by the over-the-counter (OTC) market that provides the benefits of greater flexibility of contract design and allows for customization to fit exactly the needs of the buyer. OTC derivatives lack the credit support provided by an exchange and their pricing is more opaque, given that in many cases they can be quite complicated. The most important forms of the OTC energy contracts are swaps and options.

6. OPTIONS EMBEDDED IN BILATERAL CONTRACTS AND PHYSICAL ASSETS (REAL OPTIONS)

One very important class of energy related derivatives are options embedded in energy contracts. Unlike exchange traded and OTC derivatives, they are not traded as stand alone contracts but are packaged in bilateral contracts. They typically correspond to different flexibilities and rigidities embedded in the transactions that correspond to practical needs of doing business. In principle, every flexibility granted to, or accorded by, a counterparty in terms of quantity, delivery timing, and location or quality can be translated into an option, swaption, or another derivative. The challenge of pricing options embedded in the contracts is that one is dealing with many layers of interacting optionality, and it is often difficult to separate different options (they may not be additive) and price them individually using commercially available software. It is, however, important to price such options to avoid giving them away for free or at reduced prices and to manage the exposures they create over the life of the contract.

One example of a complicated bilateral contract that may extend over many years is so-called full requirements contract. Under this contract, the energy provider takes over the resources of the customer (for example, generation plants, storage, and contractual assets like transportation and transmission contracts of a municipal utility) and commits to satisfy all the energy needs of the buyer at an agreed price. Energy is delivered using the assets of the buyer, controlled and dispatched by the supplier over the duration of the contract, and the surplus (deficit) is sold (covered) in the market. Providers also have the option to shut down the generation assets they control in case

TABLE I

NYMEX Energy Futures

Contract	Size	Delivery point	Options	Settlement type
Natural gas	10,000 MMBTUs	Henry Hub, LA	Yes	Delivery, ADP, EFP
Light sweet crude oil	1000 barrels	Cushing, OK	Yes	Delivery, ADP, EFP
Heating oil	1000 barrels	New York Harbor	Yes	Delivery, ADP, EFP
Unleaded gasoline	1000 barrels	New York Harbor	Yes	Delivery, ADP, EFP
Brent oil	1000 barrels		Yes	Financial
Central Appalachian coal	1550 tons	Ohio River, Big Sandy River	No	Delivery, EFP
PJM electricity	40 MW on peak per day, 19 to 23 days a month		No	Financial

electricity may be acquired at a lower price from the market and sell in the market fuel purchased for the generation plants. In most cases, the provider assumes the volumetric risk associated with demand fluctuations (due to weather changes) and load growth due to economic and demographic changes, within certain predetermined bounds.

Derivatives embedded in physical assets such as power plants or natural gas storage facilities are the subject of the so-called real options, the term that describes the application of the technology developed for financial markets to the analysis of investment decisions. For example, a gas-fired natural gas power plant can be looked at as a strip of spark spread options. The underlying assumption is that the power plant is dispatched if the spark spread, as defined previously, exceeds variable marginal cost. This approach is very effective but should be used with caution. Valuation of a power plant with a life extending over many years requires many inputs for which market information is not directly available. For example, one has to provide information about forward price curves for natural gas and electricity for as many as 20 years, assumptions regarding price volatility and correlations between price returns for both commodities.

In many cases, there are no markets extending that far into the future, and this means that one has to substitute forecasts for what is supposed to be market derived inputs. A more serious shortcoming of this method is that a power plants operations are subject to many physical and regulatory constraints that are difficult to accommodate in the option pricing model. For example, one has to recognize constraints related to planned and forced outages, startup and shutdown costs, emission constraints that limit the total number of hours that a plant may operate in a year, and the restriction on the number of starts (due to provisions in maintenance and service contracts). Incorporation of such restrictions increases the dimensionality of the problem and greatly increases the computational resources required to come up with realistic valuation.

In spite of the shortcomings, the real options approach represents a much better alternative to the standard discounted cash flow approach, traditionally used in making investment decisions under uncertainty. The traditional discounted cash flow approach can only address uncertainty through comparisons of a limited number of scenarios that may not capture the entire range of possible future states of the world and may sometimes represent wishful thinking of the decision makers.

Other frequent uses of the real options technology are natural gas storage facilities and pipelines. A natural gas storage facility can be looked at as a portfolio of calendar spread options. A pipeline transportation contract can be valued as a portfolio of basis (locational spread) options.

The classification of options depending on the underlying commodity is quite straightforward. One possible classification is based on the physical commodity or commodities to which the option is related. One can talk about options on crude, natural gas, and so on. If the option is written on a specific energy-related instrument, the options are referred to as options on forward, futures, other options (compound options), and swaps (swaptions).

7. VALUATION OF ENERGY-RELATED OPTIONS

Valuation of energy-related options offers many challenges due to a number of complications in their definition and market behavior of the underlyings and is an area of very intensive research efforts in a number of academic centers and many energy companies. European options on forwards and futures are valued using the so-called Black formula that represents a version of the well known Black-Scholes formula for pricing options on stocks that don't pay dividends. The call price c is given by

$$c = e^{-r(T-t)}(FN(d_1) - KN(d_2)),$$

and the put p price is given by

$$p = e^{-r(T-t)}(KN(-d_2) - FN(-d_1)),$$

where

$$d_1 = \frac{\ln\left(\frac{F}{K}\right) + \frac{\sigma^2}{2}(T-t)}{\sigma\sqrt{T-t}},\ d_2 = d_1 - \sigma\sqrt{T-t}.$$

In these formulas, F stands for the forward price as of the time of valuation (t), K represents the strike price. The expiration date is given by T. Both t and T are measured in years (1 year is equal to 1, 1 month to 1/12, etc.) and therefore $T-t$ is equal to the remaining life of the option. The risk-free interest rate is given by r and the expression $\exp(-r(T-t))$ is a discount factor. The critical input to the formulas is σ, or the volatility coefficient. Volatility, unlike other inputs, is not directly observable and represents the most critical assumption in the option pricing process. In practice, it is based on the insights

obtained from historical estimates or is inferred from market prices of traded options. In the first case, volatility is estimated as the standard deviation of the logarithmic price returns (natural logs of the price ratios, defined as price P in period t divided by price P in period $t-1$). Volatility is quoted by convention as an annualized number. Annualization is accomplished by multiplying the standard deviation of price returns by the factor that depends on the price data frequency. In the case of monthly data, the factor is the square root of 12. In the case of weekly data, the annualization factor is the square root of 52. In the case of daily prices, one uses by convention the square root of 250 (or 260)—an approximate number of trading days in a year. In some energy markets, trading continues on Saturdays (Western power markets in the United States) or over the weekend. In such cases, one should use the appropriate number of trading days in a year.

For other energy options, there are typically no closed form valuation formulas and one must use different approximation formulas or numerical solutions. The most widely used approaches are Monte Carlo simulations and binomial (or more complicated) trees (see Table II). The Monte Carlo approach is based on repetitive simulations of price trajectories and calculating option payoffs at expiration. The payoffs are then averaged and discounted back to the current date. This approach is very flexible and allows for quick implementation. The shortcoming of this approach is that it requires significant computational resources and may be time intensive. It is more appropriate for path-dependent options (for example, Asian options) where the payoff depends not only on the terminal price but also on the trajectory along which this price was reached. In general, a Monte Carlo approach is not suitable for American options valuation; though some numerical techniques address this problem.

The binomial tree technique is well suited for pricing American options and may be described as a structured simulation. The technique is based on the assumption that a price at any point in time may evolve only into two other states (this explains the use of the term binomial), up or down from the starting level, with probabilities and the magnitudes

of changes can be calibrated from the standard option pricing assumptions (including the volatility assumption). Specifically, probability of the up move is given by

$$p = \frac{1-d}{u-d},$$

and the probability of the down move is given by $q = 1-p$. The price level in the up move is given by uF, where F is the price level and the u multiplier is given by $u = e^{\sigma\sqrt{\Delta t}}$. The down move price level is given by dF, where d is given by $d = 1/u$. The term Δt corresponds to the length of the time step and is chosen by the modeler depending on the computation time and required precision requirements. The time step determines how dense is the tree (how many nodes it has for a given contract duration). Parameters u, d, and p allow for constructing the tree describing possible evolution of the price from the current level till maturity. Options can be priced through the process of backward induction by calculating the payoff of the option at terminal nodes (it is either zero or a difference between the terminal price and the strike price) and moving back in tree. At each node, (t, i), where t corresponds to the time step, i to the node level counted from the bottom of the tree, the value of the option is given by the comparison of the payoff of the option if it is immediately exercised with the expected value one obtains from keeping the option alive. This expected value is equal to the probability weighted values at two nodes connecting to the given node at time $t+1$, discounted back over the length of one time step.

The example that follows shows a tree developed for a put option with a life of 5 months using five time steps. This means that the length of one time step is 1/12 or 0.08333. The starting price is 50, the strike price K is 50, and the volatility is assumed to be 0.4 or 40%. The probability p of the up move at each node is equal to 0.471165. The risk free interest rate is 10% and this translates into a 1-month discount factor of 0.991701. For example, the value of the option at the node (3, 2), where the price level is equal to 44.554736, is equal to 6.743557. This value is calculated as follows: the immediate exercise of the option gives the option holder $50-44.54736 = 5.452$ (it's a put option). Keeping the option alive gives the holder 6.743557 that is calculated as probability weighted average of the option values at the nodes (4,3) and (4,2), discounted back one period. To be exact, $6.743557 = 0.991701 \times (0.471165 \times 2.859618 + (1-0.471165) \times 10.31065)$. Keeping the option alive is better than killing it (exercising it immediately) and therefore the last calculation gives the value of the option at the node (3,2).

The Black formula is based on the assumption that the price of the underlying commodity follows the stochastic process known as Geometric Brownian Motion. Under this process, the instantaneous price return (dF/F) is given by the following formula:

$$dF = \mu F dt + \sigma F dZ, \tag{2}$$

where μ stand for the so-called drift (instantaneous rate of return) and dz is the so-called Wiener variable ($dz = \varepsilon\sqrt{dt}$, where ε is drawn from the standard normal distribution). In case the underlying is a forward contract, the drift is equal to zero. This can be explained by the fact that entering into a forward contract has zero cost. A nonzero drift implies that the expected return is nonzero, and this implies that one would enter into a transaction with an expected loss or gain and no cost. In the first case, the market participants would bid down the price by shorting it; in the second case (gain) they would bid the price up till the potential gain disappeared.

The challenge of pricing energy derivatives is that the prices in many commodity markets do not follow this process. Energy commodity prices display behavior that is characterized by seasonality, the tendency to gap due to shocks that affect either the demand or supply side, and also they cannot be modeled without paying attention to production costs. The research in the area of energy option valuation evolves around development of new models that are based on alternative stochastic assumptions regarding price evolution. Two examples of such processes are a mean reversion process and a jump-diffusion process. Mean reversion process recognizes the fact that prices gravitate toward the levels determined by the cost of production. The simplest form of the mean reversion process is given by the so-called Ornstein-Uhlenbeck process:

$$dF = \alpha(m - F)dt + \sigma dz, \tag{3}$$

where α (>0) denotes the speed of mean reversion and the m denotes the mean price level toward which the price gravitates. If the price drops below the mean level, the difference $m-F$ is positive and given the speed reversion that is positive, the deterministic part of the Eq. (3) will be positive as well. This will help to bring the price back to the mean level. Of course, the stochastic part (σdz) may reinforce or counter the contribution of the deterministic part. If the price F is above the mean level, the mean reversion part of the process will act to bring it down. It is important to

notice that the volatility parameter has a different interpretation than the volatility parameter in the Geometric Brownian Motion process. The price change on the left-hand side of Eq. (3) is measured in dollars per commodity unit. The Wiener variable dz is dimensionless and, therefore, σ is measured in the same monetary units as dP. Volatility σ in the Eq. (2) is unitless.

The propensity of energy pieces to jump reflects one of the structural features of the energy markets. The price at any location is likely to jump (gap) due to sudden changes in supply or demand conditions that cannot be addressed due to the rigidities of the physical infrastructure (inflexible transmission or transportation grid, limited deliverability from and into storage). The modeling approach to this problem is a combination of a diffusion process (Geometric Brownian Motion or Ornstein-Uhlenbeck, for example) and a jump process. One example is the Poisson process combined with the Geometric Brownian motion:

$$dF = \mu F dt + \sigma F dz + (J - 1) F dq, \qquad (4)$$

where the variable dq assumes two possible values, 1 if a jump occurs, 0 if it does not. It is assumed that the jump occurs with the probability λdt, where dt is the time step and λ is known as the intensity of the process. J is the dimension of the jump. If the jump happens and J is equal to 0.8, then the forward price F drops immediately by 20%, in addition to changes resulting from the diffusion part of the Eq. (4). When a jump occurs, it is typically assumed to follow a log-normal distribution ($ln(J) \sim N(\gamma,\delta)$), where γ denotes the mean of the natural logarithm of the jump and δ its standard deviation. The jump diffusion process parameters may be estimated from the historical price return data and used in option valuation models based on numerical techniques. The jump diffusion approach, although very popular, suffers from many shortcomings. The parameter estimates may be unstable and it takes a long time for the results of the jump to taper off, contrary to many empirical observations that show a quick return to more normal price levels following a jump.

Mean reversion and jump diffusion are just two fairly elementary examples of the efforts under way to come up with better valuation techniques for energy options that recognize the unique features of energy markets.

3. Thermal Processes

Glossary

desalination The removal of salt, especially from seawater, to make it drinkable.
membrane desalination The removal of salt from seawater by using membranes to differentiate and selectively separate salts and water.
minimum energy of separation The thermodynamic minimum amount of energy needed to separate salts from water in the process of desalination.
thermal desalination The removal of salt from seawater by condensing purified vapor to yield a product in the form of distilled water.

This article focuses on processes involving the separation of solute and solution with the objective of reducing the solute concentration in the product stream. The focus of the following section is practical economic processes that have demonstrated sustained commercial viability.

1. INTRODUCTION

All desalination processes can be generically represented by the diagram shown in Fig. 1. Desalination processes can be segregated into two broad types, as follows:

1. Thermal processes, the most common being multistage flash (MSF); multiple-effect distillation (MED) and its variants; and vapor compression, which can be subclassified into thermal vapor compression (TVC)—most commonly combined with MED—and mechanical vapor compression;

2. Membrane processes, including reverse osmosis (RO); electrodialysis (ED); and electrodialysis reversal (EDR).

The thermal processes share the common step of condensing purified vapor to yield a product in the form of distilled water. The membrane processes have two further subclassifications with significantly different modes of operation: pressure-driven membranes and charge-selective membranes.

2. MINIMUM ENERGY OF SEPARATION

The minimum energy to separate a solute from solution can be derived from first principles. The most common approach is to consider the thermodynamic properties of pure water and a saline water, such as seawater. Two physically identical vessels, at the same temperature, containing fresh water and seawater, respectively, will have different pressures. This is due to the different vapor pressures of the two chambers, which differ because of the respective purity and salinity of the waters, and is shown diagrammatically in Fig. 2.

If the two vessels were to be connected, then the pressure difference that would exist would drive a flow in the direction of the arrow, from fresh water to saline water. A flow in this direction is not desirable for a desalination process. A day-to-day result of this situation is the reason that reverse osmosis is called reverse osmosis; some energy must be added to the system to overcome the natural direction of flow.

To achieve desalination, the pure water from the vapor space above the saline water (typically seawater) must be transported to the freshwater chamber (see Fig. 3). This can be achieved by a reversible process utilizing a hypothetical vapor compressor that can raise the pressure from the

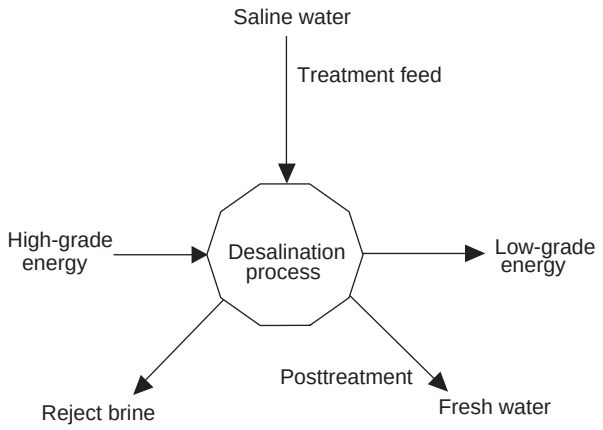

FIGURE 1 The desalination process.

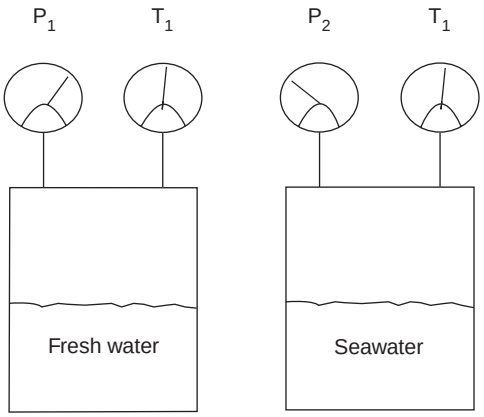

FIGURE 2 Two physically identical vessels, at the same temperature, containing fresh water and seawater, respectively, have different pressures.

freshwater vessel to a value just above that of the saline vessel. If the two vessels are held within a suitably large constant temperature reservoir, then it can be assumed that there is no temperature rise associated with this process.

Using this model, the minimum reversible energy consumption of a desalination process can be found by calculating the compressor power consumption that is a function of the vapor flow rate and partial pressure difference. This shows that the minimum energy of separation is a function of salinity (and also of temperature, since temperature relates directly to partial pressure). For seawater at 25°C, the vapor pressure is 3103 Pa and the specific volume is 44.17 m^3/kg; comparable figures for pure water are 3166 Pa and 43.40 m^3/kg. This yields a minimum energy consumption for the desalination of seawater of approximately 0.7 kWh per ton of water produced

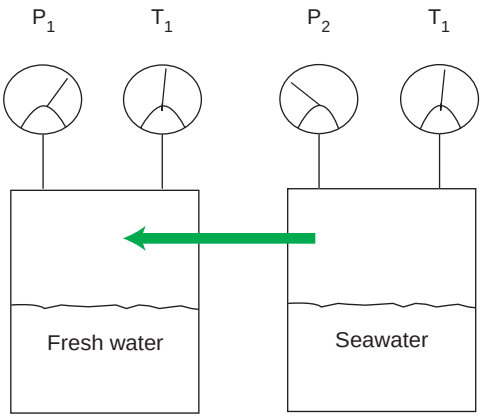

FIGURE 3 To achieve desalination, pure water from the vapor space above the seawater must be transported to the freshwater chamber.

(0.75 kWh/ton, or 2.734 kJ/kg). This minimum energy varies from 0.65 kWh/ton at 0°C to 0.90 kWh/ton at 100°C.

This analysis was considered for vapor compression processes but is valid for all processes. Why? The analysis is based on a theoretical ideal reversible process, which means that the results are valid as minima, which cannot be bested by practical processes. All practical desalination processes have these same values as targets although each of them may be restricted by different irreversibilities.

Each desalination process has a basic thermodynamic parameter that is a primary irreversible and unavoidable loss. For example,

- Distillation must always account for ΔT_b, the boiling point elevation.
- Freezing must similarly allow for ΔT_f, the freeze point suppression.
- Reverse osmosis must overcome ΔP_o, the osmotic pressure.
- Ion exchange must overcome ΔV_p, the polarization voltage, and provide ΔV_d, the diffusion voltage.

A detailed but less intuitively obviously minimum energy analysis could be completed considering each process; however, the net result would be the same. A more practical approach is to consider the state of the art for the most commonly utilized processes.

3. THERMAL PROCESSES

MSF, MED, and TVC processes are all driven by a high-enthalpy energy source, typically steam, but hot

water or oil can also be utilized. In general, all these processes incorporate a maximum operating temperature limited to between 70 and 115°C to avoid scale and corrosion associated with the solutions. This is known as the top brine temperature (TBT), which as a design parameter varies within the specified range due to slight differences in the configuration of the respective processes. This means that these processes can be heated by any energy source that is a few degrees warmer than the TBT; however, some processes utilize significantly higher enthalpy streams.

3.1 MED

MED is one of the oldest desalination methods and the simplest process with which to explain the principle of gained output ratio (GOR). GOR is a measure of how much thermal energy is consumed in a desalination process. The simplest definition is as follows:

How many kilograms of distilled water are produced per kilogram of steam consumed? Obviously, the same value for GOR is obtained when U.S. customary units of pounds are used.

Typically, the value of GOR ranges from 1 to 10 kg (H_2O)/kg (steam). Lower values are typical of applications where there is a high availability of low thermal energy. Higher values, even up to 18, have been associated with situations where local energy values are very high, when the local value or need for water is high or a combination of both.

A single-effect distiller, as shown in Fig. 4, operates with a GOR of 1 if there are no thermodynamic losses. In the absence of losses, each kilogram of steam that condenses in the effect will release sufficient heat of condensation to evaporate an equal quantity of vapor from the seawater, which then condenses in the condenser. This further assumes that the heat transfer area is infinite and there is a negligible temperature difference. Each kilogram of steam is therefore returned to the boiler as condensate and a kilogram of distilled water has been produced for other uses.

In the late 1800s, it was first noticed that this single-step process could be repeated with a gain in production, and therefore efficiency, for each effect added. This became known as Rillieux's First Principle: "In a multi-effect, one pound of steam applied to the apparatus will evaporate as many pounds of water as there are bodies in the set." This can be explained by examining the MED system depicted in Fig. 5. Once again, if losses are neglected, each kilogram of steam will release heat of condensation, which is equal to the heat of vaporization, and thus a four-effect system would produce 1 kg of condensate and 4 kg of distillate for every kilogram of heating steam utilized.

There are, however, many irreversibilities and other losses within these processes but the basic concept of Rillieux's First Principle is substantially correct and requires a 0.8–0.88 correction factor to be applied. This means that a four-effect MED system will typically yield a GOR of between 3.2 and 3.5.

MED systems have been designed and successfully operated with GORs ranging from 0.8 to approximately 10. Higher GOR designs invariably incorporate larger heat transfer areas, which then increases capital costs. The justification of higher capital costs can be made only with energy values that are appropriate or where greater demand for water suitably impacts the economics. The trade-off between capital cost (CAPEX) and operating cost (OPEX) is shown diagrammatically in Fig. 6, where it can be seen that a minimum will exist, which is project-specific, based on prevailing energy values and interest rates.

Typically, low-GOR applications include those where low-grade, low-value energy is abundant; examples include refineries and methanol facilities in arid locations where a traditional source of water is not available and a GOR of 3–4 is common. Higher GOR applications include production of distilled water for municipal supplies in areas with high-energy values such as the Caribbean Islands, where a GOR of closer to 10 is common.

Important additional points to note about the MED process are as follows:

- Each effect has an unavoidable BPE loss. Practical restrictions on TBT mean that utilizing too many effects in order to achieve high GORs is

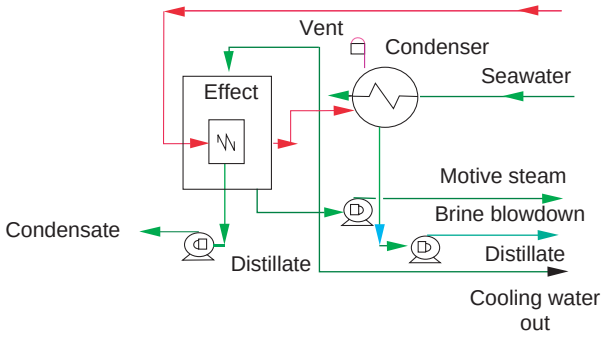

FIGURE 4 A single-effect distiller.

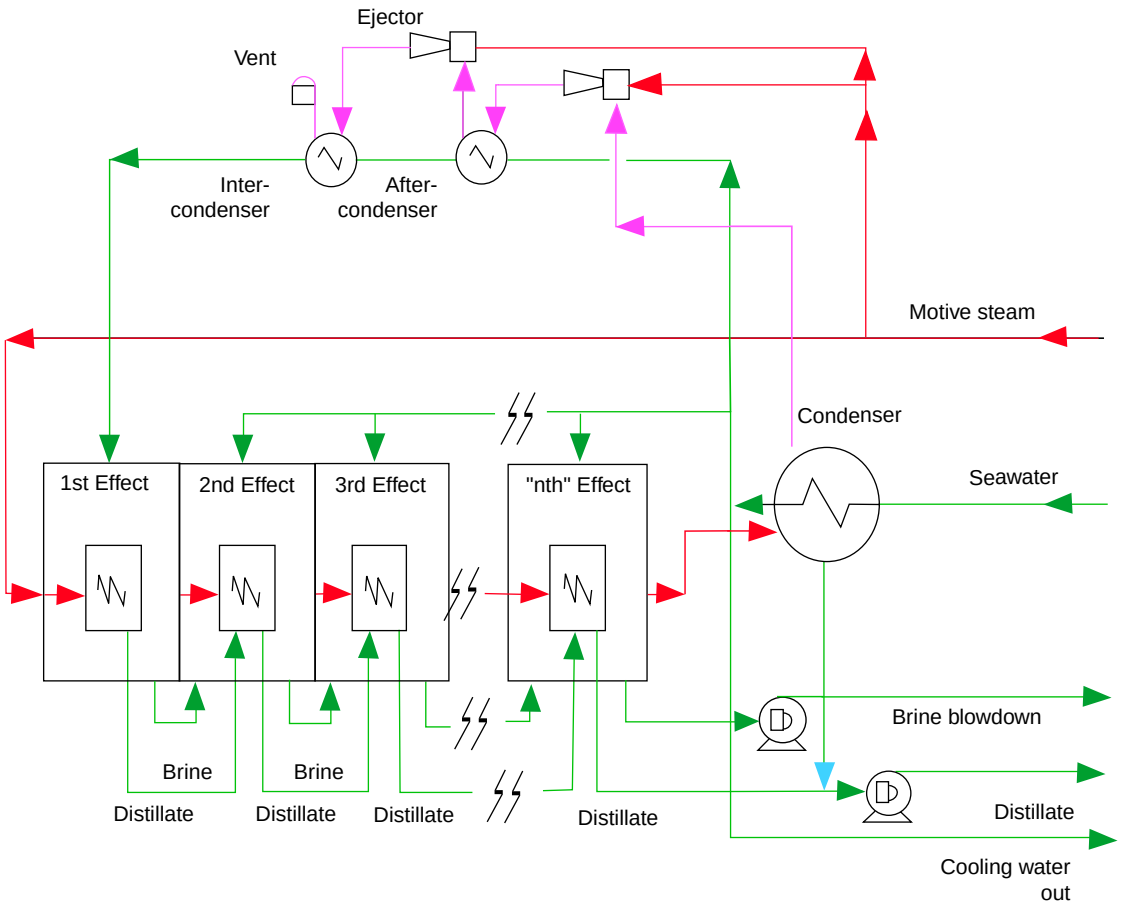

FIGURE 5 Multiple-effect distillation system.

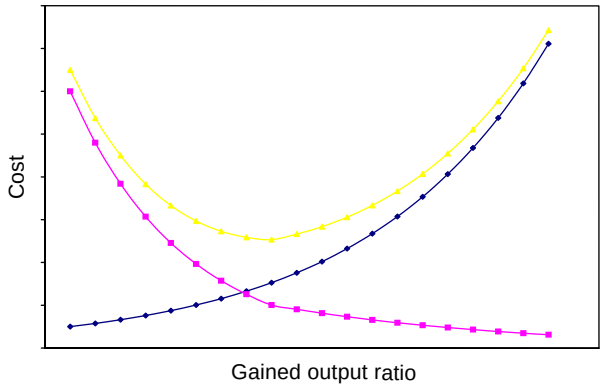

FIGURE 6 Trade-off between capital cost (CAPEX) and operating cost (OPEX). Diamonds, CAPEX; squares, OPEX; triangles, total cost.

impractical as the total BPE loss consumes a larger portion of the available ΔT.

- Pumping power is typically 0.7–1.2 kWh/ton. This includes the process pumps shown in the figures but excludes external pumps such as intake pumps. Excluding these pumps is usually valid since the cooling water that they provide is normally required even if the desalination plant is not operating as part of the facility heat balance (i.e., the steam must still be condensed). The intake pump flow rate is related to the GOR and the total dynamic head is related to site conditions, both of which also justify considering only the pumping energy within the process for comparative purposes.

3.2 MED with Thermal Vapor Compression

MED with thermal vapor compression (MED-TVC), or simply TVC, is the most rapidly growing distillation process. The process combines the basic MED system with a steam jet ejector, which enables the plant to utilize enthalpy and kinetic energy from motive steam and is shown in Fig. 7. Like the MED system, each kilogram of steam entering the first effect can yield a distillate production of $0.85N$ kg, where

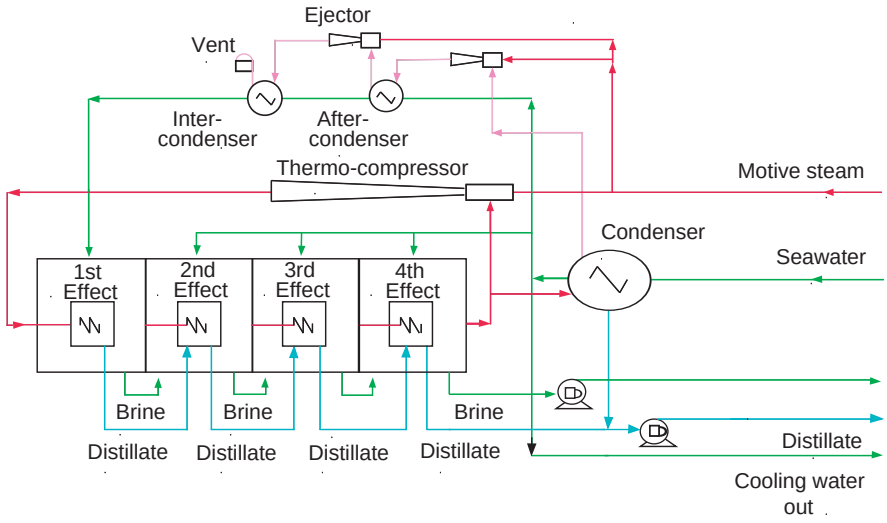

FIGURE 7 Multiple-effect distillation system with thermal vapor compression.

N is the number of effects. The important point to note is that each kilogram of steam entering the first effect is a combination of live steam and recycled low-pressure process vapor. The net result is that when utilizing medium-pressure steam, it is possible to achieve a GOR of over 8 with only four effects.

The addition of a thermocompression device adds approximately 1% to the CAPEX of a basic MED unit, yet the efficiency can be doubled. In cases where the steam is produced from waste gases, or where there is little commercial value difference between medium- and low-pressure steam, the use of TVC has grown tremendously. Using medium-pressure steam, it has been possible to achieve GORs of over 15. Such high GOR values also mean that less heat must be rejected from the system via cooling water, which can be an important consideration in many projects (for environmental or permit reasons).

The most common method for large-scale desalting of seawater had been the MSF process, which typically was combined with power production and utilized turbine extraction steam at 5 bar. Higher heat transfer coefficients, lower pumping pressures (and therefore lighter mechanical design requirements), and greater design flexibility mean that TVC designs are producing the same amount of water from this 5 bar steam but at lower CAPEX and OPEX than MSF. For distillation units in the range of 1000–25,000 ton/day capacity, the TVC process is beginning to dominate.

3.3 MSF

The MSF process is the most prevalent method of desalting seawater based on the volume of freshwater produced daily on a global basis. The process was commercialized during the 1960s based on competing Scottish and U.S. patented technology. MSF is a classic forced circulation process wherein seawater is preheated by the condensation of the vapor, which has been flashed from hot seawater. A once-through MSF process is shown in Fig. 8.

The relationship between the number of stages and the GOR is complex and also depends on the orientation of the tubes. For long tube designs where the tubes and flashing brine are always countercurrent, the number of stages, *N*, is typically 4 times the GOR. For cross-tube designs where there can be multiple tube passes within each stage and the flow through the tubes is perpendicular to the flashing brine, *N* is typically 2.5–3 times the GOR.

The once-through configuration is found mostly on marine distillation applications or similar applications that are relatively low capacity and low GOR. A typical plant of this design will have a GOR of 3 and a capacity of 1000 tons/day. Pumping power is typically 5–6 kWh per ton of distilled water. The U.S. nuclear carrier fleet utilizes this technology primarily to provide high-quality feedwater for the steam catapult launch-assist systems.

The most common MSF plants utilize cross-tube configurations in brine recycle flow schemes, shown in Fig. 9, and have unit production capacities of up to 55,000 tons/day. Many of these large systems are provided in the countries of the Gulf Cooperation Council, in Saudi Arabia, the location of the largest desalination facility at Al Jubail, and in the United Arab Emirates, the location of the largest units at Al Taweelah.

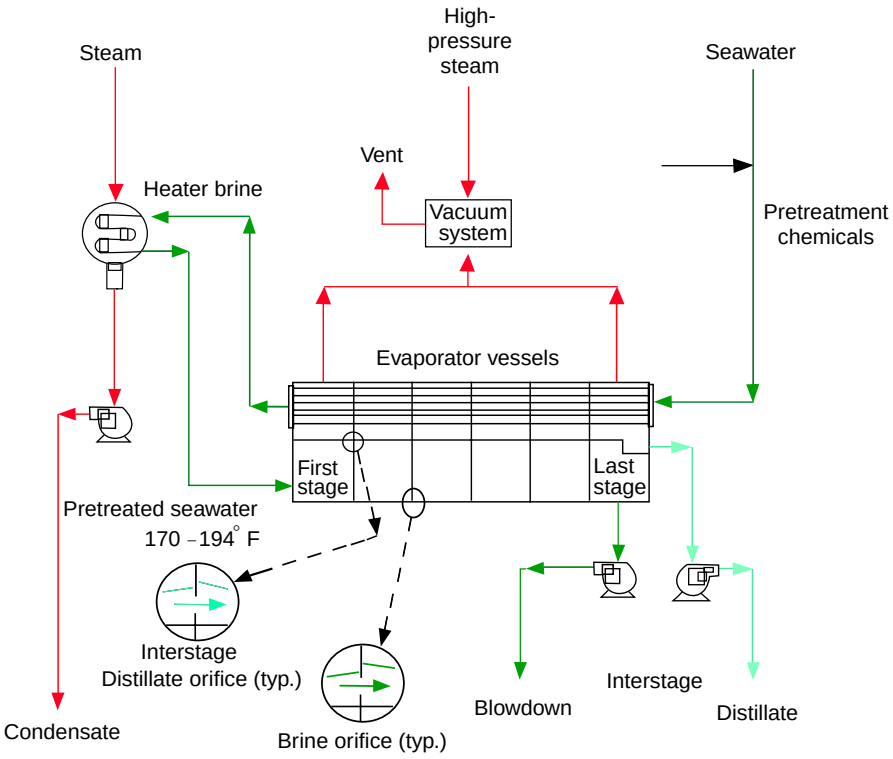

FIGURE 8 A once-through multistage flash process.

The typical GOR for these large units ranges from 7.7 to 9.0. All MSF plants are designed with electrically driven pumps but past practices included steam turbine drivers for the larger pumps. Exhaust steam from the turbines was then condensed in the brine heater, providing much of the MSF process heating. Such steam turbine drives have been replaced by electric motors not for efficiency reasons but for ease of use, simplicity, and operational flexibility. Typical pumping power for MSF units is 3.7–4.5 kWh per ton of distilled water.

3.4 RO

The RO process takes advantage of semipermeable properties of certain materials that allow solvents to pass through the material but impeding the passage of dissolved ions. The most commonly treated solvent is water. The semipermeable material can be configured in many ways but the most common is to roll flat sheets around a central pipe to create what is known as a membrane element. Even though membranes are available for performing very fine filtration, RO is not to be confused with filtration, which removes only material that is suspended within the fluid.

When a membrane is installed between saline water and fresh water, the natural flow will be toward the saline solution. The application of pressure to the saline side can stop this process, with the point of no flow being called the osmotic pressure. If a pressure above the osmotic pressure is applied to the saline side, then the flow reverses and fresh water can be produced. The basic RO flow diagram is shown in Fig. 10.

Osmotic pressure is a colligative property of the solution and generally increases as the concentration of dissolved ions increases. This means that as an RO system produces fresh water, known as the permeate, the salinity of the saline side increases, resulting in an increase in osmotic pressure. For a practical process, the RO system must be configured so that the average pressure along the membrane surface is suitably higher than the osmotic pressure, resulting in a net driving force for the process.

The osmotic pressure of typical municipal water is on the order of 0.33 bar, which is why faucet-mounted RO units can operate using the pressure of the municipal supply (typically 2 bar). The osmotic pressure of standard seawater is approximately 23 bar and seawater reverse osmosis (SWRO) systems typically operate such that the concentrated brine is

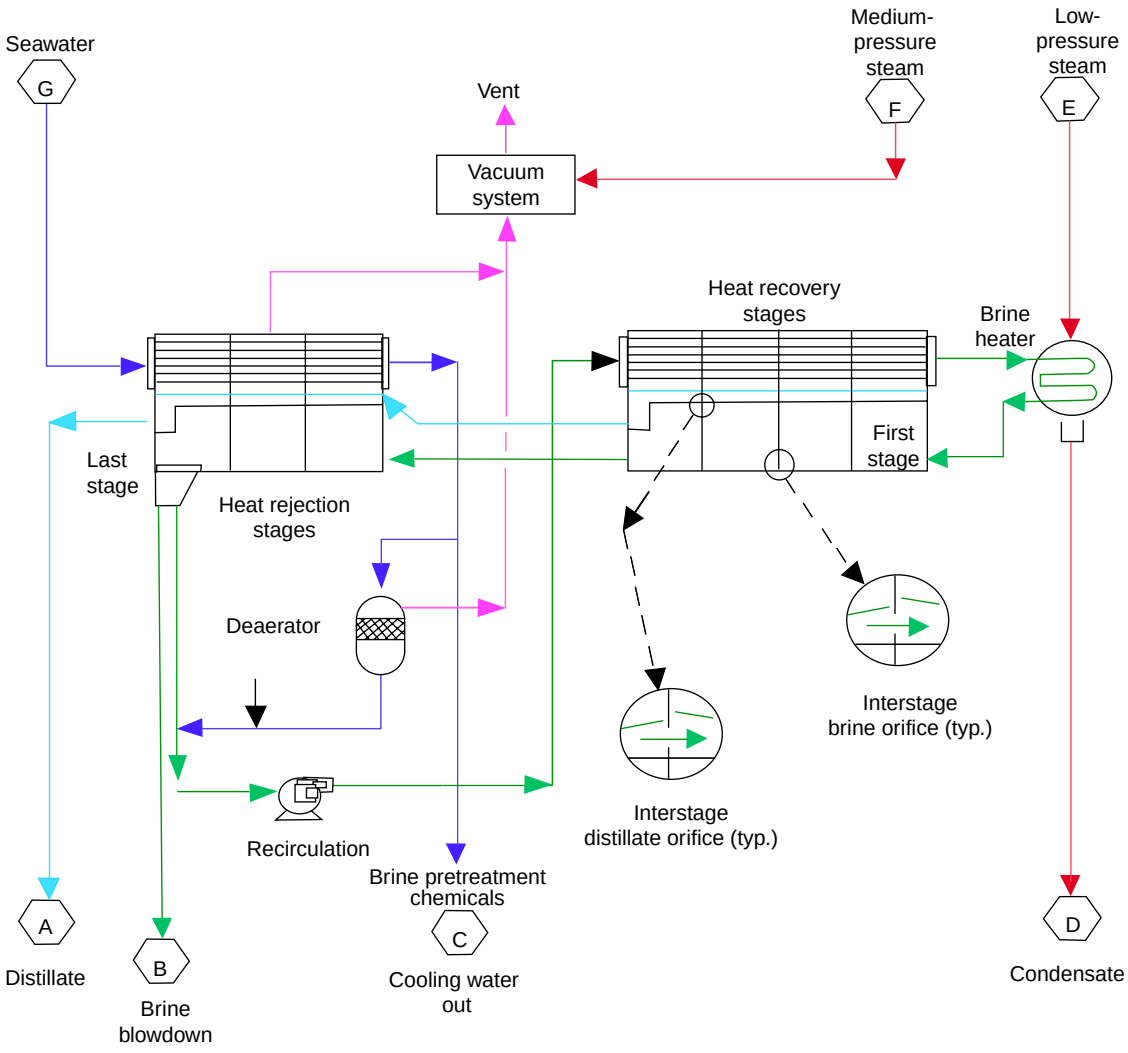

FIGURE 9 Brine recycle flow schemes.

almost two times the inlet concentration (which would be known as 50% recovery). This results in the brine having an osmotic pressure of approximately 45 bar. To achieve a practical economic driving force, the systems operate at 65–70 bar. This is close to the maximum mechanical pressure that the membranes can bear and the concentration is near the limits of solubility for certain salts. There are limited efforts in the marketplace to achieve higher concentrations, which would permit yields of more permeate than current recovery rates, which are approximately 45%.

Energy consumption for the process shown in Fig. 10 is typically 6.5 kWh per ton of permeate, which is unacceptable. The relatively large volume of high-pressure brine contains too much energy to be simply dissipated by the concentrate control valve. Energy recovery devices are installed in the brine stream to recapture the energy, as represented in Fig. 11. The most common devices are reaction turbines; often a reverse running pump; impulse turbines; normally a Pelton wheel; and pressure or work exchangers—these devices rely on proprietary methods of transferring pressure energy directly to the inlet feed stream.

The state of the art for SWRO energy consumption is approximately 2.0 kWh per ton of permeate produced; however, the average is closer to 2.75 kWh per ton of permeate produced.

Less saline water sources have much lower osmotic pressures and generally can be concentrated to 80–90% recovery before solubility limits are reached. The nature of these surface and subsurface natural waters is such that they are highly variable

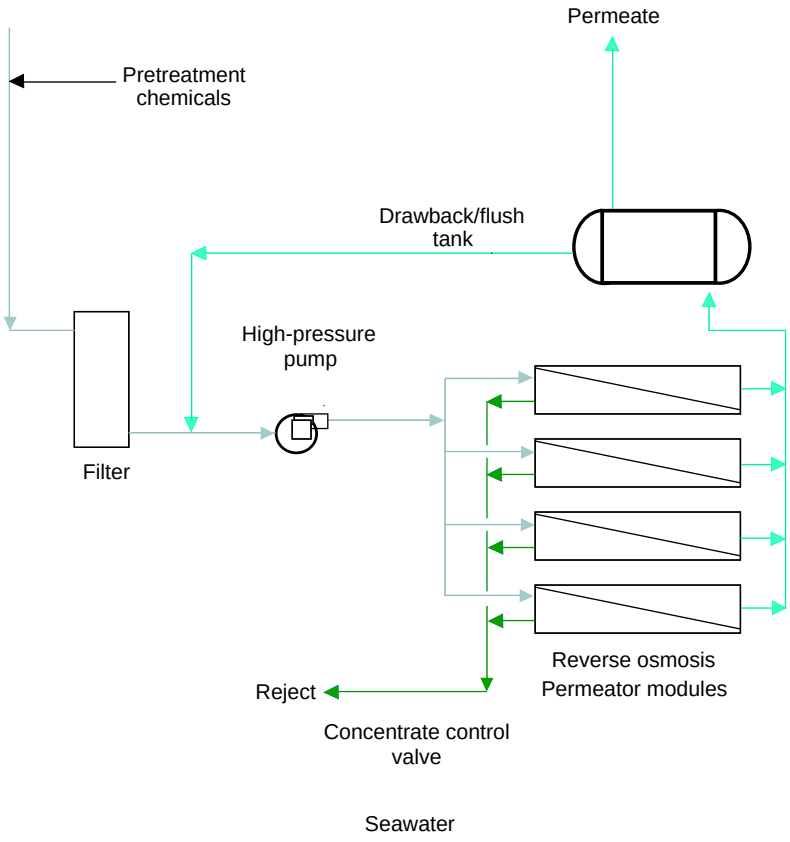

FIGURE 10 Reverse osmosis flow diagram.

from location to location and generalizations are difficult to make (unlike "standard" seawater). It is not uncommon to find waters that are already saturated in one or more ionic species and which cannot be treated (economically by standard desalination processes).

The typical brackish water RO (BWRO) operates at 85% recovery and pressures of approximately 25 bar, yielding energy consumption of 1.0 kWh/m^3. Since the pressures and brine flow volumes for BWRO are much lower than for SWRO, there has not been an economic driving force to develop energy recovery devices for BWRO. New applications of existing technology have been proposed, allowing multiple BWRO brine streams to be joined, yielding flow volumes that merit using energy recovery.

There has been work published that highlights the finding that the mechanical devices involved in RO processes (pumps, energy recovery, etc.) are reaching their practical limits and that future reductions in energy consumption must come from the membrane.

3.5 ED and EDR

Electrodialysis is quite unique among practical desalination processes since it literally desalts the feed source, whereas other processes actually remove pure water. ED is a membrane process utilizing charge-selective membranes and is pressure-based, like RO. It is possible to manufacture membranes that are charge-selective and that allow only ions with the appropriate charge to pass.

The most common configuration of ED utilizes a technique of periodically changing the polarity of the system electrodes returning in a reversed flow through the system, yielding some back-flushing of the membrane surface. This is known as electrodialysis reversal.

There are two main components of ED/EDR energy consumption: The energy of separation can be approximated as requiring 1 kWh/1000 usg per 1000 ppm of salt removed. This energy requirement varies significantly with temperature and is stated reflecting typical ambient conditions of 18–22°C.

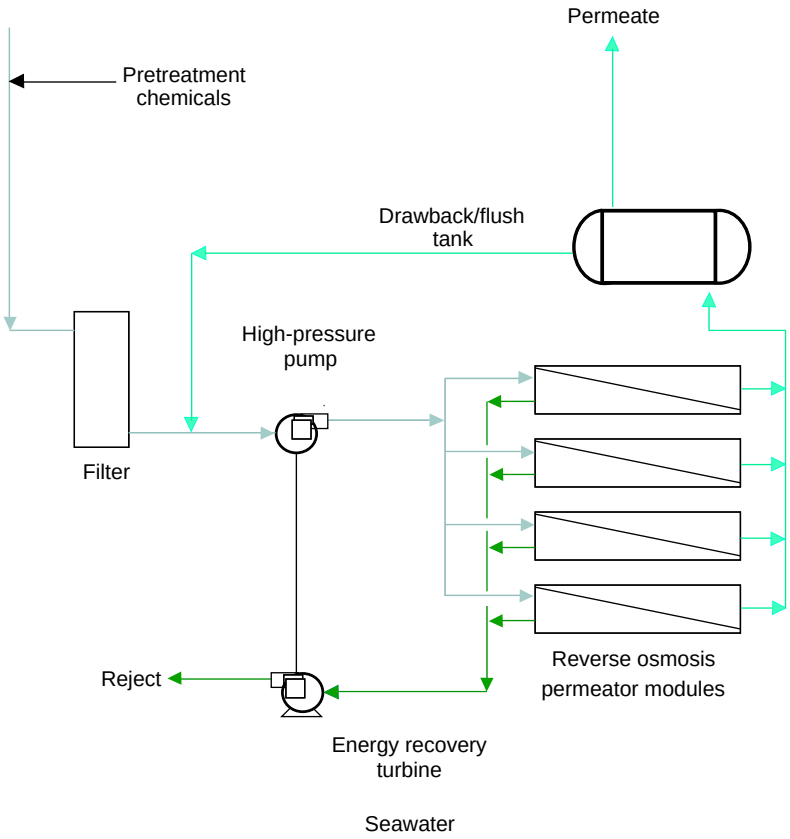

FIGURE 11 Energy recovery devices installed in the brine stream.

The energy of pumping is approximately 2 kWh/1000 usg of water produced.

Glossary

energy intensity The ratio of energy demand to gross domestic product.

gross domestic product (GDP) The total output produced within the geographical boundaries of the country, regardless of the nationality of the entities producing the output.

gross national product (GNP) Measure of the country's output of final goods and services for an accounting period (valued at market or purchaser's price).

human development index (HDI) Measures the average achievement of a country in basic human capabilities. The HDI indicates whether people lead a long and healthy life, are educated and knowledgeable, and enjoy a decent standard of living. The HDI examines the average condition of all people in a country: Distributional inequalities for various groups of society have to be calculated separately. The HDI is a composite of three basic components of human development: longevity, knowledge, and standard of living. Longevity is measured by life expectancy. Knowledge is measured by a combination of adult literacy (two-thirds weight) and mean years of schooling (one-third weight). Standard of living is measured by purchasing power, based on real GDP per capita adjusted for the local cost of living (purchasing power parity).

purchasing power parity (PPP) A rate of exchange that accounts for price differences across countries allowing international comparisons of real output and incomes. At the U.S. PPP rate, the PPP of $1 has the same purchasing power in the domestic economy as $1 has in the United States.

tonnes of oil equivalent (toe) Energy unit equivalent to 41.84 GJ or approximately 0.93 tonnes of gasoline, 0.99 tonnes of diesel oil, 0.96 tonnes of kerosene, 1.04 tonnes of fuel oil, 0.93 tonnes of liquified petroleum gas, 1.61 tonnes of coal, 6.25 tonnes of bagasse, 2.63 tonnes of fuel wood, and 1.35 tonnes of charcoal.

terawett-hour (TWh) Energy unit equivalent to 3.6 million GJ.

Although energy is a physical entity well understood and quantitatively defined, the concept of development is less well defined and there are different perceptions about its meaning. The World Bank measures development by the gross national product (GNP) and nations are classified in categories according to their GNP "per capita." This "monetization" of the concept of development is not well understood and is not accepted by many, particularly in developing countries, where income per capita varies dramatically between the poor and the rich. In 1999 U.S. dollars, high income is considered to be $9,266/year or more, whereas middle income is between $756 and $9,265 and low income is $755 or less. This is not the case in the Organization for Economic Cooperation and Development countries, where there is a large middle class and variations in income are not very large.

1. INTRODUCTION

The poor in developing countries, who represent 70% of the world's population, aspire to a "better life," meaning jobs, food, health services, housing (rural or urban), education, transportation, running water, sewage service, communication services, security of supplies of necessities, and a good environment. These things are usually measured in industrialized countries by monetary transactions,

 © 2004 Elsevier Inc. All rights reserved.

but this is not necessarily the case in many other countries. Climate and abundant and easily available natural resources can lead to a better life without great monetary resources. In some countries, cultural values are such that some items are less desirable than they are in other countries. In others, the political system privileges some solutions over others that cost much less. Thus, to compare stages of development only by gross domestic product (GDP) per capita can be quite misleading.

Energy in its various forms (mechanical, chemical, electrical, heat, and electromagnetic radiation) is essential for all the aspirations listed previously, and thus it is closely linked to a range of social issues. Conversely, the quality and quantity of energy services and how they are achieved have an effect on social issues.

The stages of the development of man, from primitive man (1 million years ago) to today's technological man, can be roughly correlated with energy consumption (Fig. 1).

- Primitive man (East Africa approximately 1 million years ago), without the use of fire, had only the energy of the food he ate (2000 kcal/day).
- Hunting man (Europe approximately 100,000 years ago) had more food and also burned wood for heat and cooking.
- Primitive agricultural man (Fertile Crescent in 5000 BC) grew crops and used animal energy.
- Advanced agricultural man (northeast Europe in 1400 AD) had coal for heating, water power, wind power, and animal transport.

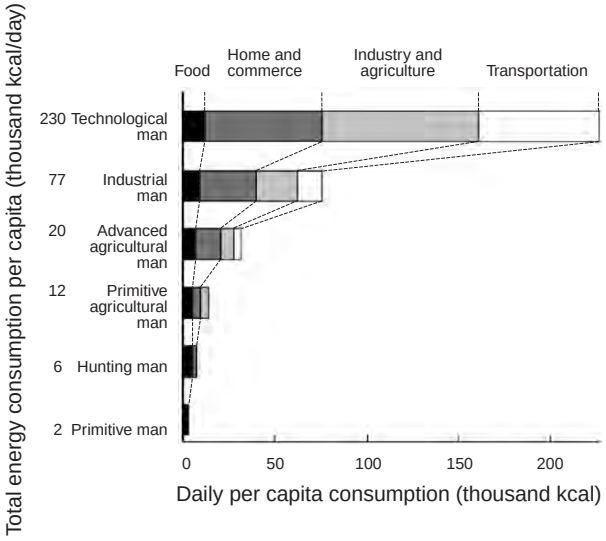

FIGURE 1 Stages of development and energy consumption. Reproduced from Cook, (1976).

- Industrial man (in England in 1875) had the steam engine.
- Technological man (in the United States in 1970) consumed 230,000 kcal/day.

From the very low energy consumption of 2000 kcal per day, which characterized primitive man, energy consumption increased in 1 million years to 230,000 kcal per day. This enormous growth of per capita energy consumption was only made possible by the increased use of coal as a source of heat and power in the 19th century; the use of internal combustion engines, which led to the massive use of petroleum and its derivatives; and Electricity generated initially in hydroelectric sites and later in thermoelectric plants. Income per capita has also increased, and one is thus tempted to determine if there is a clear correlation between energy consumption/capita and GDP/capita. Data are available for a number of countries (Fig. 2).

A linear relationship between energy consumption/capita and GDP/capita could be expected since higher income means more appliances and automobiles, larger homes, more travel, and many other activities, but empirical evidence shows that this is not the case. Clearly, there are many countries that do not fit into a linear relationship.

Moreover, some countries with the same GNP/capita can have very different energy consumption per capita, which is the case for Russia, China, and Morocco. Their GNP/capita is approximately the same, but energy consumption in Russia is four times higher than in China and 15 times higher than in Morocco.

2. THE IMPORTANCE OF NONCOMMERCIAL ENERGY

With regard to developing countries, a problem with energy data (Fig. 2), is that the vertical axis considers only "commercial energy," which is the fraction of total energy consumption that can be quantified since, by definition, it involves monetary transactions. In reality, in many areas noncommercial energy sources, such as dung, agricultural residues, and fuelwood, are used. In some countries, it represents a large percentage of total consumption, particularly for the poor. Table I shows the importance of noncommercial energy in a variety of countries.

The importance of noncommercial energy is also clearly exemplified by data that show the average energy demand by income segment in Brazil (Fig. 3).

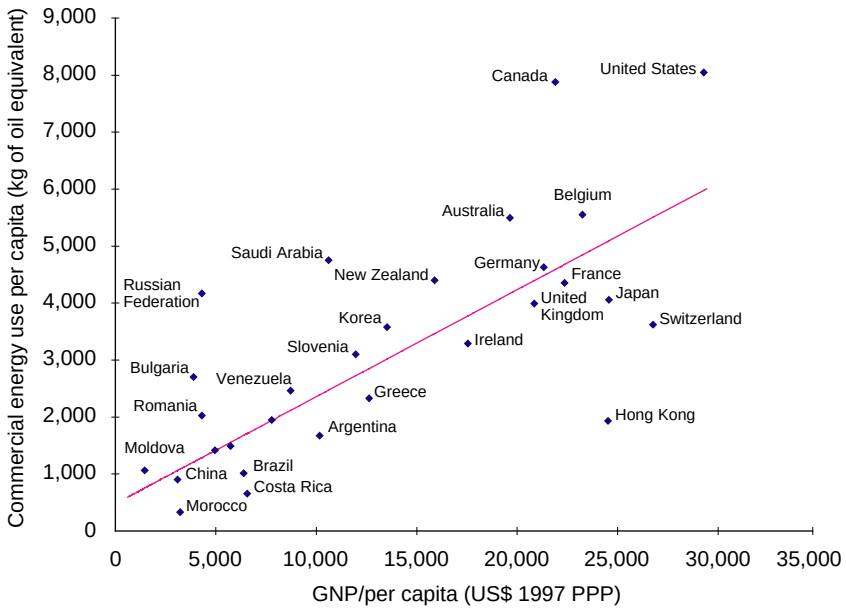

FIGURE 2 Energy use versus GNP. Reproduced from World Bank (1999).

TABLE I

Noncommercial Energy in Africa[a]

Country	1973 (%)	1985 (%)
Uganda	83	92
Malawi	87	94
Guinea-Bissau	72	67
Gambia	89	78
Guinea	69	72
Burundi	97	95
Mali	90	88
Burkina Faso	96	92

[a] Data from the World Resources Institute, United Nations Development Program, United Nations Environmental Program, and World Bank (1998).

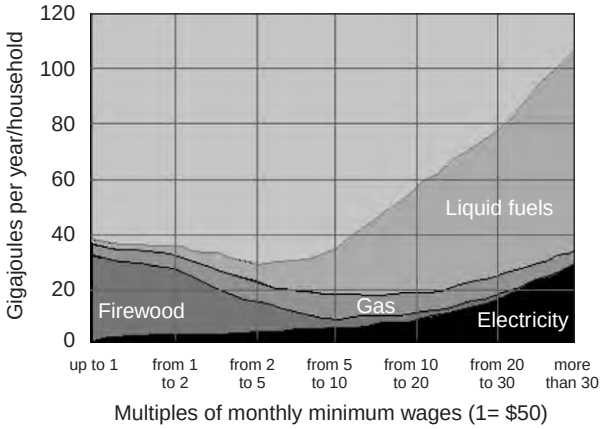

FIGURE 3 Average energy demand by income segment in Brazil, 1998. Reproduced from Almeida and Oliveira (1995).

For low-income households, firewood (usually a noncommercial energy source) is the dominant fuel. At higher income, firewood is replaced by commercial fuels and electricity, which offer much greater convenience, energy efficiency, and cleanliness. In most of Africa and India, dung and agricultural residues are used in lieu of firewood.

3. ENERGY INTENSITY

Another reason for the lack of a linear relationship between energy and GDP per capita is that the amount of additional energy required to provide energy services depends on the efficiencies with which the energy is produced, delivered, and used. Energy intensity often depends on a country's stage of development. In Organization for Economic Cooperation and Development (OECD) countries, which enjoy abundant energy services, growth in energy demand is less tightly linked to economic productivity than it was in the past (Fig. 4).

The evolution of the energy intensity ($I = E/\text{GDP}$) over time reflects the combined effects of structural changes in the economy (built into the GDP) and changes in the mix of energy sources and the

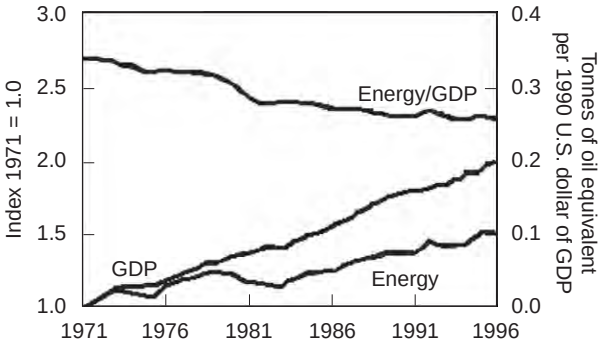

FIGURE 4 GDP and primary energy consumption in OECD countries, 1971–1996. Reproduced from the International Energy Agency (1999).

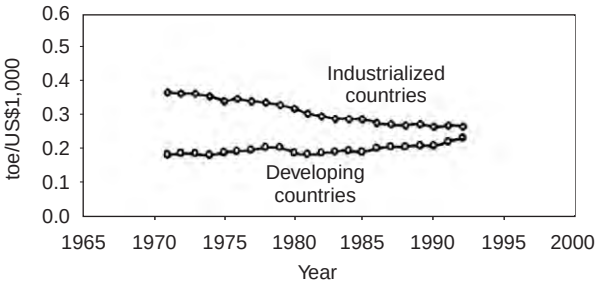

FIGURE 5 Energy intensity. Reproduced from Mielnik and Goldemberg (2000).

efficiency of energy use [built into the primary energy consumed (E)].

Although admittedly a very rough indicator, energy intensity has some attractive features: Whereas E and GDP per capita vary by more than one order of magnitude between developing and developed countries, energy intensity does not change by more than a factor of two. This is due in part to common characteristics of the energy systems of industrialized and developing countries in the "modern" sector of the economy and in part to the fact that in industrialized countries energy-intensive activities, such as jet travel, are increasingly offsetting efficiency gains in basic industries.

Energy intensity (considering only commercial energy sources) declined in OECD countries during the period 1971–1991 at a rate of approximately 1.4% per year. The main reasons for this movement were efficiency improvements, structural change, and fuel substitution. However, in the developing countries the pattern has been more varied. One study indicates that during the period 1971–1992 the energy intensity of developing and industrialized countries was converging to a common pattern of energy use. For each country, energy intensity was obtained as the ratio of commercial energy use to GDP converted in terms of purchasing power parity (PPP). The path of energy intensity of a country was given by the yearly sequence of energy intensity data during the period 1971–1994. The same procedure was followed to derive the energy intensity paths for a set of 18 industrialized countries and for 1 of 23 developing countries. The energy intensity data for each of these subsets were given by the ratio of total commercial energy use to total PPP-converted GDP for each group of countries for each year during the period 1971–1994 (Fig. 5).

4. HUMAN DEVELOPMENT INDEX

Since a clear correlation between energy and income is difficult to establish, one is tempted to search for other correlations between energy consumption and social indicators such as infant mortality, illiteracy, and fertility (Fig. 6). It is clear from Fig. 6 that energy use has many effects on major social issues, resulting in a relationship that is not necessarily casual between the parameters represented but there is strong covariance. Such behavior encouraged analysts to develop an indicator that would not only include GDP per capita but also take into account longevity and literacy. The Human Development Index (HDI), developed by the United Nations Development Program in 2001, is one way of measuring how well countries are meeting not just the economic but also the social needs of their people—that is, their quality of life. The HDI is calculated on the basis of a simple average of longevity, knowledge, and standard of living. Longevity is measured by life expectancy, knowledge is measured by a combination of adult literacy (two-thirds weight) and mean years of schooling (one-third weight), and standard of living is measured by purchasing power, based on real GDP per capita adjusted for the local cost of living (PPP).

The HDI measures performance by expressing a value between 0 (poorest performance) and 1 (ideal performance). HDI can be presented as a function of commercial energy consumption for a large number of countries in tons of oil equivalent (toe) (Fig. 7). Table II lists the characteristics of a few countries, their HDI values, and HDI rank.

An analysis of Table II indicates the importance of factors besides GDP per capita in determining the HDI rank of different countries. For example, Russia and Brazil have approximately the same GDP per capita but adult literacy in Russia (99.5%) is much

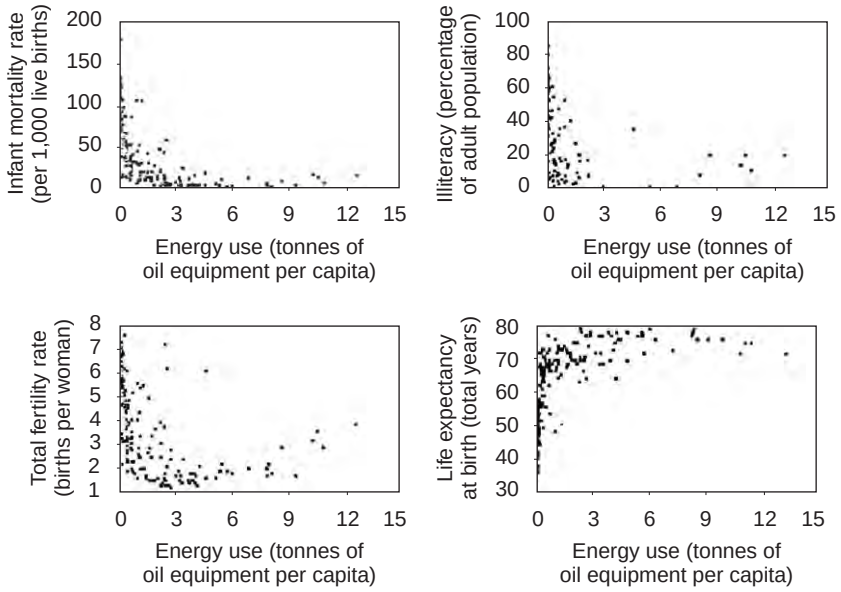

FIGURE 6 Commercial energy use and infant mortality rate, illiteracy, life expectancy at birth, and total fertility rate. Reproduced from United Nations Development Program, United Nations Department of Economic and Social Affairs, and World Energy Council (2000).

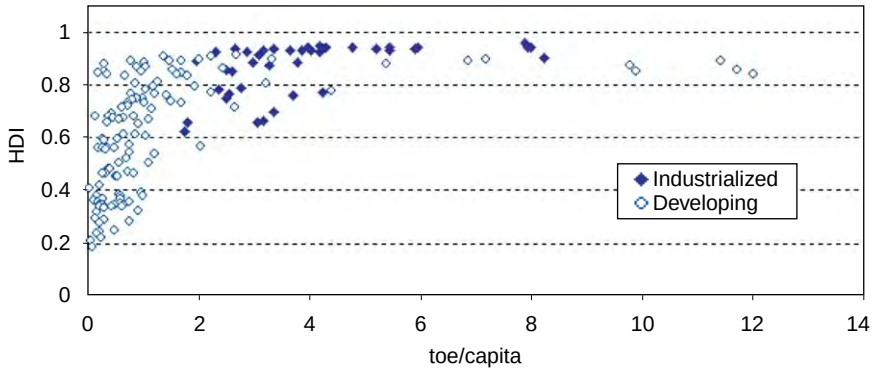

FIGURE 7 Human development index (HDI) and energy use by country. Reproduced from the World Bank (1999) and United Nations Development Program (1998).

TABLE II

Human Development (HDI) Index for Some Countries[a]

Country	Life expectancy at birth (years)	Adult literacy rate (% age 15 or older)	GDP per capita (PPR U.S. $)	HDI	HDI rank
Russia	66.1	99.5	7473	0.775	55
Brazil	67.5	84.9	7037	0.75	69
Sri Lanka	71.9	91.4	3279	0.735	81
China	70.2	83.5	3617	0.718	87
Morocco	67.2	48.0	3419	0.596	112
India	62.9	56.5	2248	0.571	115

[a] Data from the United Nations Development Program (2001).

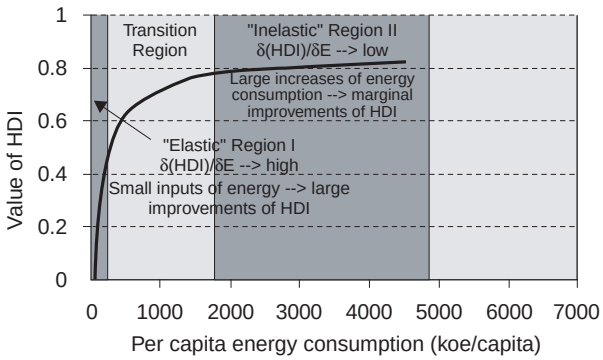

FIGURE 8 HDI versus per capita energy consumption. Reproduced from Reddy (2002).

higher than that in Brazil (84.9%), which ranks the former 55 compared to 69 for Brazil. Sri Lanka and China have a GDP per capita that is approximately the same as that of Morocco but the life expectancy and adult literacy of the former are much higher, which give Sri Lanka a ranking of 81, China 87, and Morocco 112.

It is apparent from Fig. 7 that for an energy consumption more than 1 toe/capita/year, the HDI is higher than 0.8 and essentially constant for all countries. Therefore, 1 toe/capita/year seems to be the minimum energy needed to guarantee an acceptable level of living as measured by the HDI, despite many variations in consumption patterns and lifestyles across countries.

The relationship between HDI and energy has several important implications. The relationship can be considered to consist of two regions (Fig. 8). In region I, the elastic region, – the slope δ (HDI)/δ (E) of the HDI vs E curve is high. In region II, the inelastic region, the slope δ (HDI)/δ (E) of the HDI vs E curve is low. Even large inputs of energy (large improvements of energy services) result in only marginal improvements in HDI; that is, the HDI–energy (benefit–cost) ratio is very low. In region I, enhanced energy services lead directly to improvement. Thus, the implication of the elastic and inelastic regions is that in the elastic region increased energy services guarantee direct improvement of HDI, whereas improvement of HDI via income depends on the uses of the income.

5. GENERATION OF JOBS IN ENERGY PRODUCTION

A variety of sources provide estimates of the number of jobs directly related to the production of energy.

TABLE III

Jobs in Energy Production[a]

Sector	Jobs (person-years), TWh
Petroleum	260
Offshore oil	265
Natural gas	250
Coal	370
Nuclear	75
Wood energy	1000
Hydro	250
Minihydro	120
Wind	918
Photovoltaics	7600
Ethanol (from sugarcane)	4000

[a]Data from Goldemberg (2003).

Some of these estimates are shown in Table III. These data include jobs involved in operating the generating stations, excluding the jobs involved in producing and commissioning the equipment. The very large number of jobs generated by the truly decentralized options, which are photovoltaics and ethanol from sugarcane, is striking.

Photovoltaics energy is usually generated (and used) in small modules of 100 W and the generation of 1 TWh typically requires 10 million modules to be installed and maintained. Ethanol production from sugarcane in Brazil involves agricultural production using approximately 4 million ha and industrial production in sugar–alcohol distilleries, accounting for the large number of jobs directly related to the production of energy.

There are also some rough estimates of the number of jobs generated by energy conservation. A study performed in Sacramento, California, showed that saving enough energy to operate at less than 100-MW power plant capacity requires 39 jobs compared with 15–20 jobs required to operate at the same amount of capacity at a modern coal or gas-fired power plant.

6. CONCLUSIONS

Energy has a determinant influence on the HDI, particularly in the early stages of development, in which the vast majority of the world's people, particularly women and children, are classified. The influence of per capita energy consumption on the HDI begins to decline between 1000 and 3000 kg of

oil equivalent (koe) per inhabitant. Thereafter, even with a tripling of energy consumption, the HDI does not increase. Thus, from approximately 1000 koe per capita, the strong positive covariance of energy consumption with HDI starts to diminish. The efficiency of energy use is also important in influencing the relationship between energy and development.

Another aspect of the problem is the mix of supply-side resources that dominate the world's energy scene today. Fossil fuels have a dominating role (81% of supply in OECD countries and 70% in developing countries), although, as a rule, renewables are more significant for low-income populations. However, there are significant advantages to increasing the role of renewable sources since they enhance diversity in energy supply markets, secure long-term sustainable energy supplies, reduce atmospheric emissions (local, regional, and global), create new employment opportunities in rural communities offering possibilities for local manufacturing, and enhance security of supply since they do not require imports that characterize the supply of fossil fuels.

More generally, development, including the generation of jobs, depends on a number of factors in addition to GNP per capita. Furthermore, although an essential ingredient of development, energy is more important with regard to low rather than high incomes.

Glossary

input/output analysis (**IOA**) A method traditionally used to describe the financial linkages and network of input supplies and production that connect industries in a regional economy (however defined) and to predict the changes in regional output, income, and employment; also used for environmental impact analysis today.

Intergovernmental Panel on Climate Change (**IPCC**) - Jointly established by the World Meteorological Organization and the UN Environment Program in 1998 to assess available scientific information on climate change, assess the environmental and socioeconomic impacts on climate change, and formulate response strategies.

International Vegetarian Union (**IVU**) Established in 1908 as a nonprofit-making organization with membership open to any nonprofit organization whose primary purpose is to promote vegetarianism and that is governed exclusively by vegetarians; aims to promote vegetarianism throughout the world.

life cycle assessment (**LCA**) A method to assess the potential environmental impact of a material, product, or service throughout its entire life cycle, from the extraction of raw materials, through the production process, through the user phase, and to the final disposal.

Energy use and greenhouse gas emissions in the current food system are substantial. The food system comprises the whole chain of events resulting in edible food—production of farm inputs, farming, animal husbandry, transportation, processing, storage, retailing, and preparation. Ecological impacts are not evenly distributed among products; therefore, dietary change is a possibility for environmental improvement. From a number of studies, it is possible to detect patterns of dietary recommendations that would lower energy use and greenhouse gas emissions in the food system. They include reducing consumption of meat, exotic food, food with little nutritional value, and overprocessed food. Overall trends in dietary patterns are not conducive to higher environmental efficiency, but the trends toward vegetarianism have an environmental potential. Policy instruments for encouraging more efficient diets include information, supportive structures, and financial incentives. However, they have scarcely been used in mitigation strategies for climate change.

1. INTRODUCTION

For a long time, it has been known that the production of certain food products takes a larger toll on natural resources than that of others, and at times dietary change has been proposed as a way of conserving such resources. During the 1960s, when global concern was about overpopulation and starvation, Georg Borgström proposed a diet lower down on the food chain, implying less use of cereals for animal feed. During the same period, Francois Lappé composed a diet for a small planet based on vegetarian ingredients only to save agricultural land. During the 1970s, when the concern was about energy resources, David and Marcia Pimentel presented calculations of energy inputs over the life cycle for bread and beef. The beef was found to be

 © 2004 Elsevier Inc. All rights reserved.

more energy demanding by a factor of 29 when the two products were compared on a weight basis.

Today, when climate change has emerged as perhaps the most controversial global environmental issue, the question of dietary change as a mitigation strategy has partly resurfaced. This is because energy use and greenhouse gas emissions from the current food system are substantial. Energy use in the food system typically amounts to 12 to 20% of the total energy consumed in developed countries. Current anthropogenic emissions of carbon dioxide (CO_2) are primarily the result of the consumption of energy from fossil fuels, the main energy source in the developed parts of the world. Another 10 to 30% of the current total anthropogenic emissions of CO_2 are estimated to be caused by land-use conversion, partly related to production of cash crops. In addition, the agricultural sector is a large source of emissions of methane and nitrous oxides. It accounts for half of the global anthropogenic emissions of methane through rice farming and rearing of ruminants, whereas 70% of the global anthropogenic emissions of nitrous oxide come from agricultural soils, cattle, and feedlots.

In looking more closely at where energy is used in the food system, one finds that a surprisingly large amount is used by the consumer. For the United States, a review of several studies showed that home preparation contributed between 23 and 30% of the total, figures comparable to processing, which contributed 24 to 37%. For Sweden, a recent survey showed that household energy use for cooking and storing food was 28% of the total, whereas processing contributed 25% (Fig. 1). A different pattern may emerge when looking at emissions of carbon dioxide (Fig. 1). Here, the system for electricity production may alter the energy pattern. For Sweden and some other Nordic countries, extensive use of hydropower results in low emissions, as does nuclear power production.

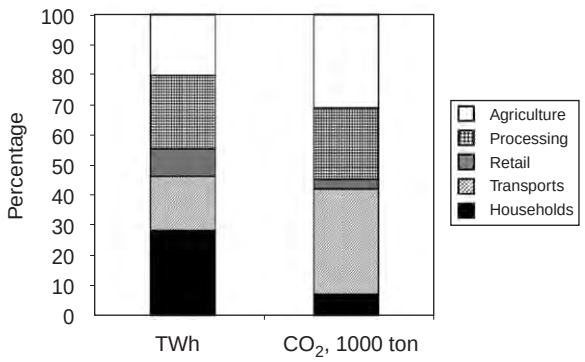

FIGURE 1 Energy use and emissions of carbon dioxide in the Swedish food system in the year 2000.

The purpose of this article is to provide an overview of current research about energy, greenhouse gas emissions, and dietary change. The approach is product oriented with a life cycle perspective, meaning that individual products are considered "from cradle to grave."

The article begins with some recent results from calculations of the environmental impacts over the life cycle for food products and diets. Several studies conducted in Europe and the United States provide sufficient basis for an informed discussion about the potential for change. In the subsequent section, some recent trends in global food consumption are reviewed for their environmental implications, and the trend toward vegetarianism is evaluated. Some lessons from research about policy instruments and dietary change are discussed with a focus on information and its efficiency. Finally, conclusions of relevance for further mitigation efforts are drawn.

2. CALCULATIONS OF ENERGY-EFFICIENT AND LOW-POLLUTION DIETS

Investigating possibilities for low-impact diets involves analyzing the resource use and emissions of the numerous individual food products that constitute a diet throughout the life cycle. Several attempts have been made to this end, and as a result broad patterns of dietary recommendations can be detected. Based on several studies, a diet with less meat and cheese, more in-season vegetables, more locally produced and fresh foods, better use of products, and more use of products from the "wild" could be recommended. The results from some of these studies are discussed in what follows, as are the methods used for computing the environmental impacts.

A team of Dutch researchers used a combination of life cycle assessment (LCA) and input/output analysis (IOA) to estimate greenhouse gas emissions from food products consumed in The Netherlands. The results were expressed as greenhouse gas emissions per Dutch florin (Dfl), and calculations were performed for more than 100 products. This method is useful in that the results can be directly combined with household expenditure profiles to estimate impacts of a whole consumption pattern but lack some detail when it comes to differentiation among various processing methods and so on. Some

results from these calculations were that greenhouse gas emissions during the life cycle of rice are nearly five times the emissions during pastry life cycles and that tomatoes emit four times as much greenhouse gases as do green beans. The reasons for these differences relate to the paddy field cultivation methods for rice and the fact that tomatoes are usually cultivated in fossil fuel-heated greenhouses. Regarding the food consumption emission profile of a Dutch household, methane emissions came mainly from products originating from cattle farming and dairy production. Enteric fermentation by ruminants explains much of this. The dietary recommendations made by these authors included substituting meat and cheese with eggs, nuts, or certain vegetable products and shifting from greenhouse-cultivated vegetables to those grown in the open.

In the United States, two researchers used IOA to calculate greenhouse gas emissions for 44 food products sold in the country. Their results were expressed as amount of emissions per dollar and were combined with household expenditures to calculate total household emissions. Regarding dietary change, the authors' proposal was to lower the expenditure on meat and poultry in favor of expenditure on vegetable products such as pasta. This was because the emissions intensity of beef and pork was 166 g per U.S. dollar, whereas the same intensity for pasta was only 75 g per U.S. dollar. Lowering meat consumption was also considered to be of major importance when all activities of the household were assessed for greenhouse gas emissions and other environmental pollutants.

A Swedish researcher investigated energy use over the life cycle for food supplied in Sweden using a life cycle inventory approach. The study covered 150 food items, and results were expressed as megajoules per kilogram of product. The advantage of this approach is that results can easily be combined with dietary information and that the level of detail in the environmental calculations is high. Among the results from this study are that energy use per kilogram of ready-to-eat food can vary from 2 to 220 MJ/kg, that is, by a factor of more than 100. The highest values were found for certain kinds of fish and seafood. A multitude of factors determine the level of energy inputs, and they relate to animal or vegetable origin, degree of processing, choice of processing and preparation technology, and transportation distance. The study confirmed several earlier findings about environmentally efficient diets while adding some new perspectives. One is the role of food preparation (which can add substantial energy inputs if food is cooked in small portions), another is the remarkably high energy inputs for certain fish-harvesting techniques, and a third is the impacts from food losses on total energy inputs in food life cycles. Examples of daily total life cycle energy inputs for diets with similar dietary energy were calculated, and the result was that energy inputs could vary by a factor of 3. Table I shows meal components for two meals with high and low energy inputs but with the same amount of dietary energy.

In a study of six food products for which LCA was used, detailed calculations of greenhouse gas emissions confirmed the large differences between some products of animal origin and some of vegetable origin. In this study, emissions of greenhouse gases per kilogram of ready-to-eat beef were 135 times higher than the emissions per kilogram of ready-to-eat potato (Table II). There are several explanations for the high emissions for beef: enteric fermentation causing emission of methane, energy use during animal feed production, and transportation of food ingredients. The reasons for lower emissions for pork and chicken are partly related to the digestive systems of pigs and poultry but are also due to the fact that they are much more efficient feed converters than cattle.

TABLE I

Meal Components, Dietary Energy, and Life Cycle Energy Inputs for Two Different Dinners: High and Low

Meal component	Kilograms	Megajoules dietary energy	Megajoules life cycle inputs
Dinner: High			
Beef	0.13	0.80	9.4
Rice	0.15	0.68	1.1
Tomatoes, greenhouse	0.070	0.06	4.6
Wine	0.30	0.98	4.2
Total	0.65	2.51	19
Dinner: Low			
Chicken	0.13	0.81	4.37
Potatoes	0.20	0.61	0.91
Carrot	0.13	0.21	0.50
Water, tap	0.15	0.23	0.0
Oil	0.02	0.74	0.30
Total	0.60	2.61	6.1

Source. Carlsson-Kanyama *et al.* (2003).

TABLE II

Emission of Greenhouse Gases per Kilogram Ready-to-Eat Food for Six Food Products Supplied in Sweden

	Grams CO_2 equivalents per kilogram ready-to-eat product
Beef	13,500
Pork	4,200
Chicken	1,400
Potatoes	100
Milk	870
Bread	500
Lettuce	230

When David and Marcia Pimentel revised their book, *Food, Energy, and Society,* in 1996, they concluded,

> *One practical way to increase food supplies with minimal increase in fossil energy inputs is for the world population as a whole to consume more plant foods. This diet modification would reduce energy expenditures and reduce food supplies, because less food suitable for human consumption would be fed to livestock.*

As described previously, a number of studies have certainly shown this to be true, although detailed calculations of energy use and greenhouse gas emissions over the life cycle of different kinds of meat show that there are large differences between, for example, chicken and beef. This opens the scope for discussing the role of meat in a more environmentally efficient diet as well as for questioning the role of certain kinds of fish and vegetables and the total amount of food consumed.

How can food consumption patterns be influenced, what are the current food trends, and what is the role of information for disseminating environmental knowledge about diets? The next section contains a review of some significant elements in current food trends and their implications for energy use and greenhouse gas emissions.

3. TRENDS IN DIETS

From the statistics databases provided by the Food and Agricultural Organization (FAO), it is possible to provide some global figures on dietary trends of interest for the environmental impacts in the food system. Figure 2 shows some developments with respect to this using starchy roots, wheat, pulses, meat, fish, and sweeteners as examples. The rationale

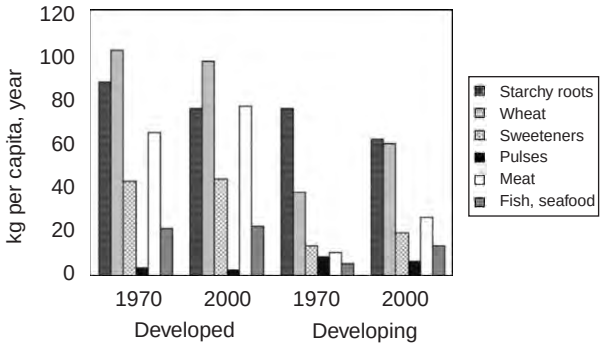

FIGURE 2 Consumption levels of some food products in 1970 and 2000 in the developed and developing worlds.

for choosing these products was that the life cycle-related levels of energy inputs and greenhouse gas emissions are commonly substantially different. Starchy roots and pulses are expected to have much lower impacts than do meat and fish, whereas sweeteners are interesting because they represent food products with considerable production-related energy inputs but with little or disputed nutritional value. Wheat is grown mainly in the Northern Hemisphere but is increasingly replacing traditional starch-rich crops, such as cassava and millet, in the developing parts of the world. Although wheat is not a very energy-demanding food item compared with meat and fish, it requires higher life cycle energy inputs than do some domestic starchy crops due to long transportation distances and intensive cultivation methods.

Figure 2 shows that the consumption of the selected food products in the developing parts of the world is still quite different from that in the developed world. This is particularly evident when it comes to meat consumption and sweeteners, with the 2000 levels per capita in the developed world exceeding those in the developing world by a factor of between 2 and 3. Figure 2 also shows that the most notable changes in the developed world during the past three decades were a 25% decrease in the consumption of pulses and an 18% increase in the consumption of meat. In the developing world, the changes were even more spectacular in that the consumption of meat and fish more than doubled and the consumption of wheat and sweeteners increased by approximately 50%.

The environmental implications of these dietary changes can only be interpreted as negative with respect to the prospects for lowering energy use and greenhouse gas emissions. Whether or not actual emissions have increased depends on the magnitude

of efficiency improvements in the food supply system. More efficient trucks, ships, processing equipment, and refrigerators have to some extent counteracted the negative environmental impacts of dietary change.

Along with the negative dietary changes experienced on a global scale, certain trends in the developing parts of the world (e.g., vegetarianism) hold some promise for more efficient diets in an affluent environment. Vegetarianism is not a new phenomenon in Western societies but has become a mainstream feature in several countries. According to the International Vegetarian Union (IVU), there is a vegetarian subculture in nearly every European country today. It is becoming increasingly common to have vegetarian options in nonvegetarian restaurants as an alternative for those who do not adhere to a vegetarian diet on an everyday basis. No statistics exist on how many vegetarians there are globally, but estimates from several European countries show the highest percentages in the United Kingdom, Germany, and Switzerland (~8–9% of these populations) and much lower percentages in Spain, Norway, and France (~2% of these populations).

The main reasons for choosing a vegetarian diet are commonly better health and nutrition as well as animal welfare considerations. The potential for environmental efficiency has been less investigated, and when it is claimed it is mostly mentioned as a way in which to avoid excessive use of agricultural land. Recent findings about energy inputs and greenhouse gas emissions during the life cycle of food products provide a new tool for evaluating the effects of vegetarianism. A problem with such an evaluation is that the dietary recommendations for vegetarians are only exclusive. They describe what not to eat but do not prescribe any alternatives. So, meat may be replaced by a very energy-efficient alternative, such as legumes, but also by other less efficient alternatives, such as vegetables grown in greenhouses and fruits transported by airplane. However, the trend toward vegetarianism should be considered as an environmentally promising one provided that the alternatives to animal food products are chosen among those vegetable products with moderate life cycle-based resource demands. When discussing potential environmental gains from a vegetarian diet, it is important to know that the environmental impacts from meat in an ordinary diet might not be dominant. One example of this is shown in Fig. 3, where the life cycle-based energy inputs for typical diets in Sweden are displayed. The figure shows that the energy inputs from meat and fish may constitute about a third of the total. The meat and fish part of the diets in other countries may contribute differently, and if the greenhouse gas emissions profile becomes available, it could also alter this conclusion to some extent.

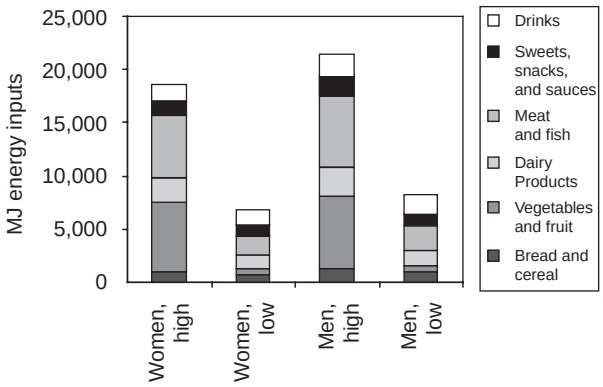

FIGURE 3 Life cycle energy inputs for the annual food consumption of average men and women in Sweden. The ranges indicate possible levels with various food choices.

Having reviewed current trends and commented on those with potential for environmental efficiency, we now turn to the issue of how policy could be used to influence diets so as to decrease energy inputs and greenhouse emissions from the food system. First, it is important to remember that experiences from large-scale campaigns for environmentally friendly diets are lacking and that the few results that can be drawn on come from isolated and relatively small research projects. In this context, it is also interesting to note that the Intergovernmental Panel on Climate Change (IPCC) does not mention dietary change among the mitigation potentials in its recent report about mitigation. Unfortunately, the same "blindness" toward dietary change as a possible environmental measure is not uncommon in policy documents. This article does not speculate on the reasons for this but rather concentrates on the results of some research in which information was used as a policy instrument.

4. POLICY INSTRUMENTS FOR DIETARY CHANGE

How to make everyday behavior more environmentally friendly has been on the agenda for nearly a half-century, and much has been learned. Both external and internal barriers must be overcome. There has been an optimistic belief in the use of information in the hope of fostering environmentally

sound behavior among members of the general public. However, it has been found that there is no automatic link between knowing and doing. Norms, values, feelings, and consumption opportunities have been shown to be a vital part of the picture.

However, there are several policy tools, in addition to information, that can be used for changing everyday behavior, and they differ in influence and effect (Table III).

Four groups of policy instruments can be identified—information, economic instruments, administrative instruments, and physical improvements—and they are often used in various combinations to increase efficiency.

Information can be mediated in several ways. When conveying environmental information about products, written information in pamphlets and advertisements is often used, as is product labeling. The common denominator for all of these ways is that they should attract attention. The receiver of information is supposed to notice and benefit from the new arguments voluntarily.

Economic instruments include taxing, pricing, and refund schemes. Besides increasing the costs for pollution and providing economic benefits for environmentally friendly consumption, these instruments inspire polluters to reflect over changes in behavior or use of technology and to make plans for behavioral change to minimize the costs for polluting the environment. Economic instruments function as catalysts for changes in the future.

Administrative instruments have an immediate effect on all of the actors they are intended to affect from an announced date. The success depends largely on the negative sanctions with which those with deviant behavior are punished. Examples include fines, imprisonment, and prohibition of trade.

Physical improvements, such as construction of waste depositories and bicycle lanes, are intended to facilitate a new pattern of behavior. Such improvements are very often combined with some other instrument pushing the behavior in the same direction. For example, separate lanes for cars and bicycles are followed by traffic rules regulating where the two kinds of vehicles may be driven.

TABLE III

Policy Instruments, Influence on Actors, and Effects

Instrument	Influence	Effect
Information	Voluntary	Slow
Economic instruments	Catalytic	Short range
Administrative instruments	Immediate, forcing	Middle range
Physical improvements	Reminding, repeating	Change habits

From this knowledge, it is obvious that information will be more efficient if it is combined with other policy instruments. As an example, if households are given life cycle-based environmental information about their diets and food choices, the chances that they will lower environmental impacts of their diets increase if (1) there are tax subsidies for low-polluting food products (economic instrument), (2) the sale of food products with very high environmental impacts is prohibited (administrative instrument), and (3) a steady and diverse supply of low-polluting food products is available in nearby shops and restaurants (physical improvement).

Having reviewed the various policy instruments and how they can be integrated, this article now presents some results from research where the potential or actual impacts of environmental information given to households have been tested. In both of these examples, scientific methods were used for evaluation.

4.1 Negative versus Positive Labels

A team of environmental psychologists tested the impact of negative versus positive ecolabels on consumer behavior. The background was that all ecolabels today signal a positive outcome, for example, "Choose this product; it is better for the environment than the average product." Another strategy would be to signal a negative outcome with the purpose of making consumers avoid a product. A laboratory test was carried out on 40 students in Sweden who were asked to choose between products labeled with a three-level ecolabel inspired by traffic lights: red, green, and yellow. The red label was defined as much worse in terms of environmental consequences than the average, the green label was defined as much better than the average, and the yellow label was defined as average. All participants were asked to rate the importance attached to environmental consequences when purchasing everyday commodities. The results showed that those who attached high importance to environmental consequences when purchasing everyday commodities were most strongly affected by ecolabels of any kind. The results also showed that those who attached little importance to environmental consequences when purchasing everyday commodities were unaffected by any kind of label. However,

those who had an intermediately strong interest in environmental issues were more affected by the red label than by the green one. The conclusion was that the ecolabels in use today affect mostly individuals with a strong interest in environmental issues and that a negative label influences a wider range of individuals.

4.2 Households and Researchers in Partnership When Experimenting with Alternative Diets

In a research project titled "Urban Households and Consumption-Related Resource Use," 10 households participated in an experiment where they tried to reduce life cycle energy inputs related to their food consumption. A manual for low-energy foods habits was developed, and based on this information, the households planned and implemented food habits demanding fewer life cycle energy inputs. The effect of participation in the experiment was evaluated.

Among the changes of most importance for lowering energy inputs were a reduction in consumption of meat (mostly pork); an increase in vegetables and fruits, especially vegetables grown in the open; an increase in poultry, eggs, and fish; and an increase in legumes. The households frequently bought organic food, chose products from Sweden instead of imported ones, and used electric kettles for boiling water for coffee and tea as part of their efforts to achieve more energy-efficient diets. Life cycle energy inputs decreased by at most a third. Environmental aspects other than energy inputs (e.g., animal welfare) were also important to the households. Some recommendations, such as supplementing meat with pulses, were hard to follow because the households did not know how to prepare them.

The overall conclusion from this project was that it takes time to educate households to become "green" and that forces from both inside and outside the household must support such an effort. Being involved in an experiment can affect everyday habits, as can feedback on one's own resource use. However, misconceptions and distrust are deeply rooted, and complex information is difficult to convey to consumers. All of this must be considered if we want to count on the collaboration of households for ecologically sustainable development. Table IV shows the changes in food consumption that occurred as a result of the experiment.

TABLE IV

Changes in Quantities of Food Consumed in the 10 Households Participating in the "Urban Households and Consumption-Related Resource Use" (URRU) Project

Food category	Percentage change
Legumes and seeds	132
Egg	97
Poultry	55
Vegetables	86
Fruit, berries, and jam	25
Fish	22
Pork	−30
Lamb	−22
Bread, beef, drinks, fermented milk, cheese, and yogurt	Negligible
Food composed of several food items, porridge and cereals, potatoes, pasta and rice, pastries and sweets, ice cream and desserts	Negligible

Source. Carlsson-Kanyama *et al.* (2002).

5. CONCLUSIONS

Greenhouse gas emissions and energy inputs in the current food system are substantial. Results from case studies of food products followed throughout their life cycles show important differences depending on animal or vegetable origin, degree of processing, transportation distance and mode of transport, preparation methods, and so on. This leaves room for discussing dietary change as a mitigation strategy for curbing climate change. The theoretical potential for such a strategy is large and is open mainly to affluent consumers.

A successful mitigation package will have to recognize that a combination of policy instruments will be most efficient and that any information applied by itself will have a slow change potential. However, there are many different ways in which to produce and disseminate information that will affect the outcome in terms of changes in general behavior. In general, information with feedback is more efficient than one-way communication. Moreover, involving households in experiments with alternative lifestyles has been shown to produce lasting results. Information should also be tailored to the everyday situation of the household for most impact. Although current global trends in food consumption are not promoting higher environmental efficiency, there are some trends that could develop in that direction.

Policymakers should recognize and support such trends for successful mitigation.

Discount Rates and Energy Efficiency Gap

RICHARD B. HOWARTH
Dartmouth College
Hanover, New Hampshire, United States

1. Introduction
2. The Hidden Costs Argument
3. High Discount Rates?
4. Imperfect Information and Bounded Rationality

Glossary

bounded rationality The notion that people behave in a manner that is nearly but not fully optimal with respect to their goals as their available information and cognitive limitations will allow.

discount rate The rate at which someone prefers present over future benefits in a multiperiod model.

efficiency gap The difference between the actual level of investment in energy efficiency and the higher level that would be cost beneficial from the consumer's standpoint.

imperfect information This refers to a situation in which an individual makes decisions without full knowledge of costs and benefits.

Investments in enhanced energy efficiency typically involve a trade-off between short-term costs and long-term benefits. Consider, for example, a home insulation project that would generate energy savings of $130 per year during a 30-year expected life span. If the project required an initial investment of $900, would it be justified from a financial perspective? A naive answer to this question is that the project would provide a long-term net savings of $3000, thereby warranting its implementation. However, although this type of reasoning seems intuitive to many people, it departs from the standard methods of financial analysis, in which costs and benefits that accrue in the future should be discounted relative to the present.

1. INTRODUCTION

The logic behind discounting is linked to people's observed behavior in financial markets. Suppose, for example, that an investor would receive an r percent rate of return on standard financial instruments such as corporate stocks. If the investor was well informed and rational, then he or she would be willing to pay no more than $B/(1+r)^t$ dollars in the present for an asset that he or she could resell to obtain B dollars t years in the future; otherwise, the investor would be better off investing his or her money at the market rate of return. In this example, economists say that r measures the discount rate or time value of money (i.e., the rate of return that people demand on each unit of investment). Based on typical rates of return in the private sector, analysts commonly use "real" (i.e., inflation-adjusted) discount rates on the order of 6% per year in evaluating projects with average degrees of risk.

More generally, consider a project that would yield a stream of costs and benefits C_t and B_t in years $t = 0, 1, \ldots, T$. In this formulation, year 0 represents the present, whereas the project yields impacts that extend a total of T years into the future. Then the project is considered financially attractive if its net present value (NPV), calculated according to the formula

$$NPV = \sum_{t=0}^{T} (B_t - C_t)/(1+r)^t,$$

is positive. In this event, the project's discounted net benefits exceed the initial investment cost. This implies that the project generates a rate of return that exceeds the discount rate, thereby justifying the investment from an economic perspective.

Given a 6% discount rate, the net present value of the home insulation project described previously is

 © 2004 Elsevier Inc. All rights reserved.

$NPV = -900 + 130/1.06 + 130/1.06^2 + \ldots + 130/1.06^{30} = \$889$. Although this example is purely illustrative, it signals an important fact about real-world investments in energy efficiency: In many cases, energy-efficient technologies are cost-effective in the sense that they generate positive net benefits when evaluated using conventional discount rates.

Empirical work on a broad range of energy use technologies, however, points to an important paradox that is known as the energy efficiency gap. Replacing incandescent light bulbs with compact fluorescents, for example, typically reduces electricity use by 75% while generating simultaneous cost savings. In a similar vein, a study by the U.S. National Academy of Sciences found that the fuel economy of passenger vehicles could be increased by as much as 33% for automobiles and 47% for light trucks (pickups, minivans, and sport utility vehicles) by implementing cost-effective design options that leave vehicle size and performance unchanged. On an economywide basis, the Intergovernmental Panel on Climate Change estimates that the energy use of advanced industrialized nations could be reduced by up to 30% through the full adoption of cost-effective technologies. However, households and businesses have shown little enthusiasm for energy-efficient technologies, so market decisions seem insufficient to realize this potential.

Three interpretations of the efficiency gap have been set forth in the literature:

1. Energy-efficient technologies have "hidden costs" that are overlooked by conventional financial analysis.
2. Households and businesses use unusually high discount rates in decisions concerning energy efficiency.
3. The adoption of cost-effective, energy-efficient technologies is impeded by issues of imperfect information, "bounded rationality," or structural anomalies in markets for energy-using equipment.

The remainder of this article discusses these themes.

2. THE HIDDEN COSTS ARGUMENT

Studies of the costs and benefits of energy-efficient technologies typically employ an engineering approach that accounts for purchase price, operations and maintenance costs, and anticipated energy savings. However, energy use technologies can have intangible costs that are not easily measured. The failure to include such hidden costs introduces a potential bias or source of error in financial analysis.

Consider the case of compact fluorescent light bulbs mentioned previously. Although this technology yields well-documented direct cost savings, it involves two types of hidden costs that are well recognized in the literature. First, compact fluorescent bulbs tend to be bigger and bulkier than the conventional incandescents that they replace. Although progress has been made in addressing this problem since this technology was first mass marketed in the 1990s, the fact remains that compact fluorescents do not work well with certain lighting fixtures. Second, compact fluorescents produce a different light spectrum than incandescent light bulbs. Some people find their light to be "cold" and aesthetically inferior. Although these costs are difficult to measure in financial terms, they legitimately affect people's willingness to adopt this technology.

A second example is provided by the case of automobile fuel economy. In the United States, the energy efficiency of new vehicles is regulated under the Corporate Average Fuel Economy (CAFE) standards that were introduced in response to the Arab oil embargo of 1973. Although these standards have been effective in reducing fuel consumption, some analysts argue that car manufacturers achieved increased fuel economy by reducing the size and weight of new vehicles. Since (all else being equal) the crashworthiness of vehicles is inversely proportional to their size and weight, authors such as Crandall and Graham argue a case can be made that the CAFE standards have compromised safety, increasing highway fatalities by up to 3900 persons per year. This impact, of course, is not reflected in standard engineering studies of the economic costs of improved fuel economy, although it clearly is relevant to the purchase decisions of car buyers. To be fair, it is important to note that the energy savings potential identified by the U.S. National Academy of Sciences attempted to control carefully for this effect. However, safety considerations trump fuel economy in the eyes of many consumers.

In general, examples such as compact fluorescent light bulbs and vehicle fuel economy suggest that the hidden costs issue is a real-world phenomenon with significant implications for consumer decisions. Nonetheless, it is important to consider at least two caveats that cast doubt on the generality of this reasoning. First, certain energy efficiency measures yield intangible benefits that are typically overlooked

in conventional cost calculations. Weather stripping a leaky building shell, for example, yields direct cost savings through reduced energy use. In addition, it improves the comfort of building occupants by reducing drafts and hence the subjective sense that a building is cold. In a similar vein, the use of day lighting in passive solar building technologies can substantially enhance a building's aesthetic appeal, although this benefit is difficult to reduce to simple economic terms.

Second, there are many technologies for which changes in equipment characteristics yield energy savings without altering the quality of energy services provided to end users. In refrigerators, for example, the use of energy-efficient motors and compressors leads to pure energy savings through technical measures that have no observable effect on the equipment's size, functionality, or performance. Similarly, programming computers to enter a "sleep state" during periods of nonuse generates substantial energy savings without reducing the benefits of this technology.

The bottom line is that energy analysts should be aware of and sensitive to issues of comfort, convenience, and safety. In some instances, hidden costs can provide good reasons not to adopt a technology that yields apparent cost savings. On the other hand, there is no good evidence that hidden costs explain the overall empirical magnitude of the efficiency gap.

3. HIGH DISCOUNT RATES?

As explained previously, the discount rate reflects the rate at which people are willing to exchange present and future economic benefits. According to standard economic reasoning, discount rates are revealed by people's observed behavior in markets for savings and investment. A homeowner who takes out a loan at a 4% real (inflation-adjusted) interest rate, for example, reveals a willingness to pay back $3.24 30 years from the present to obtain just $1 dollar today. Similarly, a worker who invests $1 in a mutual fund would expect to receive $10.06 upon retiring three decades in the future given an 8% annual return.

Economists generally agree that market rates of return reveal people's discount rates. It is important to note, however, that different types of financial assets yield different rates of return. In particular, safe investments, such as money market funds, certificates of deposit, and short-term government bonds, yield real returns on the order of just 1% per year. Risky assets such as corporate stocks, in contrast, pay average real returns of 6% or more on a long-term basis. The high returns paid by stocks constitute a risk premium that rewards investors for accepting the fluctuations associated with financial markets.

If households and businesses were well informed and rational, then economic theory suggests that they would discount the benefits of energy-efficient technologies at a rate equal to the market return available on investments with similar risk. In general, the volatility of energy prices implies that the benefits of energy efficiency are uncertain. On the other hand, investments in energy efficiency reduce people's vulnerability to large swings in energy prices. In this sense, energy efficiency measures have ambiguous effects on the overall financial risk faced by households and businesses. In practical analysis, it is common to assume that investments in energy efficiency have risk characteristics similar to those associated with typical private sector investments. In theoretical terms, this assumption favors the use of a 6% discount rate.

Despite this body of theory, empirical studies have found that people behave as if they discounted benefits of energy-efficient technologies at an annual rate far in excess of 6% per year. An early study by Hausman, for example, suggested that people discounted the energy savings provided by air conditioners at a 25% annual rate. Later studies summarized by Train and Ruderman *et al*. pointed to the existence of implicit discount rates ranging from 25% to 300% for refrigerators, heating and cooling systems, building shell improvements, and a variety of other technologies. These studies employ sophisticated econometric and/or engineering–economic models to gauge the rate of time preference at which people's actual technology choices could be considered economically rational. As noted by Howarth and Sanstad, the fact that people reject efficiency technologies that yield high rates of return suggests that actual behavior may diverge from the assumption of perfect rationality.

Analysts such as Hassett and Metcalf have attempted to explain this anomaly by arguing that improvements in the state of technology over time can provide a reason to defer investing in technologies that are apparently cost-effective in the short term. The reason is that purchasing an item such as a fuel-efficient car implicitly raises the cost of buying an even more efficient vehicle a few years later. To better understand this point, consider the case of a mid-1990s computer user weighing the merits of purchasing an upgraded machine. For a cost of

$2000, the user could step up from a good system to a very good system with enhanced speed and performance. Alternatively, the user could defer the purchase for 1 or 2 years and expect to buy a far better machine for an equal or lower price. Hassett and Metcalf reasoned that this type of behavior could explain the high discount rates revealed in markets for investments in energy efficiency.

According to this perspective, the benefits of waiting imply that the early adoption of energy-efficient technologies may have a type of hidden cost (or option value) that is sometimes ignored in naive technology cost studies. An empirical analysis by Sanstad *et al.*, however, suggests that the magnitude of this effect is too small to have much impact on decisions about energy efficiency given anticipated developments in energy prices and the pace of technological change. This line of reasoning therefore appears not to explain why technologies that yield positive discounted net benefits or (equivalently) attractive rates of return are often passed up in markets for energy-using equipment.

4. IMPERFECT INFORMATION AND BOUNDED RATIONALITY

The preceding arguments attempt to explain the paradoxes surrounding discount rates and the efficiency gap in terms of the workings of what Sutherland terms normal or economically efficient markets. An alternative explanation offered by Stanstad and Howarth focuses on market barriers or market failures that impeded the adoption of cost-effective, energy-efficient technologies. In broad terms, at least two sources of market failure are emphasized in this context: imperfect information and bounded rationality.

Behavioral studies have established that households and businesses are often poorly informed about the technical characteristics of energy-using equipment. In summarizing this literature, Stern argues that people's knowledge of opportunities to save energy is "not only incomplete, but systematically incorrect. Generally speaking, people tend to overestimate the amounts of energy used by and that may be saved in technologies that are visible and that must be activated each time they are used." At a cognitive level, many people do not focus on energy trade-offs in making decisions about purchasing goods, such as appliances, new cars, or even a home. This holds true because (i) the energy requirements of most goods are not vividly observable prior to a purchase decision, and (ii) energy costs are typically only a small fraction of the total cost of equipment ownership. Hence, buyers emphasize factors such as a refrigerator's features and aesthetics, a vehicle's acceleration, and a home's location and architecture without fine-tuning their decisions to optimize energy efficiency.

The problem of imperfect information is linked to the concept of adverse selection in information economics. As Akerlof showed in his seminal "markets for lemons" article, low-quality products can crowd out high-quality products in markets in which product quality is not easily observed by consumers. In the case of the efficiency gap, the inference is that poorly informed buyers would pass up opportunities to purchase technologies that would simultaneously save energy and produce net economic benefits.

Issues of imperfect information have been partially addressed through measures such as advertising campaigns and energy labeling for appliances, vehicles, and (in recent years) new homes. According to Robinson, these efforts have typically met with limited success. One reason is that from a psychological perspective, human beings do not have the cognitive capabilities required to make perfectly informed, rational decisions in complex, real-world settings. Instead, Kempton and Layne argue that people are boundedly rational, using simple but cognitively efficient rules of thumb to make decisions in environments that are too complex to be fully understood. The literature on this subject suggests that people aim to achieve goals such as cost minimization but in practice make decisions and are flawed and (in many cases) systematically biased.

In cases in which consumer decision making is marked by imperfect information and/or bounded rationality, targeted policy interventions can often facilitate the adoption of cost-effective, energy-efficient technologies. Under the U.S. Appliance Efficiency Standards, for example, equipment manufacturers must meet minimum performance standards that are explicitly based on the criterion of cost-effectiveness. Studies by McMahon *et al.* and Geller suggest that these standards alone will yield 24 exajoules of energy and $46 billion between 1990 and 2015. These standards are set in a process of information exchange and rule making that involves a relatively small number of technology experts in government and industry. Through this process, technologies are optimized in a manner that does not occur through the engagement of buyers and sellers in the unregulated marketplace.

A second policy that has facilitated the adoption of cost-effective, energy-efficient technologies is the Green Lights program of the U.S. Environmental Protection Agency (EPA). Under Green Lights, the EPA provides technology assistance and public recognition for businesses and nonprofit organizations that voluntarily agree to implement energy-efficient lighting technologies that yield net cost savings without negative impacts on energy services. In its first 5 years of operation, EPA estimates that this program achieved $7.4 billion kWh of electricity savings that remained unexploited prior to its implementation in 1991. According to DeCanio, the typical investment carried out under Green Lights yielded a 45% annual rate of return. This example illustrates how market barriers and the efficiency gap can affect the production sector of the economy as well as how voluntary cooperation between government and the private sector can facilitate improved market performance.

Of course, programs and policies can have administrative costs that should be carefully considered in evaluating their net economic benefits. These costs are small for the U.S. Appliance Efficiency Standards and Green Lights but are quite substantial in certain situations. Joskow and Marron, for example, found that administrative costs are a major component of the total cost of reducing residential electricity use through utility-sponsored demand-side management programs. In addition, regulations that depart from the goal of cost-effectiveness can have unintended negative impacts on product characteristics and consumer choice. This issue is illustrated by the possible increase in highway fatalities caused by the CAFE standards imposed on new vehicles in the 1970s.

Nonetheless, the empirical literature on the efficiency gap suggests that there is ample scope to improve energy efficiency through well-designed policy interventions. In this context, using the net present value criterion and conventional discounting procedures provides a mechanism to identify programs and policies that would enhance consumer welfare and economic efficiency, provided that all of the relevant costs and benefits are taken into account.

Glossary

buyback tariff The price paid to the owner of the distributed energy (DE) resource for electricity sold back to the electricity grid. The price paid depends on how much and when power is exported, how regularly it is guaranteed, and where in the distribution system the DE resource is located (and hence the impact on the operation of the network).

capacity factor Also known as load factor. Electricity delivered during a time period divided by the rated electricity capacity.

combined heat and power (CHP) Also known as cogeneration. The use of waste heat to provide steam or hot water, or cooling via an absorption chiller. This can raise the overall efficiency to over 80%

efficiency Electric efficiency is the total electricity output divided by the total fuel input taking into account generation efficiency and transmission losses. Total efficiency includes the use of waste heat.

heat to power ratio (HPR) The ratio between heat use and electricity generation in a combined heat and power application. For example, if electric efficiency and total efficiency are 30 and 80%, respectively, then HPR = (80−30)/30, or 1.67.

higher heating value (HHV) Includes the heat of vaporization of water. For natural gas, HHV efficiency = lower heating value efficiency/1.1.

installation cost The cost necessary to implement a distributed energy technology or resource in an application. Includes technology cost (dollars per kilowatt), engineering studies, permitting, interconnection, and setup expenses.

interconnection The link between a distributed energy generator and the load being served by the utility electricity network

lower heating value (LHV) Assumes the heat of vaporization of water cannot be recovered. For natural gas, LHV efficiency = higher heating value efficiency × 1.1.

modularity Increments of new capacity that can be simply and flexibly added or removed to change the unit's energy output.

operation and maintenance costs (O&M Costs) These are divided into fixed costs and variable costs depending on the relation to hours of operation and capacity factor.

photovoltaic (PV) cells Also known as solar cells. A distributed energy technology that converts sunlight directly into electricity.

Distributed energy (DE) represents an alternative paradigm of generating electricity (and heat) at, or close to, the point of demand. DE includes fossil technologies (fuel cells, microturbines, internal combustion engines and Stirling engines), renewable technologies (photovoltaics and wind turbines), and energy storage options. Potential DE advantages include higher efficiency and lower cost through waste heat recovery and avoidance of transmission and distribution, reduced global air pollutants, enhanced flexibility of electricity grids, reduced investment uncertainty through modular increments of new capacity, and greater system and infrastructure reliability and security. Potential DE disadvantages include higher costs through loss of economies of scale, higher local air pollution near population areas, economic losses from stranded capital investments in generation and distribution, and increased reliance on natural gas.

1. INTRODUCTION

Distributed energy (DE) represents an alternative paradigm of generating electricity (and heat) at

 © 2004 Elsevier Inc. All rights reserved.

or close to the point of demand. DE includes fossil technologies—fuel cells, microturbines, internal combustion engines, and Stirling engines; renewable technologies—photovoltaics and wind turbines; energy storage options; and energy efficiency. Potential DE advantages include higher efficiency and lower cost through waste heat recovery and avoidance of transmission and distribution, reduced global and local air pollutants, enhanced flexibility of electricity grids, reduced investment uncertainty through modular increments of new capacity, and greater system and infrastructure reliability and security. Potential DE disadvantages include higher costs through loss of economies of scale, higher local air pollution near areas of population, economic losses from stranded capital investments in generation and distribution, and increased reliance on natural gas.

DE has generally been considered and studied in the context of niche applications, as emergency back-up power, or as limited to a small portion of grid-connected electricity supply. In many countries, the economies of scale of centralized generation, the low price of coal as a fuel for electricity generation, and regulatory barriers or disincentives to on-site generation have precluded the widespread adoption of DE. These institutional barriers have included lack of interconnection protocols, low electricity buy-back tariffs, and little consideration of the system's benefits of distributed resources. However, changes in the relative economics of centralized versus distributed energy, the increasing use of natural gas, restrictions on new electricity transmission lines, recognition of the environmental benefits of DE, and improved DE control technologies have resulted in the reconsideration of the widespread use of DE. For example, the Netherlands has seen the greatest penetration of DE technologies. By the year 2000, 6% of national electricity capacity was DE units of <1 MWe and 35% of national electricity capacity was DE units of <50 MWe.

This article gives an overview of DE. Sections 2 and 3 define DE and give an historical context. Sections 4 and 5 summarize the market status of DE and the major DE technologies. Sections 6, 7, and 8 summarize the characteristics of DE technologies including their economic, environmental, and reliability performance, as well as compatibility with existing electricity infrastructure and investment requirements. Finally, Section 9 details the opportunities and barriers to future DE deployment.

2. DEFINITION OF DE

DE has been defined by the size of the technology or by specific technologies. It has also been defined on the basis of connection (connected to either the electricity distribution system or, in some cases, the medium-voltage network), dispatch (not centrally dispatched), whether it is located on the customer side of the meter, and noninclusion in system production optimization studies.

However, defining DE by its relationship to the electricity network ensures that DE is a function of the characteristics of that network. For example, a country dominated by very large centralized units, such as France, may define DE as <100 MWe, but another system configuration, such as that in the Netherlands, may define DE as <1 MWe, or two orders of magnitude smaller. The size range of DE technologies thus varies from a few watts to approximately 50 MWe.

A preferable definition is as follows: Distributed energy represents an alternative paradigm of generating electricity (and heat) at, or close to, the point of demand. This definition allows discussion across national electricity infrastructures and across demand sectors, as various applications may require different characteristics of energy supply and different institutional arrangements may require different coupling to the electricity network. Second, it allows for DE to cover a range of sizes of generation for residential through industrial applications. Third, it emphasizes the opportunity for energy efficiency through the use of waste heat, which cannot be transported across distances outside the immediate area. Fourth, it allows for the consideration of a host of current and future technologies and, crucially, also energy storage and energy efficiency in a broad definition of DE. And finally, this definition does not constrain DE to specific functions within current energy delivery networks. These functions include standby power, peak load shaving, remote sites, and grid support. However, an energy infrastructure based solely on DE, bypassing the need for large-scale electricity generation, is feasible and may be desirable.

3. HISTORICAL DEVELOPMENT OF DE

The shift toward DE can in many ways be viewed as power generation coming full circle. In the 1880s, Thomas Edison's Pearl Street electricity system

serving Wall Street and the surrounding city blocks was distributed power. This paradigm was continued over the next 20 years with schemes in the United States and across the world serving limited urban areas with small-scale direct current (DC) systems. Also popular were installations serving individual factories and supplying electricity and heat in combined heat and power (CHP) applications. One large drawback of using DC was the large losses from this low-voltage system when transmitting power over distance. An alternative system based on alternating current (AC) was promoted by a number of competitors, including George Westinghouse. AC systems had the advantage when serving larger and more spread-out service areas, as the voltage could be stepped up using a transformer to minimize losses. The superiority of the AC system was ensured when, in the late 1880s, Nikola Tesla invented the three-phase AC arrangement, which simplified the number and size of wires, and in 1893 when the universal system, a series of technical standards, allowed the interconnection of AC and DC systems and users.

With technology facilitating AC systems, a significant financial impetus for larger, more centralized systems was the requirement for consistently high-load factors on the electricity network. Large amounts of electricity cannot be stored, thus requiring that demand meets supply at all times. Economical use of the transmission and generation capacity thus requires that a diverse customer base maintain electricity demand through the days and seasons. A combination of residential, commercial, and industrial applications enables the demand profile to be smoothed out as much as possible and this generally requires a large service area.

Another stimulus of larger electricity networks was the availability of energy inputs. Hydroelectric power and coal mines for electricity generation are usually located some distance from population and industrial centers. Either the fuel source was transported to distributed power plants (an impossibility in the case of hydroelectricity sites) or electricity was transmitted at high voltages.

An additional driving force of the centralized electricity network was the rise of natural monopolies. Although the institutional structure of emerging systems was very different, ranging from private companies to state-owned enterprises, competition in electricity generation was viewed as infeasible due to the prohibitive costs of laying competing wires and the institutional difficulties (at that time) of being able to verify and charge for use of an electricity network by different firms and organizations. By the 1930s, industrialized countries had set up large electricity utilities, coalescing around the dominant generation design of the steam turbine. Smaller systems were either absorbed or shut down.

This centralized paradigm led to the developments of larger and larger generating plants as economies of scale were pursued to raise total electricity system efficiencies and reduce costs. The size of the largest generating units jumped from 80 MWe in 1920, to 600 MWe in 1960, to 1400 MWe in 1980. In order to finance these enormous capital investments in generation and related transmission, utility monopolies relied on guaranteed revenue streams from predetermined electricity prices to their "locked-in" customer base. Other advantages of this system included reliability due to the integrated nature of the electricity network and reductions of local air pollution near population centers as generation took place in remote areas. In addition, large-scale nuclear power stations were well suited to this paradigm as they required the enormous initial investment and guaranteed investment recovery promised by the centralized electricity network paradigm.

The turning point of the return to DE came with the oil shocks of the 1970s and the drive toward higher efficiencies. Despite economies of scale, overall electricity system efficiencies were restricted to 30–33% of input energy. A major reason for this was the inability to capture the large amounts of waste heat during the electricity production process and hence renewed efforts were made toward technological and regulatory arrangements to allow distributed CHP facilities with overall efficiencies of greater than 80%. The most impressive technological development was in high-efficiency combined-cycle turbines (CCGT) using natural gas. This technology became the mode of generation of choice, capturing most incremental capacity growth in most markets. Progress on smaller DE technologies (see Section 5) included significant cost, reliability, and emissions improvements of engines, microturbines, fuel cells, and photovoltaics (PV). In parallel, and especially in the past 10 years, there have been developments in control and monitoring technologies. The telecommunications revolution has enabled cheap, real-time operation and integration of small-scale power technologies.

Institutional progress has centered around the drive to restructure electricity markets, from monopolies (often publicly owned) to a competitive generation market in which market participants are free to choose technology type and their customer base. The motivations for this shift were to lower power costs and improve customer choice and also to raise revenues in the case of state-owned enterprises.

A major consequence of this market restructuring was the increase in volatility and the resultant uncertainty in recovering investment costs. Firms were less and less willing to commit huge sums in centralized plants with repayment occurring over decades. The average size of a new generating unit in the United States declined from 200 MWe in the mid-1980s, to 100 MW in 1992, and to 21 MWe in 1998. This is approximately equivalent to the average unit sizes in the years 1915–1920.

Additional incentives have stemmed from changing public pressures. It has become increasingly difficult to build additions to electricity networks, especially near population centers. In addition, the demand for very reliable and higher quality power has emerged, spurred by the rapid penetration of electronic appliances and industrial processes that are extremely sensitive to supply disruptions or degradations. Finally, other energy delivery infrastructures, especially the natural gas system, have emerged to compete with electricity transmission. Energy must be moved from source to demand, but where the conversion to electricity is carried out, and at what scale, will be part of the emerging paradigm to come. This is particularly relevant to developing countries where it may or may not be optimal to construct a capital-intensive centralized electricity network.

4. DE MARKET STATUS

It is extremely difficult, or even impossible, to provide values for the total installed capacity of DE technologies and resources. This is due to the range of technologies, their varying levels of use in different countries, and ambiguity over what constitutes a DE application as unit sizes become larger and units are sited further from demand centers. In addition, some of the most promising technologies, including fuel cells, photovoltaics, and microturbines, either are just entering commercialization or are used only in niche applications. The relative rate of technological progress and the regulatory structure of energy markets will determine to what degree and how quickly DE will penetrate the mainstream market. In addition, fuel constraints, stemming from the availability of natural gas, hydrogen, or other fuel networks, and the available renewable energy resource may limit some of the spread of DE technology.

An example of DE installed capacity from the very broadest definition is the DE database of Resources Dynamics Corporation, which as of 2003 lists DE capacity in the United States at 10.7 million DE units with an aggregate capacity of 168 GW. This constitutes 19.7% of the total U.S. installed capacity, although the definitions in this database include back-up and energy units, remote-application small-scale technologies, and a range of larger CHP units.

Better documented market penetration totals and rates can be given for some countries and DE technologies to elucidate the current and potential global DE market size. The Netherlands has the largest market percentage of DE technologies in the world. During the 1980s and 1990s, this was primarily in the form of natural gas-fired engines of less than 2 MWe each in size. By the end of the 1990s, this DE technology was found in over 5000 installations with 1500 MWe of installed capacity. This represents over 6% of the total national capacity.

The Dutch DE units are primarily operated as base-load, CHP applications. If larger gas turbine units are also considered as DE, then the total DE capacity rises to 7500 MWe or 30% of national capacity. Other DE technologies, including microturbines, fuel cells, and Stirling engines, are being introduced as relative costs, emission characteristics, reliability, and power quality considerations are traded off in different applications.

The range of typical DE applications in the Netherlands is given in Fig. 1. The largest sector was commercial horticulture, with greenhouses providing an ideal DE–CHP application with demands for heat as well as electricity for artificial lighting. The Netherlands has many DE units in various commercial building sectors, including hospitals, industry, multiresidential complexes, industrial sites, and sewage operation facilities, where they can also utilize waste gases.

Other countries, including the United Kingdom, Germany, Japan, and the United States, have also seen considerable penetration of internal combustion (IC) engines as a DE resource. These can be either diesel engines, which are often used for back-up and emergency power (as is common in the United States), or gas engines, which are used in CHP applications and can replace the need for an on-site heat boiler plant, and, depending on the regulatory structure and buy-back tariffs, can provide electricity back to the grid. Figure 2 details the numbers and capacity of total worldwide sales of engines that are 1 to 5 MWe each in size, showing both the growth in overall sales and the trend toward gas-fired base-load DE units.

Finally, regarding a nonfossil DE technology, Fig. 3 charts the shipments of PV units in the United States. The largest sectors have traditionally been in applications that are incorporated into buildings to

provide water heating and electrical requirements and in remote applications, such as communication facilities. However, grid-connected PV units have seen the fastest growth.

5. OVERVIEW OF DE TECHNOLOGIES

DE technologies have a range of technical characteristics, making different technologies more suitable in specific applications, depending on whether the determining criterion is electrical output, provision of usable heat, fuel availability, reliability, or emission levels, to name just a few criteria. However, all DE technologies have the capacity to be remotely operated and controlled. This is achieved through monitoring a range of operating parameters via a communication link and allows simplified maintenance, avoids unexpected shutdowns, and eases the grid control issues that arise from locating DE units within the electric distribution network. Another common characteristic of DE technologies is that following factory fabrication they are straightforward to install, thus minimizing implementation costs.

A useful parameter when comparing DE technologies is the heat to power ratio (HPR). This is the ratio between heat use and electricity generation in a CHP application. For example, if electric and total efficiencies are 30 and 80%, respectively, then HPR = (80−30)/30, or 1.67. Depending on the application, electrical or thermal output may be valued or required. Also, note that all electrical efficiencies in this article are quoted as higher heating value (HHV). This includes the heat of vaporization of water. For natural gas, HHV efficiency = Lower Heating Value efficiency/1.1.

This section provides a brief overview of the major DE technologies, discusses their principal strengths and weaknesses, and provides a quantitative comparison of their technical characteristics (see Tables I and II). This section is designed to be illustrative as site-specific variation, differing models, and continuing technical progress will alter these characteristics. Economic and environmental comparisons are detailed in Sections 6 and 7.

5.1 Engines

Reciprocating IC engines are an established and well-known technology. Engines for stationary power are

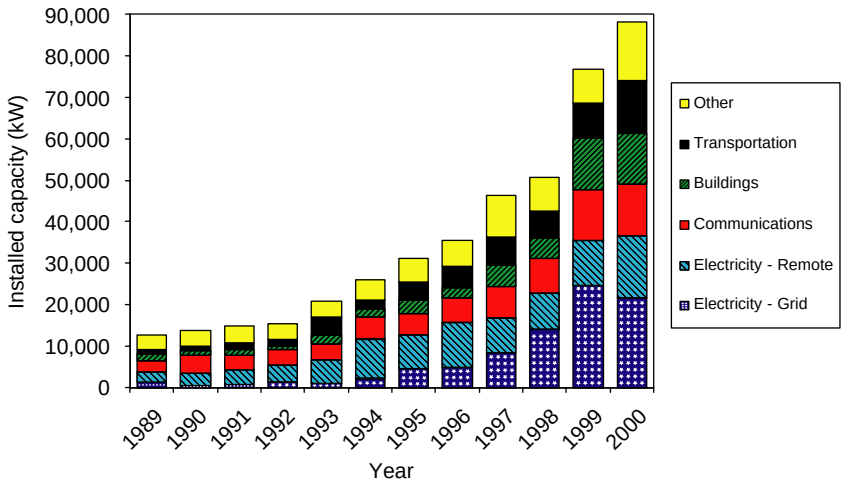

FIGURE 3 U.S. photovoltaic shipments. From Energy Information Administration (2001), Renewable Energy Annual, Table 10, U.S. Department of Energy, Washington, DC.

TABLE I

Qualitative Strengths and Weaknesses of DE Technologies

Technology	Strengths		Weaknesses	
Reciprocating engines	Low capital cost	Fuel flexibility	High air pollutant emissions	Noisy
	High reliability	Quick startup	Frequent maintenance	Thermal output at low temperatures
	Established technology			
Gas turbines	Proven reliability and availability	Low capital cost	Reduced efficiencies at part load	Sensitivity to ambient conditions (temperature, altitude)
	Established technology	High-temperature steam	Required maintenance	
	Larger sizes available			
Microturbines	Compact size	Lightweight	Low electricity efficiencies	Sensitivity to temperature, altitude
	Low emissions	Can utilize waste fuels		
Fuel cells	High electrical efficiencies	Low emissions	High capital costs	Fuel infrastructure constraint
	Quiet	Modular	Reforming natural gas	
	Operates well at part load	High reliability		
	Synergy with vehicle power trains			
Stirling engines	Low noise and vibrationless operation	Low emissions	High capital costs	Low electrical efficiency
	Low maintenance and high reliability	Multifuel capability, including solar power	Durability unresolved	
	Long life			
PV	Low maintenance	No emissions	High capital costs	Intermittency
	Free fuel		By-products of manufacture and disposal	
Wind	Low maintenance	No emissions	High capital costs	Variable power output
	Free fuel		Visual impact

derived from automobile engines. These engines are fired by either natural gas or diesel and use spark ignition or compression ignition depending on the compression ratio used. A typical energy balance is electricity, 26–39% (this range is due to type, size, and operation of engine); useful heat, 46–60%; losses (radiation from engine and exhaust, lubrication, gearbox, generator), 10–20%.

Power production engines are typically less than 1 MWe and have become the most common DE technology for both standby and peaking applications and are increasing in use as base-load combined heat and power units. Engines have low capital costs and high reliability, although they require a regular maintenance and overhaul schedule. Regular maintenance is essential for good performance and ranges from weekly oil changes to major overhauls after 25,000–40,000 h of operation. Heat recovery is from the engine jacket and cylinder head cooling water and from the hot engine exhaust, resulting in hot water at 80–120°C. A combination of combustion modifications and the use of catalytic converters has greatly reduced local air pollutant emissions, although in this regard engines are still inferior to other DE technologies.

5.2 Gas Turbines

Derived from aero-applications, power generation with gas turbines is commonplace, with an extensive installed capacity and sizes ranging from 500 kWe to ≥ 50 MWe. Low maintenance costs and high-grade heat recovery have made gas turbines a favorite in industrial DE applications.

The unit has a turbine and compressor on the same shaft and compressed combustion products at high temperature drive the turbine. Compressor losses and materials restrictions inhibit the upper temperature of the cycle and thus constrain efficiency. Hot exhaust gases are used to preheat incoming air (regeneration). The remaining thermal energy of these exhaust gases can be reclaimed as waste to heat a boiler. A typical energy balance is as follows: electricity, 30%; high-grade heat, 50%; stack losses, 14.5%; other losses, 6.5%. Turbines are classified as temperature-limited cycles and increases in efficiency continue to occur through materials developments and cooling technologies to allow the turbine to run at higher maximum temperatures.

5.3 Microturbines

Microturbines follow the same cycle as conventional gas turbines, although they are at a less developed stage of commercial development. Their development has come from the design of small, very high speed turbines (with compressors on the same shaft) rotating up to 100,000 rpm. Additional scaling down of components, particularly nozzles and burners, has been achieved. The marketed size range is 30–500 kWe.

Microturbines use regeneration, with resultant lowered exhaust gas temperatures (~ 300°C). The unit is air-cooled. Maintenance requirements are reduced due to the elimination of an oil-based lubricating system in favor of air bearings and because the microturbines have no gearbox. Efficiencies are a few percentage points less than those of conventional gas turbines, due primarily to lower operating temperatures.

5.4 Fuel Cells

Fuel cells convert chemical energy directly into electrochemical work without going through an intermediate thermal conversion. Thus, the second law of thermodynamics does not apply, they are not limited by Carnot's theorem, and, therefore, they offer the potential of very high electrical efficiencies. In a fuel cell, the fuel (H_2) and the oxidizer (O_2) are supplied continuously (unlike in a battery). A dynamic equilibrium is maintained, with the hydrogen being oxidized to water with electrons going around an external wire to provide useful electrical work. A major limitation of fuel cells is that direct efficient oxidation of natural gas (CH_4) is not yet possible. Therefore, a reformer is used to convert CH_4 to H_2, with resulting losses in overall efficiency and creation of CO_2 as a by-product.

There are four main types of fuel cells in development. Fuel cells can either use additional heat for the reformer or their own waste heat. They are compared in Table III.

Fuel cells have many admirable qualities for power production including a high potential efficiency, no loss in performance when operating at partial load, ultralow emissions, and quiet operation. Their high capital costs are a major barrier to development.

5.5 Stirling Engines

Stirling engines are an external combustion engine, where the fuel source is burned outside the engine cylinder. This energy source drives a sealed inert working fluid, usually either helium or hydrogen, which moves between a hot chamber and a cold chamber. Stirling engines can be very small in scale (as little as 1 kWe), which in combination with very

TABLE III

Categorization of Major Fuel Cell Types

Type	Operating temperature	Reforming	Efficiency (HHV)	Comments
Phosphoric acid (PAFC)	200°C	External heat required	33–40%	Commercialized
Proton-exchange membrane (PEMFC)	80–100°C	External heat required	33–40%	Poisoned by traces of CO
Molten carbonate (MCFC)	600–650°C	Internal heat	48–55%	Internal reforming can cause variable H_2
Solid oxide (SOFC)	900–1000°C	Internal heat	42–58%	Current R&D favorite

low maintenance, low noise, and low emissions makes them ideal for residential CHP applications. Another advantage of Stirling engines is that they can utilize almost any fuel, including direct solar energy. However, significant challenges remain in reducing the high capital costs and overcoming remaining technical barriers, primarily related to durability.

5.6 Photovoltaics

PV cells, or solar cells, convert sunlight directly into electricity. PV cells are assembled into flat plate systems that can be mounted on rooftops or other sunny areas. They generate electricity with no moving parts, operate quietly with no emissions, and require little maintenance. An individual photovoltaic cell will typically produce between 1 and 2 W. To increase the power output, several cells are interconnected to form a module. Photovoltaic systems are available in the form of small rooftop residential systems (less than 10 kWe), medium-sized systems in the range of 10 to 100 kWe, and larger systems greater than 100 kWe connected to utility distribution feeders.

Two semiconductor layers in the solar cell create the electron current. Materials, such as silicon, are suitable for making these semiconducting layers and each has benefits and drawbacks for different applications. In addition to the semiconducting materials, solar cells consist of two metallic grids or electrical contacts. One is placed above the semiconducting material and the other is placed below it. The top grid or contact collects electrons from the semiconductor and transfers them to the external load. The back contact layer is connected to complete the electrical circuit.

Commercially available PV modules convert sunlight into energy with approximately 5 to 15% efficiency. Efforts are under way to improve photovoltaic cell efficiencies as well as reduce capital costs. Considerable attention is also being given to fully building-integrated PV cells, where the PV cells are an alternative to other construction materials. A principal drawback of PV cells is their reliance on an intermittent power source.

5.7 Wind Turbines

Wind-based power generation may or may not be a DE technology, depending on whether it is located near the demand source or at a remote wind farm. Generally, wind turbines are located in areas with good winds and have annual capacity factors ranging from 20 to over 40%. The typical life span of a wind turbine is 20 years. Maintenance is required at 6-month intervals.

A wind turbine with fan blades is placed at the top of a tall tower. The tower is tall in order to harness the wind at a greater velocity and to be free of turbulence caused by interference from obstacles such as trees, hills, and buildings. As the turbine rotates in the wind, a generator produces electrical power. A single wind turbine can range in size from a few kilowatts for residential applications to greater than 5 MW.

Drawbacks of wind power include high capital costs and reliance on an intermittent resource.

5.8 Energy Storage

Energy storage technologies produce no net energy but can provide electric power over short periods of time. The principal storage options include the following.

5.8.1 Battery Storage

The standard battery used in energy storage applications is the lead–acid battery. A lead–acid battery reaction is reversible, allowing the battery to be reused. There are also some advanced sodium–sulfur, zinc–bromine, and lithium–air batteries that are

nearing commercial readiness. Batteries suffer from limited storage capacity and environmental concerns over their manufacture and disposal processes.

5.8.2 Flywheel

A flywheel is an electromechanical device that couples a motor generator with a rotating mass to store energy for short durations. Conventional flywheels are "charged" and "discharged" via an integral motor/generator. The motor/generator draws power provided by the grid to spin the rotor of the flywheel. Traditional flywheel rotors are usually constructed of steel and are limited to a spin rate of a few thousand revolutions per minute and hence offer limited storage capacity.

5.8.3 Superconducting Magnetic Energy Storage

Superconducting magnetic energy storage (SMES) systems store energy in the field of a large magnetic coil with DC flowing. It can be converted back to AC electric current as needed. Low-temperature SMES cooled by liquid helium is commercially available. High-temperature SMES cooled by liquid nitrogen is still in the development stage and may become a viable commercial energy storage source in the future. SMES systems are large and generally used for short durations, such as utility switching events.

5.8.4 Supercapacitor

Supercapacitors (also known as ultracapacitors) are DC energy sources and must be interfaced to the electric grid with a static power conditioner. Small supercapacitors are commercially available to extend battery life in electronic equipment, but large supercapacitors are still in development.

5.8.5 Compressed Air Energy Storage

Compressed air energy storage uses pressurized air as the energy storage medium. An electric motor-driven compressor is used to pressurize the storage reservoir using off-peak energy and air is released from the reservoir through a turbine during peak hours to produce energy. Ideal locations for large compressed air energy storage reservoirs are aquifers, conventional mines in hard rock, and hydraulically mined salt caverns. Air can be stored in pressurized tanks for small systems.

5.9 Hybrid Systems

A combination of various DE technologies or inclusion of energy storage options (including batteries and flywheels) has been proposed to overcome specific limitations (e.g., intermittency) and to boost primary performance characteristics (e.g., electrical efficiency). Several examples of hybrid systems include the following:

- Solid oxide fuel cell (SOFC) combined with a gas turbine or microturbine;
- Stirling engine combined with a solar dish;
- Wind turbines with battery storage and diesel backup generators;
- Engines combined with energy storage devices such as flywheels.

The SOFC/gas turbine hybrid system can provide electrical conversion efficiencies of 60 to 70%, through a combined cycle where the waste heat from the fuel cell reaction drives a secondary microturbine. Stirling engine/solar dish hybrid systems can also run on other fuel sources during periods without sunlight. Wind turbines can be used in combination with energy storage and some type of backup generation (e.g., an IC engine) to provide a steady power supply to remote locations not connected to the grid. Energy storage devices such as flywheels are being combined with IC engines and microturbines to provide a reliable backup power supply. The energy storage device provides ride-through capability to enable the backup power supply to get started. In this way, electricity users can have an interruption-free backup power supply.

6. ECONOMIC CHARACTERISTICS OF DE

6.1 DE Technology Comparison

Table IV details the major cost parameters of DE technologies. These values are intended only to be illustrative due to the site-specific and application-specific factors that alter individual plant costs. Installed cost covers the capital price of the unit plus implementation costs to connect the unit to its electric load and integrate it with its fuel infrastructure, the electricity network, and, if required, the heating system of the building. Operation and maintenance (O&M) costs cover regular maintenance and scheduled overhauls. Fuel costs are based on typical U.S. prices for industrial customers and do not include any additional mark-up from distribution to commercial or residential sites.

As Table IV shows, the more mature DE technologies, engines, gas turbines, and wind turbines, have

TABLE IV

Economic Comparison of DE Technologies

	Installed cost ($/kWe)	O&M cost (cent/kWh)	Input fuel cost (cent/kWh)
Reciprocating engines			
Gas	600–700	0.8–1.4	0.7–1.7
Diesel	300–400	0.7–1.2	0.8–1.5
Gas turbines			
Simple	500–700	0.2–0.8	0.7–1.7
Micro	800	0.3–1	0.7–1.7
Fuel cells			
MCFC	2500–3000	0.3	0.7–1.7
PAFC	3000	0.3–0.5	0.7–1.7
PEMFC	3000–4000	0.1–0.4	0.7–1.7
SOFC	2500–3000	0.2–0.3	0.7–1.7
Stirling engines	2500–4000	0.1	0–1.5
PV	5000–8000	0	0
Wind	850–2500	0.1	0

Note. MCFC, molten carbonate fuel cell; PAFC, phosphoric acid fuel cell; PEMFC, proton-exchange membrane fuel cell; SOFC, solid oxide fuel cell.

the lowest costs. DE technologies utilizing renewable resources have the advantage of an essentially free fuel. Finally, a number of DE technologies with highly appealing technical and environmental characteristics (fuel cells and PV) have high capital costs that are a focus of considerable research and development efforts.

The more mature DE technologies are competitive with centralized electricity generation, especially if they are operated as CHP units, and the comparison is made with both electricity generation and on-site heat boilers. Any investment in DE technologies will depend on a number of site-specific factors including fuel availability, input fuel costs, average and peak power and heating requirements, and the negotiation of interconnection, emergency backup, safety, maintenance, and electricity export charges and tariffs. In addition, DE is likely to impose charges or produce benefits for the wider electricity network, including reduced use of existing assets, retention of stand-by capacity, or the defraying of costs of distribution upgrades.

DE technologies have additional characteristics that influence their economic attractiveness. Whereas centralized units benefit from economies of scale from larger plant size, DE technologies achieve economies of scale through mass production. This effect is expected to be enhanced by the phenomena of learning by doing and of learning by using in the production and use by early adopters. In addition, DE technologies that require significant maintenance benefit from economics of geographic scale. As a greater density of DE units is installed in a given area, the cost of maintaining each unit falls because a significant proportion of maintenance costs arises from on-site visits to maintain and repair the DE unit. Taken together, as more and more DE units penetrate the market, the economic costs of any single unit will fall, leading to higher levels of dispersal and a cycle of improving economics.

A number of factors will limit this cycle of improving costs, including costs imposed on the electricity network, less suitable sites and applications for DE units, rising costs on input fuels, and stresses on the fuel infrastructure. Unless the DE unit is powered by renewable resources at the point of use, the primary fuel delivery infrastructure will likely be natural gas. A rapid rise in natural gas demand from DE technologies will be tempered by rising natural gas prices and increasing delivery costs as the gas network is extended and reinforced.

A final general driving force of economic costs is path dependency. The lifetime of traditional large-scale energy investments (both plants and networks) is measured in years or decades. This gives rise to path-dependent technological trajectories that can "lock-in" energy supply into nonoptimal portfolios of generation and transmission infrastructure. As large amounts of DE market penetration would amount to a paradigm shift in the generation and supply of energy, closing of an older plant and bypassing of existing transmission capacity may allow a more efficient overall system, especially if DE technologies are operated as CHP plants. However, recompense for long-lived generation and transmission assets remains one of the most contentious issues as energy markets are liberalized.

6.2 Valuing DE within Electricity Networks

The benefits or costs that DE technologies bring to an electricity network are a function of the level of penetration. If DE is limited to a relatively small percentage of overall capacity, it can be incorporated into the existing paradigm of remote generation of electricity with extensive transmission and distribution networks. Within this paradigm, DE can fulfill a number of functions in addition to providing electricity and heat to individual customers. These include

grid reinforcement, standby power, meeting peak demands, remote sites, and hedging against fuel volatility.

The use of DE in areas where it is difficult or expensive to upgrade the distribution network can alleviate bottlenecks in the system and enable greater system capacity and reliability. For grid reinforcement benefits to occur, utilities should know, at a minimum, when, where, and how much electricity will be exported to the grid. The use of DG for network management is much improved if utilities also have some measure of control over DG resources. DE can also be used for peak shaving to meet demands for electricity at times of highest usage. This can be particularly cost-effective using low-capital-cost DE technologies, such as engines. Other DE technologies can be used in remote areas where it is not economically feasible to extend the distribution network. Historically, this has been the application where renewable DE technologies have been employed, despite their high capital costs. Finally, as DE technologies have a range of fuel sources, including natural gas, waste gases, oil, and renewable fuels, they can contribute in a portfolio of supply technologies to hedge against volatility in fuel costs.

As DE capacity increases in the electricity sector, a range of issues related to costs imposed on the wider electricity sector become more prominent. If, as in many developing countries, the national electricity grid is only in its infancy, then a system based on DE and alternate fuel delivery options is perfectly feasible and will offer distinct characteristics in terms of environmental, economic, and reliability performance. However, in all developed nations, a national electricity network that has been designed to move large amounts of power from remote generation sites to meet a diverse set of demand loads is already in place. Incorporating DE into this system necessitates consideration of interconnection, buy-back (or export) tariffs, net-metering, stranded investment costs, and impacts of changing demands.

A general theme in the relationship between DE and the electricity network is that DE users should compensate the utility for any costs imposed on the centralized network, but also be rewarded for any benefits the use of DE gives to the network. Experience has shown that coordination between users, utilities, regulators, and technology vendors is essential for optimal use and recompense of DE to be achieved. Specific regulatory structure will dictate whether utilities can be direct partners in DE projects. Utilities constrained by a cost plus revenue arrangement, where their income is driven by the amount of electricity that flows down their wires, are most likely to view DE as a threat to their core business.

Interconnection charges are imposed on the DE user to connect a unit to the electricity network for both emergency and backup power and to allow export of DE-generated electricity back to the grid. The general small size of DE schemes makes individual assessments impractical and cost-prohibitive and a number of countries have, or are developing, protocols for simple and equitable interconnection of DE. Buy-back tariffs (or prices for electricity export) are the price paid to the DE user for electricity sold back to the grid. The fair price for this electricity will depend on where the DE unit is located in the distribution network, how much electricity is exported, when it is exported (especially in reference to peak demand times), and whether electricity exports are guaranteed. Figure 4 illustrates the range in electricity buy-back tariffs in the Netherlands and United Kingdom. Larger volumes for longer periods of time are valued more highly. The overall difference between the two countries is a result of the level of cooperation with the incumbent utilities and their willingness to use DE as an integral part of their generation and distribution portfolios. An extension of buy-back tariffs is net-metering, where a DE user can reverse the flow of electricity from the grid to offset electricity purchases at other times. A flat rate for net-metering unfairly imposes costs on the electricity utility, whereas flexible net-metering tariffs dependent on time, place, and level of guarantee have much to recommend them.

Wider cost issues for electricity networks include stranded assets, where a capital-intensive generation and distribution plant is not utilized and hence does not recover its investment. This can also occur if

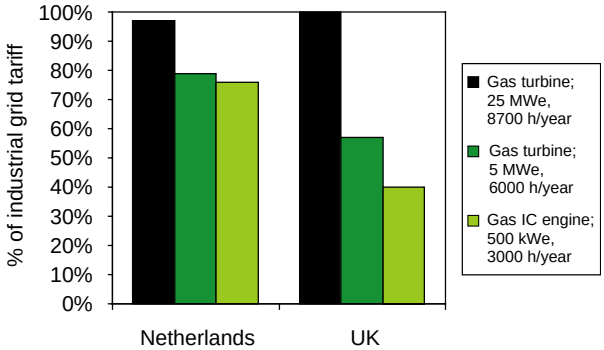

FIGURE 4 Electricity buy-back tariffs for DE technologies. From Cogen Europe (1995), The Barriers to CHP in Europe, SAVE Program of the European Commission, Brussels, Belgium.

capacity must be kept available to meet energy demands from DE unit failure. As electricity markets have been liberalized in many countries, recompense for stranded investments has been a dominant feature of the regulatory debate. Finally, as DE capacity grows, it will affect the demand profile of the area the electricity network serves. If the DE units primarily meet base-load demand, the remaining load will become more variable and hence more expensive to service with a conventional centralized generation portfolio.

7. ENVIRONMENTAL CHARACTERISTICS OF DE

DE technologies exhibit a range of emission characteristics. Carbon dioxide (CO_2) and sulfur dioxide (SO_2) emissions depend only on the carbon or sulfur content of the fuel and the efficiency of generation and supply. Local pollutants including nitrogen oxides (NO_x) also depend on the specifics of the combustion or generation process. The relative environmental performance of DE depends on what centralized electricity technology and fuel they are competing against and whether the DE technology is being used for electricity only or CHP applications. If it is a DE–CHP application, then the emissions from the heat boiler plant must also be factored in. Higher relative DE efficiencies are also aided by the avoidance of electricity distribution losses. Further issues in comparing environmental characteristics of technologies include what control technologies are assumed to be fitted and whether the comparison units are the average of the installed capacity base or only of new units.

Table V gives the latest controlled technology, efficiencies, and controlled emission rates of a range of DE technologies, as well as for a centralized coal steam turbine plant, combined cycle gas turbines (CCGT), and an on-site heat boiler plant. For calibration to alternative units, 1 lb/MWh is approximately equivalent to 0.45 g/kWh and approximately equivalent (for NO_x only) to 22 ppm.

Table V shows that some DE technologies (fuel cells, Stirling engines, PV, and wind turbines) have very low levels of global and local air pollutants. Diesel engines and coal steam turbines are the most polluting distributed and centralized technologies, respectively. Although CCGT is a much cleaner centralized technology, once emissions from heat boilers are factored in, even gas engines are equivalent in emission rates for CO_2, SO_2, NO_x, and particulate matter (PM_{10}). Engine emissions of carbon monoxide (CO) and unburned hydrocarbons (HC) remain a significant problem.

Comparing emission rates is only a first step in evaluating the environmental impact of DE technologies. It is also important to note that emissions will occur closer to population centers, and hence increase the health impacts of local air pollutants, and may also happen at specific times when environmental loading is at its peak. An example of this would be significant levels of diesel engine use in urbanized areas during hot summer afternoons when ozone (O_3) formation is at its peak. Thus, the specific health and environmental impacts of significant DE use require atmospheric

TABLE V

Emission Characteristics of DE and Power/Heat Technologies (lbs/MWh)[a]

	Control technology	CO_2	SO_2	NO_x	CO	PM_{10}	HC	Mercury (Hg)
Reciprocating gas engine	Ignition timing and SCR	1394	0.08	1.11	4.01	0.03	1.20	0

[a] Divide by 2.2 to convert to g/kWh.

SCR, selective catalytic reduction; FGD, flue gas desulfurization.

modeling. As many DE technologies have thus far been "under the radar" in regulatory efforts for air pollution, such detailed analysis will be paramount.

Finally, it should be noted that there are non-emission environmental issues that ensure that all DE technologies have some environmental concerns to be addressed. Noise pollution, particularly near workplaces and residences, is a concern (see Table II for uncontrolled noise levels of DE technologies). Even renewable DE technologies with no noise or air pollution consequences need to address concerns over hazardous materials during manufacture and disposal (PV and batteries) or visual impacts (wind turbines).

8. OTHER CHARACTERISTICS OF DE

8.1 Reliability

Reliability considerations for DE can be divided into plant and system impacts. At the plant level, high levels of availability of DE units are achieved through remote monitoring and real-time control. As there can be a large number of DE units, reliability can be ensured for scheduled maintenance and unscheduled outages by transferring the electricity load to the remaining DE units. Building or process management systems can turn off nonessential loads if required. Energy storage devices can also be used to maintain supply for short periods. Finally, the dual-fuel capabilities of many DE technologies or the use of different DE units at the same location can ensure supply in the case of fuel disruptions.

In comparing DE reliability to a centralized electricity network, it should be noted that the existing electricity grid is extremely reliable, operating in excess of 99.9% availability. The majority of outage events in the centralized network are due to accidents and climatic events in the transmission and especially distribution system. DE offers a route to bypass these outages. In addition, in countries such as India, where widespread theft of electric power from the distribution network, and hence reduced reliability, is commonplace, DE can offer an alternative.

The comparison, and possible coordination, between DE and the electricity network depends on which generation source is the back-up. Traditionally, the electricity grid has been employed as emergency or stand-by generation for DE units. This imposes costs on the electricity grid (see Section 6.2) as the utility must maintain spare generation and distribution capacity to meet a potential additional load from a DE outage event. However, this disadvantage is avoided if a cluster of DE units can provide emergency power without the grid. Taking this paradigm one step further, a DE cluster can act as a source of emergency or stand-by generation to the grid, especially in times of peak demand when generation costs or distribution bottleneck issues are of utmost concern.

A final reliability issue is the comparison between the electricity network and the fuel distribution (primarily natural gas) that DE units would depend on. This is discussed below in the context of robustness.

8.2 Robustness

The robustness of an energy generation and distribution network has received considerable attention for its performance under conditions of conflict, whether in terms of war or terrorist events. A system based on DE would do little to alleviate dependence on oil imports, which is primarily related to transportation. On an individual generation unit basis, the small size and low profile of DE units make them a less important target. Although DE can be powered by a range of renewable, waste, and fossil fuels, the reliance on a natural gas infrastructure has been debated and compared to the system robustness of the electricity network. Table VI details some of the advantages and disadvantages of a natural gas DE network.

8.3 Power Quality

Evolving demands for high-quality electricity in a range of sensitive industrial processes and information technologies has refocused attention on the need for extremely high-quality power. DE technologies can help respond to this demand in a number of ways. The use of DE technologies can avoid movement of electricity where the majority of power quality problems, especially voltage sags, occur. Energy storage devices are a DE resource that is often used to provide uninterrupted power supply either as a support to the power grid during periods of very short term instability or as a bridge to allow stand-by DE technologies to begin operation and ramp up to meet the required load.

TABLE VI

Potential Robustness Advantages and Disadvantages of DE Systems

Features of natural gas DE	Conflict context advantages	Conflict context disadvantages
Increased number and smaller size of DE generators	When one generator is damaged, a much smaller proportion of the generating capacity is unavailable	Harder to physically protect individual generation sites
Greater use of natural gas	May replace nuclear facilities	More prone to risks of foreign supply interruptions (pipelines and LNG)
Decreased reliance on electricity transmission and distribution	The electricity T&D system is harder to protect than generators; having generation close to the load reduces the reliance on the vulnerable transmission system	Unless DE units are arranged in clusters to back up one another, may still have to deal with electricity grid outage effects
Increased reliance on natural gas transmission and distribution	Underground natural gas T&D systems (which would be needed anyway for on-site heat-only plants) are generally underground and therefore better protected than electrical T&D lines	Long-distance over-ground natural gas pipelines are very difficult to protect and are vulnerable to attack (with explosives or high-powered rifles)
T&D real-time operational advantages	Gas pipelines do not have the same strict real-time operational problems as electric power grids; in electric power grids, a disturbance to one part of the grid can result in cascading failures that knock out power to a much wider area than the original disturbance	
Fuel substitutability and storage	A natural gas DE system can have greater robustness through dual fuel technologies and local storage facilities for gas and/or other fuel suitable for use in ICE DE units	A centralized electricity network can also build in a diverse supply portfolio

Note: T&D, transmission and distribution; LNG, liquified natural gas.

As there are a range of customer types, each requiring, and willing to pay for, a range of power quality levels, those users requiring extremely high quality power (e.g., information technology firms) have been investigating the concept of microgrids, where a range of DE technologies, along with energy storage options, are geared to provide very high quality power in a designated geographical area. DE microgrids could be based on DC power if required for sensitive electronic equipment.

8.4 Modularity

A final characteristic of DE technologies is that they represent modular or increment investment and capacity additions, especially in comparison to large centralized power plants. This feature has been even more advantageous following the liberalization of many nations' electricity industries and the resultant increase in electricity price uncertainty. The ending of the monopoly systems where investment revenues were guaranteed to be recovered has placed a premium on projects with a shorter, less expensive construction period. Many factory-made and –assembled DE units come packaged with heat recovery, acoustic enclosure, and control interface and can be installed at a site and connected to the electricity and heating systems in 1 or 2 days.

In addition to improving investment under price uncertainty, modular capacity extensions can more easily follow increments in demand growth, alleviating shortages in generation capacity. Adding further value, the geographical flexibility of modular DE capacity allows it to alleviate bottlenecks in the distribution capacity. Finally, mobile DE units can be quickly moved to meet peak demand periods or moved on a seasonal basis to meet climate-driven high-demand periods.

9. FUTURE ROLE OF DE

The traditional policy driving forces for DE, and indeed for all energy supply and distribution options, have been the lowest economic cost and security of supply. Increasingly, motives for evolving policies will also be concerns over global and local environmental issues, reliability, robustness, and quality of electricity supply, and integration with energy infra-

structures, notably electricity, natural gas, and any future hydrogen infrastructure.

Along with continuing technical developments in DE technologies, cost reductions will be largely delivered by economies of scale in production, geographical economies of scale, and the processes of learning by doing and learning by using as DE penetrates the market. Regulatory developments, especially facilitating flexible ownership and operational arrangements, will be necessary if these cost reductions are to be realized.

Any new regulatory design will have to accommodate and value the impacts of a widespread penetration of DE technologies on existing infrastructures and especially electricity generation and distribution utilities. Utilities need to be fairly compensated for costs incurred for interconnection, ensuring emergency supply, altered demand profiles, and possible stranding of investments in generation and distribution equipment. These costs need to be transparent and standardized, as the introduction of DE can be incorporated to reduce peak requirements, defray distributional capacity expansions, and meet the range of daily and seasonal demands at lowest cost. Regulatory decisions over the ownership, technical protocols, market structure, and liability aspects of the electricity industry will all affect whether and how DE is incorporated into the electricity paradigm.

A diverse range of DE technologies, including renewable DE and multifuel DE units such as microturbines and Stirling engines, can help contribute to the diversity and hence the security of energy supplies. However, if the great majority of DE units are fired on natural gas, this could exacerbate price volatility and upward price pressure on natural gas supplies, particularly in North America.

Renewable DE and CHP DE technologies have the potential to significantly reduce emissions of CO_2 and thus may be a major tool in any concerted drive to limit and reduce greenhouse gas emissions. Although most DE technologies emit very low levels of SO_2, only some (fuel cells, microturbines, Stirling engines, PV) have very low levels of a variety of local air pollutants. Given the distributional location of DE near population centers, all local air pollution impacts need to be fully assessed and further controlled if necessary. In addition, any doubts of affected local populations need to be understood and addressed.

Evolving demands for high reliability, high robustness, and high quality in liberalized electricity markets will likely result in customers specifying criteria of supply. For those customers who have very strict requirements for reliable and high-quality power, DE technologies can either supplement the grid or be used in microgrids to meet specialized demands. The use of DE can hedge against both supply and price uncertainties, particularly in view of the modularity of capital investments required for DE.

Significant expansion of DE capacity may impose greater strain, increased price levels, and greater price volatility on the natural gas network. It may also change seasonal demand profiles as more summer electricity is generated and may require rethinking of natural gas storage requirement and locations. Finally, DE may or may not be integral or compatible with the growing use of hydrogen. If hydrogen is created at central facilities (for example, using fossil fuels and carbon sequestration), the energy distribution carrier could be electricity, taking advantage of economies of scale in plants, or hydrogen, taking advantage of economies of scale in DE unit production and higher efficiencies with CHP DE units. If the transportation sector moves to a hydrogen system with a distribution pipeline to fueling stations, this is likely to support hydrogen-fueled stationary DE applications.

Finally, DE technologies and their associated infrastructure impacts and ownership arrangements potentially represent a very different paradigm than the norm of centralized electricity generation and distribution with on-site heat provision. These two paradigms have advantages and disadvantages, but in countries that already have a developed energy infrastructure, any widespread move toward DE will entail significant transitional concerns over a period of decades due to the long life of electricity-related equipment.

Glossary

cogeneration Method of simultaneous generation of electricity and heat; also known as combined heat and power (CHP).
community heating Synonym for district heating, common in Great Britain.
customer substation Installation in customer building transferring heat from the heat network to the internal heat distribution systems in the building.
district cooling Method of fulfilling many cooling demands by a seldom citywide cooling distribution network, chilled from one or many large chillers or transferring facilities.
district energy Collective term for district heating and cooling.
district heating Method of fulfilling many city heat demands by an often citywide heat distribution network, which receives heat from one or many large heat-generation or transmission facilities.
trigeneration Method of simultaneous generation of electricity, heat, and cold.

The fundamental idea of district heating is to use local fuel or heat resources that would otherwise be wasted to satisfy local customer heat demands by using a heat distribution network of pipes as a local marketplace. This idea contains the three obligatory elements of a competitive district heating system: the suitable cheap heat source, the market heat demands, and the pipes as a connection between source and demands. These three elements must all be local in order to obtain short pipes for minimizing the capital investment in the distribution network. Suitable heat demands are space heating and preparation of domestic hot water for residential, public, and commercial buildings. Low-temperature industrial heat demands are also suitable.

1. FIVE STRATEGIC RESOURCES

The five suitable strategic local energy resources are useful waste heat from thermal power stations (cogeneration); heat obtained from refuse incineration; useful waste heat from industrial processes; natural geothermal heat sources; and fuels difficult to manage, such as wood waste, peat, straw, or olive stones. These heat sources must be cheap in order to compensate for capital investments in the distribution network and complementing heat-generation plants for peak and backup heat demands. The latter is needed in order to meet customer heat service demands at extremely low outdoor temperatures and when the regular heat source is temporarily unavailable.

District heating is an energy service provided for immediate use directly by the customer and was commercially introduced in the 19th century as a very early example of outsourcing.

2. MARKET PENETRATION

Citywide district heating systems exist in Helsinki, Stockholm, Copenhagen, Berlin, Munich, Hamburg, Paris, Prague, Moscow, Kiev, Warsaw, and other large cities. Many systems supply a downtown district (such as in New York, San Francisco,

 © 2004 Elsevier Inc. All rights reserved.

Minneapolis, St. Paul, Seattle, Philadelphia, and other cities) or a university, military base, hospital complex, or an industrial area.

Total annual heat turnover is approximately 11 EJ in several thousand district heating systems operating throughout the world. The amount of heat delivered corresponds to 3.5% of the total global final energy consumption (1999). The market penetration for district heating in various countries is presented in Table I which is based on international energy statistics. However, many countries have undeveloped or no routines for gathering statistical information from district heating systems. This is valid for the United States, Great Britain, France, China, and some other countries. An independent analysis estimated the total annual heat deliveries from all district heating systems in the United States to be more than 1000 PJ. Hence, the real-world market penetration is probably higher than that presented in Table I.

Fulfilling heat demands for space heating and domestic hot water preparation for residential, public, and commercial sectors constitutes the majority of deliveries. Among the Organization for Economic Cooperation and Development (OECD) countries, district heating has a strong, almost dominating, market position in Denmark, Finland, Sweden, Poland, and the Czech Republic. Among non-OECD countries, district heating has a strong market position in Russia, Belarus, Romania, and the three Baltic states.

3. HISTORY OF DISTRICT HEATING

Birdsill Holly, an inventor and hydraulic engineer, is often credited with being the first to use district heating on a successful commercial basis. As a result of an experiment in 1876 involving a loop of steam pipes buried in his garden, Holly developed a steam supply system in October 1877. Several district heating systems were started in North American cities in the 1880s. The fuel source was steam coal. In New York, the Manhattan steam system went into operation in 1882. It exists today as the steam division of Consolidated Edison, and it delivered 29 PJ of heat during 2000.

The oldest district heating system still in operation is located in Chaudes-Aigues, France. It is based on a geothermal heat source with a temperature of 82°C and was in operation as early as the 14th century. Old municipal documents indicate that two citizens did not pay their heat fees properly in 1332. The hot water was partly distributed using drilled tree trunks as distribution pipes.

In Europe, an early district heating system was built in Dresden in 1900, although it was not a commercial project. The main purpose was to reduce the fire risk in 11 royal and public buildings containing invaluable art treasures. A more commercial project was initiated by Fernheizwerk Hamburg Gmbh for the city of Hamburg in 1921. According to Abraham Margolis, the company chief engineer, the driving force for the project was the high cost of fuel after World War I. The Hamburg system was followed by systems in Kiel in 1922, Leipzig in 1925, and Berlin in 1927. Outside Germany, district heating systems were started in Copenhagen in 1925, Paris in 1930, Utrecht in 1927, Zürich in 1933, and Stockholm and Helsinki in 1953. Reykjavik, Iceland, started a geothermal district heating system in 1930, which today supplies almost all the 160,000 inhabitants with heat for space heating and domestic hot water (10 PJ during 2000).

In Russia, a general utilization of cogeneration and district heating was outlined in the electrification plan in 1920 in order to reduce future fuel demand. The first heat was delivered in St. Petersburg in 1924. Teploset Mosenergo was established in 1931 to manage heat distribution in Moscow, although the heat deliveries had begun in 1928. This department of Mosenergo delivered 268 PJ during 2000 and an additional 70–80 PJ was supplied by Mosteploenergo, another local distributor. Together, these companies constitute the most extensive district heating system in the world. The second largest is the St. Petersburg system.

4. TECHNICAL DESIGN AND CONSTRUCTION

Heat is transferred from the network to the building heating systems by customer substations located in the connected buildings. A building has at least two internal distribution systems that must be heated—one system for supplying heat to the radiators and one system for distribution of domestic hot water. Sometimes, a separate system also provides heat for heating the supply air in the mechanical ventilation system.

Each internal system is heated and regulated separately. The heat is often transferred by the use of heat exchangers, in which case the connection is indirect. There are also direct variants with only valves and elevator pumps. If domestic hot water is prepared by mixing district heating water and

[a] According to the energy balances for OECD and non-OECD countries published by the International Energy Agency. Differences between supply and deliveries constitute distribution losses. Differences between total deliveries and sum of deliveries to customers constitute own use. All other demands do not include the transportation sector.

domestic cold water, the open connection method is used, whereas when a heat exchanger is employed, the closed connection method is used. The open connection method occurs is used in Russia, resulting in high feed water demands in the distribution network.

The most typical part of a district heating system is the citywide distribution network of pipes buried

in the ground under streets, pavement, and park lawns or installed in building basements. Water is normally used as the heat carrier in heat distribution networks. Steam is completely or partly used in systems that were installed before approximately 1940 and for high-temperature industrial heat demands.

The water temperature in the forward pipes varies between 70 and 150°C, with an annual average of 80–90°C. The higher temperature is used at extreme low outdoor temperature, whereas the lower temperature is used during the summer to enable domestic hot water preparation. The temperature of the return water varies between 35 and 70°C, with an annual average of 45–60°C. However, return temperatures of 30–35°C may be obtained in the future. The current high return temperatures depend on malfunctions in substations, short-circuited radiator systems in customer buildings, and short-circuits between forward and return pipes in the distribution networks. The lower the return temperature, the more heat can be transported in the network.

The pipes are constructed so that they accommodate thermal expansion and avoid outer corrosion. Construction methods for pipes buried in the ground have varied throughout the years. In the early days of district heating, double steel pipes were insulated with mineral wool and laid in a common concrete square box duct. This early generation of distribution pipes were expensive to build but were reliable if the ducts were well ventilated and well drained. Today, the most common method is to use prefabricated steel pipes with polyethylene casing and insulated with polyurethane foam. This method has the advantages of low distribution cost, low heat losses, and high reliability. During the past 30 years, plastic pipes have been developed as heat carrier pipes. With respect to limitations in pressure and possible long-term temperatures, the new generation of district heating pipes are mostly used in secondary distribution networks separated from the primary distribution networks by heat exchangers.

The heat loss in the distribution network depends on the thermal resistance in the pipe insulation, the pipe size, the supply and return temperatures, and the linear heat density. The latter is the heat sold annually divided by the route length of double pipes in the network. Typical values for linear heat densities are 15–25 GJ/m for whole networks, more than 40 GJ/m in concentrated downtown and commercial areas, and less than 5 GJ/m in blocks with single-family houses. Typical heat loss in whole networks is 5–10% of heat generated in plants, but up to 20–30% can occur in areas with low linear heat densities. Also, the distribution cost depends on the linear heat density. The cost is low beyond 20–30 GJ/m but increases very quickly below 6–8 GJ/m.

The district heating system is operated using control equipment at four independent levels. Two of these are located in the buildings connected and two are managed by the district heating operator. The first level is the heat demand control by thermostatic valves at the radiators and mixing valves for domestic hot water. The second level is in the customer substations. The heat transfer is controlled by valves that adjust the flow of district heating water. One valve is used for each connected customer system. The third level is the control of the pressure difference between the supply and return pipes in the network, which is accomplished by adjusting the speed of the distribution pumps. This control level allows for all customer substations to receive heat since this pressure difference is the driving force for the flow to circulate through the customer substations. The final level is the control of the supply temperature by adjusting the capacity in the heat-generation facilities.

These levels of control result in an efficient demand-oriented district heating system. The district heating operator can never deliver more heat than the customers request. However, the first three levels are often not available in Russian and Eastern European systems. This situation creates a production-oriented system in which it is difficult to properly allocating the flow in the network, resulting in both low and high indoor temperatures in the buildings connected. When these systems are rehabilitated, the first step is to install at least control at the second and third levels.

5. CUSTOMER RELATIONS

The customers usually pay for the heat received according to a heat rate, which normally consists of one fixed portion related to the capacity needed and one variable portion related to the amount of heat bought. Sometimes, a water volume portion is also used in order to promote low return temperatures from the customer substations. The capacity portion is based on either the maximum heat load or the maximum water flow capacity. The amount of heat sold to the customer is recorded by integrating the product of water flow and the temperature difference between the supply and return pipes. A heat meter in each customer substation measures the district

heating water flow, the supply temperature, and the return temperature. These three measurements are integrated with media constants to derive an accumulating heat volume in gigajoules or megawatt hours by the heat meter.

The point of delivery varies from system to system. If the customer owns the substation, the point of delivery is before the substation; otherwise, it is after the substation. Sometimes the customer pays a connection fee.

The pricing principle for the heat rate varies. Municipal district heating systems generally have lower prices, reflecting lower returns of capital investments. Privately owned systems often price the district heat according to the available alternative for the customer, usually the price of light fuel oil or natural gas with a discount in order to keep the customer. In some countries, the price levels in district heating systems are supervised or approved by national or regional regulatory authorities.

Typical prices for district heat deliveries were $6–13/GJ in OECD countries in 1999 and 2000. An exception was the geothermal system in Reykjavik, which sold heat for only $4/GJ. Typical prices in Eastern Europe were $3–7/GJ, except in Russia, where world market energy prices are not allowed due to a low ability to pay market prices. Heat was sold from the Moscow system for approximately $1/GJ. All these prices are lower than or equal to those from local boilers using fossil fuels with different national energy taxes, such as carbon dioxide taxes.

The lower prices in countries in Eastern Europe and the former USSR just cover the operating costs. The returns of capital investments made in the former planned economies are currently kept low by the national regulatory authorities since the average ability to pay for heating is low in the population.

Requests for deregulation of district heating systems, allowing third-party access, have been put forward from customers and competitors, for example, in New York. The requests are for the deregulation processes of telecommunication, aviation, railway, gas, and electricity markets. These markets are large, international, and mature with many market actors. The goal of deregulation of these markets is an effective price determination with many sellers and buyers in each market. However, district heating systems are normally small local markets, which are often immature, with low market penetration. One operator can easily supply a town of 150,000 inhabitants with heat from one site; thus, more operators are not needed in many district heating systems. Hence, deregulation of district heating systems cannot easily be implemented.

6. ENERGY SUPPLY

The base load heat-generation capacity in a district heating system must have a strong correlation with the five strategic resources discussed previously: cogeneration, refuse incineration, industrial waste heat, geothermal heat, and fuels difficult to manage. Internationally, the strongest driving force for district heating is the simultaneous generation of electricity and heat in cogeneration plants. Base load capacities are associated with low operating costs and high capital investment costs.

Conventional fossil fuels dominate the fuel supply for cogeneration, but the use of biomass is increasing in some countries. One example is the newly built biomass cogeneration plant in Eskilstuna, Sweden, which meets the majority of heat demand of a city with 65,000 inhabitants. Another example is the new biomass cogeneration plant for the St. Paul system. In general, cogeneration plants use more carbon lean fuels than conventional thermal power stations since natural gas, renewables, and waste are more common fuels than coal and oil. It is also possible to recover heat from nuclear power stations, but this is employed to a very limited extent due to long distances between nuclear reactors and heat demands in cities, loss of some electricity generation, fear of strong dependence on one large heat source, and lack of trust in nuclear technology in some countries.

Waste incineration is an acceptable treatment method compared to landfill for the burnable industrial and municipal waste stream. This waste remains after separation of streams for hazardous waste, recycling, and biological waste treatment. Normally, this waste stream from a city comprises only approximately 5–15% of the design capacity in a mature district heating system with a high local market penetration. However, 10% of the design capacity corresponds to approximately 30% of the annual heat generation. Within the European Union, up to 50% of municipal waste is allocated for incineration. Denmark, Switzerland, and Sweden incinerate the highest percentages of waste.

Many industrial processes release heat at a temperature higher than 100°C either in flue gases or in cooling water. This heat can be directed to a district heating system by using heat-recovery boilers or heat exchangers. In Gothenburg, the district heating system receives useful waste heat from two

oil refineries, comprising 30% of the annual heat demand in the system. Revenues from the heat sale cover a major portion of staffing, operating, and maintenance costs for the refineries. This heat recovery gives them a competitive advantage over other oil refineries in Europe.

Geothermal heat is a natural energy source for heating in the same manner that wind, hydro, and solar power are natural renewable energy sources for power generation. However, this resource is not available everywhere since it is restricted to areas with the appropriate geophysical conditions. There are geothermal district heating systems in Iceland, the United States, France, China, Japan, Turkey, Poland, Hungary, and some other countries. However, the total heat delivery worldwide is low, estimated to be approximately 30 PJ/year, where one-third is supplied in the Reykjavik system.

Biomass is an example of a fuel that is normally difficult to manage for conventional heating. Regarding transport, fuel feeding into boilers, and environmental impact, these types of fuel are easier to handle in one central boiler than in several small boilers. Biomass fuels can be obtained from agricultural sources or from the forest industry. Wood waste can be delivered as raw chips or refined as small pellets or powder from forest companies or sawmills. In the early 1990s, the Cree Nation of Ouje-Bougoumou determined that a biomass district heating system would be an enormously positive tool in contributing to the development of the community's future financial base. This aboriginal community, located 1000 km north of Montreal, Canada, uses wood waste from a nearby sawmill for their two biomass boilers, which are connected to the district heating system. Importing fuel oil to this village was considered a less favorable option.

Peak and backup capacity plants complement the base load capacity plant in a district heating system. These plants are needed to meet customer heat service demands at extremely low outdoor temperatures and when the regular heat source is temporarily unavailable. These plants are normally associated with high operating costs and low capital investment costs.

The optimal heat-generation cost is obtained by choosing the base load capacity so that its marginal capacity will have the same annual total cost as peak load capacity for the same operating hours. The typical optimal base load capacity is approximately half the nominal system design capacity based on the local design outdoor temperature. The base half of the capacity represents approximately 90% of the volume of heat generated.

The frequency distribution for the outdoor temperatures determine the limit of capacity utilization in a district heating system. The annual average capacity factor is 25–50% for extreme inland and maritime climate locations. The capacity factor is defined as the actual heat generation divided by the heat generation that is possible. This situation occurs since less heating is required during autumn and spring compared to winter, and no heating is needed during summer.

7. ENVIRONMENTAL IMPACT

High contents of dust, sulfur dioxide (SO_2), and nitrogen oxides (NO_x) in urban areas were among the first pollution problems to be identified. District heating improved the urban air quality in many towns since local heat boilers were replaced and high chimneys for heat-generation plants were required.

Acidification from SO_2 and NO_x is a major problem in many regions. District heating systems provide a centralized and cheap way to eliminate these emissions by separation, use of fuels with low sulfur content, have higher conversion efficiencies, and have higher combustion quality, resulting in lower NO_x emissions.

Global warming due to the greenhouse gases is a problem more difficult to solve than the problems of urban air quality and acidification. In this respect, district heating can be considered the fifth possibility for carbon dioxide emission reduction, after deposition, lowering final energy demands, higher conversion efficiencies, and fuel substitution. District heating uses mainly waste heat from other processes, replacing the use of fossil fuels for heating buildings.

It is estimated that in 1998, all cogeneration plants and district heating systems throughout the world reduced carbon dioxide emissions by 900 Mtons. This corresponds to approximately 4% of all carbon dioxide emitted from fuel combustion. Hence, district heating systems can play an important role in the mitigation of carbon dioxide emissions.

8. DISTRICT COOLING

District cooling systems distribute chilled water to supply air-conditioning or process cooling. Cities with major downtown or commercial districts with district cooling systems include Stockholm, Hamburg, Paris, Tokyo, Chicago, Minneapolis, St. Paul, New Orleans, and Houston. The first major district

cooling system was employed in Hartford, Connecticut, in 1962. Other systems were built in the 1960s and 1970s. District cooling experienced a renaissance during the 1990s, when many countries demanded the termination of the use of CFC due to ozone depletion. District cooling systems are much smaller than district heating systems. Annual cold generation is approximately 1 or 2 PJ in the largest district cooling systems.

The distribution network is similar to that of a district heating system, with one supply pipe and one return pipe. Cold water is circulated instead of warm water. The supply temperature is normally 6 or 7°C, but an ice mixture of 0°C is sometimes used. Customers heat the chilled water in the supply pipe by cooling air supplied to a building or a industrial process. The typical temperature in the return pipe is 12–17°C. The water is again chilled when it circulates through the cold-generation plant. District cooling systems are never used citywide. The low temperature difference makes district cooling distribution expensive, so district cooling networks can only be built in areas with high cooling demand densities, such as downtowns and commercial areas.

Cold generation can be accomplished by central compression or absorption chillers. Free cooling with deep, cold lake or seawater can also be used, as is the case in Toronto and Stockholm. However, this is only possible in areas with cold winters, which annually create cold reservoirs for summer use. Since the diurnal variation of the cooling demand is large at peak load, a significant portion of the peak demand can be met by cold energy storage capacity with a cold water storage tank or an ice storage facility.

Two major associations exist between district heating and district cooling systems. The evaporator of a heat pump can be used for cold generation in a district cooling system and the condenser can simultaneously generate heat in a district heating system. One part of bought electricity will then create two parts of sellable cold and three parts of sellable heat, giving a higher return of the heat pump investment. The other association is the possible use of low-cost district heat for operation of local absorption chillers in connection with customer cooling demands. In this way, citywide deliveries of cooling can be accomplished without installing a citywide district cooling system. This variant is sometimes called warm district cooling, in contrast to cold district cooling, which refers to ordinary district cooling systems. District heating systems using this warm variant are employed in Gothenburg, Mannheim, New York, and Seoul.

These two associations can be integrated into a trigeneration plant, in which power generation is integrated with the generation of both cold and heat. First, a cogeneration unit can generate electricity and heat. These products are then used for feeding a compression chiller or a absorption chiller.

There is an operation optimization benefit for district cooling. Cold generation can be optimized by using different generation technologies to meet various cooling demands. The base load demand can be met by an absorption chiller if low-cost heat is available. Next-generation units in merit order include a compression chiller with heat recovery and a similar chiller without heat recovery. Extreme peak load can be met by a cold storage.

Major advantages of district cooling systems are reduced grid power demand by supplying cooling energy through the district cooling system rather than through the local power grid, shifting power demand to off-peak periods through cold energy storage, and the use of free cooling. Advantages for customers with district cooling are the requirement for less space for cooling equipment inside the building, less operation and maintenance costs, and less electricity cost. The subscribed cooling capacity can also be adjusted to the actual measured customer cooling demand. The customer does not have to buy an expensive oversized chiller.

9. CONCLUSIONS

District heating significantly increases the overall energy system efficiency since the heat supply is coordinated with generation of electricity, refuse incineration, or industrial processes. It is also possible to use geothermal heat sources or biomass fuels such as wood waste. Demand for commercial fossil fuels for heating is reduced, resulting in lower carbon dioxide emissions.

District heating also benefits from economy of scale. This is especially valid with regard to distribution since the cost of pipes is proportional to pipe size, whereas transmission capacity increases with the square of the pipe size. Also, the investment cost for heat-generation capacity decreases with size. The variation in heat demand is also lower, especially with respect to the demand for domestic hot water preparation. However, these advantages are not sufficient to motivate centralized use of conventional fossil fuels in district heating systems. At least one of the five strategic resources must be used to develop a competitive district heating system. When using

more than one of the strategic resources, an internal competition is created within the system, which will increase the competitiveness of the system.

A district heating system becomes more competitive when the advantages of higher overall system efficiency and lower environmental impact are priced by the heat market. Hence, district heating is highly competitive when fuel prices are high and when low environmental impact is appreciated. Many countries use fiscal taxes for fossil fuels and are also introducing carbon dioxide taxes for fuels. International, regional, and national carbon dioxide trading schemes have also been discussed. All these measures increase the long-term competitiveness of district heating systems.

Although district heating has many advantages, the method is still unknown in many communities, whereas it is taken for granted in other communities. Since district heating reduces the operating costs of heating buildings due to capital investment in central heat-generation facilities and distribution pipes, the local view of long-term investments in urban infrastructure is very important. Historically, district heating systems have been built in communities in which district heating has been considered part of the urban infrastructure, along with roads, bridges, water supply, and electricity distribution. The current strong market penetration of district heating in some countries in Europe can be explained by this view. The municipal electrical and technical departments became the district heating entrepreneurs in Finland, Sweden, Denmark, Germany, and Austria since by tradition they were responsible for the urban infrastructure.

Glossary

agricultural revolution The period prior to England's industrial revolution, when significant improvements in agricultural production were achieved through changes in free labor, land reform, technological innovation, and proto-industrial output.

capitalism A socioeconomic and political system in which private investors, rather than states, control trade and industry for profit.

industry Economic activity concerned with processing raw materials and producing large volumes of consistently manufactured goods, with maximum fuel exploitation.

industrial revolution The period of technological innovation and mechanized development that gathered momentum in 18th-century Britain; fuel shortages and rising population pressures, with nation-states growing in power and competing for energy, led to dramatic improvements in energy technology, manufacture, and agriculture and to massive increases in the volume of international trade.

plague Referred to as the Black Death, or Bubonic Plague, which killed one-third the population of England and Europe from the mid-14th century until around 1500; millions of people perished, and commerce, government, energy production, and industry waned as farms were abandoned and cities emptied.

proto-industry Supplemented agricultural income via the production of handcrafted work; this piecework was especially common in the creation of textiles by spinning, weaving, and sewing.

steel A strong hard metal that is an alloy of iron with carbon and other elements; it is used as a structural material and in manufacturing.

work energy Defined by natural scientist James Joule as kg m^2/s^2 or a joule (J); it enabled physicists to realize that heat and mechanical energy are convertible.

Population growth and competition for resources have continuously been an impetus for the control and use of energy. In harnessing energy, inventions evolved from previous innovations, ebbing and flowing with changes in population pressures and the availability of resources—necessity shaping history. For millennia, societies depended on resources provided by solar energy (radiation stored as vegetation), wind (a type of solar energy), animal and human energy, water, and fossil fuels. The advent of mechanized labor and its synchronized production demands transformed the lives of workers previously tuned to seasonal energy rhythms. Technological innovations during the early 18th century resulted in enormous growth in the economic wealth and sociopolitical power of nation-states. Sustained growth in Western Europe and Britain spread via exploration and trade. The competition to colonize and control the raw natural resources in the Caribbean and the Americas, in conjunction with imperialism in Indochina, the Mideast, and the Mediterranean, changed the global energy map.

1. AGRICULTURE AND URBANIZATION

Preindustrial economies in Britain and Europe were widespread in scale, dominated by agricultural

 © 2004 Elsevier Inc. All rights reserved.

production, processing, and manufacture, with populations based primarily in rural villages. A range of processed goods were essential to farms and households, although restricted incomes reduced purchasing power. Solar energy, water, regional fuels, and the ebb and flow of the seasons dictated the energy of labor expenditure in workers' lives.

There was little capital accumulation or technological progress during the widespread population destruction of the Black Death in medieval Britain and Europe. In Italy, Spain, France, and Poland, agricultural output per worker diminished, and nonagricultural employment tended to be based in rural areas, corresponding with only minor increases in urban populations. The subsequent recovery of populations after the plague led to the growth of urbanization, and local and national government structures increased their control of energy resources.

The Netherlands, Belgium, and England were distinguished from the rest of Europe by the interrelated factors of rising agricultural productivity, high wages, and urbanization. At the end of the medieval period, rural industry and urban economies expanded. Despite rates of population growth exceeding those elsewhere in Europe, economic development offset population growth, wages were increased or maintained.

By 1750, Britain had the highest portion of population growth in cities, and agricultural output per worker surpassed Belgian and Dutch levels. Urban and rural nonagricultural populations grew more rapidly in England than anywhere else in Europe. The share of the workforce in agriculture dropped by nearly half, while the trend of providing real wages rose.

The wool and cotton textile industry was the first widespread manufacturing enterprise in Britain. When farm laborers began producing piecework for cash, the social and labor organization of agrarian economies changed dramatically. Labor–market interactions and productivity growth in agriculture required a degree of labor mobility that was incompatible with previous agricultural economic models such as serfdom. England's division between landlords and tenant farmers caused reorganization to occur through reductions in farm employment, enclosure, and farm amalgamation. In Europe, where landowners/occupiers were more prevalent, farm amalgamation and enclosure were disruptive to productivity and institutional change was less profitable.

Rural industrialization was a response to population growth combined with increased urban demands for farm products, and sustained urbanization created dependency on labor based in the countryside. Substantial migrations of people to cities, and the spread of industry to the countryside, provided opportunities to escape the restrictions of guilds.

Providing enough farm produce for cities required increasing agricultural output and value per acre and introducing new crops. By the dawn of the 18th century, the industrial and commercial sectors of the British economy contributed at least one-third of the gross national product.

2. COMPETITION FOR ENERGY RESOURCES

For millennia, the Mediterranean had been the center of international trade, with trade routes among Europe, Africa, and Asia. After the plague during the 15th and 16th centuries, Mediterranean networks of international trade with Europe declined. European nation-states were not powerful enough to govern beyond their transient borders, and inadequate local resources could not support population growth. This led to each state employing protective measures to stimulate domestic industrial production, self-sufficiency, and competition for resources. During the 16th and 17th centuries, these policies were formalized, extended, and consolidated, severely limiting the growth of trade.

The high costs of inland transportation and restrictive national practices inhibited trade opportunities and led to an economic crisis. As trading opportunities ceased to expand after the plague's decimations, the need for new sources of revenue provided the impetus to search far afield for resources. With the diminishing extent of accessible markets, Europeans explored the Atlantic, Africa, the Caribbean, and the Americas, where raw resources and cheap commodity production offered immense opportunities for trade expansion. During the 15th century, the Portuguese established trading posts along the west coast region of Africa, produced sugar on slave-worked plantations, and traded gold.

The advent of the Atlantic world trading system and its abundant resources extended the production and consumption frontier of Western Europe. Because available transportation of goods was slow and expensive, unit cost of production in the Americas had to be sufficiently low for commodities to bear the cost of trans-Atlantic transportation. Large-scale production in the Americas increasingly depended on coerced labor. Indigenous peoples of the Americas were forced into slavery to mine silver in the Spanish

colonies and provision Europeans. Native American land was appropriated, and populations were decimated by an unwelcome import, Old World diseases. Colonizers obtained vast quantities of acreage, becoming land rich beyond the limits of European caste and class systems. The average population density in the Americas was less than one person per square mile during the 17th century.

As indigenous peoples in the colonies suffered disease, displacement, and slavery, the production of commodities for Atlantic commerce became more dependent on slaves from Africa. Labor costs on plantations throughout the Caribbean and the Americas were below subsistence costs, enabling large levels of production and maximum exploitation of human energy resources. From Barbados to the Carolinas and the Mississippi delta, a major source of power were the thousands of enslaved Africans and Native Americans as well as indentured servants from England, Scotland, and Ireland. Plantations prospered due to the high value of cotton in the world market and by producing coffee, sugar, cocoa, tobacco, and rum. As these export commodities increased in volume, prices fell in Europe, with the commodities becoming commonly consumed goods rather than rarified luxuries. The production of raw materials for mass markets contributed greatly to the development and economic homogenization of industry and energy exploitation.

England combined naval power and commercial development to secure choice Atlantic territories and create advantageous treaties to control the colonies' resources. The majority of commodity shares, production, and trade of the slave-based economy of the Atlantic world trading system were primarily British controlled.

The estimated percentage share of these commodities produced by enslaved Africans and indentured servants in the Americas was 50 to 80%. Between 1650 and 1850, the slave-based economy of the Atlantic system transformed international trade, transformed European and British economics, and spurred technological innovation. Slavery failed as an energy source due to the socioeconomic upheavals that eventually prevented and censured its expansion as well as the fact that it could not compete with developing sources of industrial energy such as steam power. Slave labor, rather than free labor, failed as a socioeconomic source of power.

In per capita terms, the exposure of England's economy and society to the development of the Atlantic world market was greater than that of any other country, although Europe profited immensely from participation in the slave-based Atlantic world economy. Newly acquired gold and silver from the Americas bolstered weak European economies. Imported textiles from England were welcomed in the Americas, with these sustained sales creating employment in England's manufacturing regions and stimulating population growth and changes in agrarian social structures. Combined with export demands, this created a ripe environment for transforming the organization and technology of manufacturing in domestic and export industries. This international economic energy propelled the technological industrial revolution.

The transition of intensified industrialization depended on improvements in transportation systems to provide dispersion networks of fuels and raw materials. With the advent of the Victorian empire, improvements in the infrastructure of transportation (e.g., roads, canals, shipping) spread. The construction of railroad systems in Britain, Europe, Asia, Russia, Africa, and the Americas connected, amalgamated, and exploited energy resources in most regions of the world, creating an engine of economic dynamism that itself was a product of mechanized industry.

3. WOOD ENERGY

Woodlands have been an essential resource for constructing homes, vehicles, ships, furniture, tools, and machines as well as for providing heat for households and cooking. Poor management of woodlands caused low productivity, and as timber stands became more remote, logging and transporting timber became less economical. During the 13th century in England, lime kilns devoured hundreds of ancient oaks in Wellington Forest. By the 1540s, the salt industry was forced to search far afield for the wood used in its processing furnaces. British navel power judged this shortage to be a national security threat. Authorities attempted to impose stiff fines for timber poaching and forbade bakers, brewers, and tile makers from purchasing boatloads of wood.

Severe timber shortages reached national crisis proportions in Britain, impelling the import of expensive timber from the Baltic and North America. Native turf, peat, reeds, gorse, and other plant fuels simply could not provide adequate supplementation. The climate did not cooperate. Between around 1450 and 1850, winters became unusually long and harsh, the Thames river froze, and diseases and cold increased in their killing power. Populations suffered

as low birth rates could not keep up with expanding death rates.

In Scotland, woodlands were carefully managed during the early medieval period, and native oak supplied the needs of developing burghs. Norse incursions pushed populations inland, allowing woodland regeneration in coastal areas. During the 15th century, the quality and quantity of native oak dwindled, and alternative sources (e.g., imported oak, conifers) were increasingly exploited. France had abundant internal supplies of timber, so there was no need to invest time, money, and politico–military resources in obtaining timber from elsewhere.

By the close of the 17th century, industry and manufacturing devoured more than a third of all the fuel burned in Britain. The textile industry's immense scale made it a leading consumer of fuels, although fuel cost was not a major constituent in manufacturing textiles, dyeing, calendaring, and bleaching. Energy consumption by industries increased in local and national terms because industry was not uniformly distributed, and this exacerbated and caused severe local and regional scarcity. Local needs concerning brewing, baking, smithing, potting, and lime processing had survived on whatever fuel was available. High temperatures were required to brew ale and beer and to process salt and sugar. The construction industry depended on kilns and furnaces for the production of bricks, tiles, glass, firing pottery, and burning lime. Smelting and working metals, and refining the base compounds of alum, copperas, saltpeter, and starch, were expensive processes.

Even when located within extensive woodlands, levels of consumption by iron forges, glass factories, and lime kilns led to shortages. Fuel needs grew voraciously as industries expanded in scale and became more centralized and urbanized. There was a fine balance between fuel needs in communities and industrial demands. Urban centers consisting of large concentrations of consumers inherently tended to outgrow the capacity of adjacent woodland fuel supplies. Transport costs commensurately inflated as supply lines were extended.

4. WIND AND WATER ENERGY

Windmills were developed in Persia by the 9th century BCE. This technological innovation was spurred by the need to mill corn in areas lacking consistent water supplies. Early windmills used an upright shaft, rather than a horizontal one, to hold the blades. This system was housed in a vertical adobe tunnel with flues to catch the wind (similar to a revolving door). The concept of harnessing wind energy via windmills reached Britain and Europe by 1137, where it underwent significant changes, with horizontal (rather than vertical) shafts and horizontal rotation. A form of solar energy, climate-dependent wind power has been unreliable and difficult to accumulate and store.

Roman aqueducts provided a system of fast-flowing water to watermills. By the 1st century BCE, Romans used an efficient horizontal axis where the waterwheel converted rotary motion around a horizontal axis into motion around a vertical axis; water passed under the wheel, and kinetic water energy turned the wheel. Draft animals and waterpower were harnessed to turn millstones. Rudimentary primitive watermills used vertical axes, with millstones mounted directly to waterwheel shafts. In mountainous regions, water was channeled through a chute into the wheel. Although power output was minimal ($\sim$300 W), this type of watermill was used in Europe until the late medieval period.

During the late 18th and early 19th centuries, waterwheel efficiency was improved. English engineer John Smeaton, expanding on the systems of early Roman waterwheels, found that more energy was generated when water was delivered to the top of the wheel via a chute. An overshot waterwheel used both kinetic and potential water energy and was capable of harnessing 63% more potential energy than was the undershot. The growing demand for energy intensified use of the waterwheel. While toiling in the gold mines of California during the 1870s, a British mining engineer, Lester Pelton, discovered that a waterwheel could be made more powerful if high-pressure jets of water were directed into hemispherical cups placed around its circumference. This waterwheel design, generating 500 horsepower (hp), was used 20 years later in the sodden mines of Alaska.

5. THE TRANSITION TO COAL ENERGY

Coal had been widely harvested and exploited as an energy source for thousands of years. In Asia, coal provided little illumination but plenty of heat. Romans in Britain found that stones from black outcrops were flammable, and Roman soldiers and blacksmiths used this coal to provide heat. During the 13th and 14th centuries, a multitude of industries

became dependent on a regular supply of coal. In salt production, coal was used to heat enormous pans of sea water. If woodlands had not been devoted nearly exclusively to the production of timber, their yield could not have met the fuel value generated by that produced by coal mines. It took an annual yield from 2 acres of well-managed woodlands to equal the heat energy of a ton of coal. Timber became more scarce and expensive to procure during the Tudor and Stuart periods. Consequently, the processes of salt boiling, ironworking, brewing, baking, textile manufacturing, and lime burning adopted coal, rather than wood, as a readily available and economical fuel source.

Confronted by the unrelenting scarcity and high price of timber, manufacturers in fuel-intensive industries were further prompted to restrain costs and enhance profits by switching to coal. The problems caused by burning coal in processes previously dependent on wood (e.g., producing glass, bricks, tiles, pottery, alum, copperas, saltpeter, and paper; smelting lead, tin, and copper; refining soap and sugar) swelled the demand for progressive technology. Increased energy efficiency in industrial processes stimulated competition, innovation, and the emergence of fuel economies. Urbanization expanded, and the availability of inexpensive coal enabled agriculture to supplant arboriculture.

During the late 17th century, British coal mining employed 12,000 to 15,000 people, from miners to those involved in the transportation and distribution of coal to the consumer. During this period, coal prices remained virtually constant and were not dependent on revolutionary changes in structure or technology, and mine shaft depth did not increase dramatically (safe ventilation of deep pits did not occur until the 19th century). Conservatively estimated, coal production increased 370% between 1650 and 1680, creating an environment in which profound industrial advances in mining and trade occurred.

The substantial expansion of the textile industry was accommodated within preexisting systems of production, relying on traditional procedures, artisan workshops, and piecework arrangements. Advances were built on the potential that had existed in preindustrial economies, while labor and finance, marketing, transportation, and distribution evolved. Industrial enterprises incorporated factories, warehouses, forges, mills, and furnaces, and small collieries produced thousands of tons of coal per year. By 1750, the British population had nearly doubled, and urbanization and industrialization continued to amalgamate.

During the 1790s, French engineer Philippe Lebon distilled gas from heated wood and concluded that it could provide warmth, conveniently light interiors with gas in glass globes (fuel distributed via small pipes within walls), and inflate balloons. Gregory Watt, son of inventor James Watt, journeyed to France to investigate these experiments. In Cornwall, England, William Murdock lit a house with gas generated from coal. Concerned with commercial possibilities, he experimented with coal of varying qualities, different types of burners, and devices that could store enough gas to make portable light. In 1798, he returned to the foundry in Soho, England, where he illuminated the main building with coal gas using cast-iron retorts.

By 1816, London had 26 miles of gas mains, and soon there were three rival gas companies. With the availability of kerosene and gas light, the whale oil industry futilely attempted to compete. The advent of gas light enabled Victorian readers to become increasingly literate. During the 1860s, gas utilities spread in England and Europe, while the eastern United States and Canada adopted gas lighting for streets. At the turn of the 20th century, coal gas cooking and radiant heat to warm homes from gas fires became more common. The gas industry was determined to increase efficiency in all of these domestic and industrial heating functions.

Massive petroleum and gas industries resulted from the need for improved lighting during the industrial revolution. Although oil lamps had improved, the illuminating capabilities of vegetable and animal oils were limited. Gas light was superior but was restricted to urban areas. Gas oil, consisting of the fraction intermediate between kerosene and lubricants, was inexpensive and less dangerous than petroleum and also provided a convenient means of enriching the coal gas.

At the turn of the 20th century, when the automobile industry was still rudimentary, crude petroleum and rubber remained insignificant, while coal gas reached its zenith of full technological development as an energy source. Versatile and inexpensive kerosene continued to provide illuminating energy in much of the world, while gas and electricity competed in urban centers. As an illuminant, gas light began to lose momentum, while electrical power grew enormously.

The turning point for the British coal industry, and a defining moment of the industrial revolution, came with the innovation of the steam engine. It was used in processing both coal and metals, and by the close

of the 18th century more than 15 million tons of coal were produced annually.

6. STEAM POWER

In the 6th century BCE, Greek philosophers described the universal elements as consisting of air, earth, fire, and water. It was established that water displaced air and that steam condensed back to liquid and could rotate wheels. During the 17th century, the physical nature of the atmosphere was explored in qualitative rather than quantitative terms; water and other liquids entering vacuous space was attributed to nature abhorring a vacuum. The persistent problem of mine drainage inspired understanding of atmospheric pressure, leading to the earliest steam engines.

When engineers failed to drain excess water from Italian mines during the 1600s, Galileo was enlisted. In 1644, his pupil, Evangelista, found that atmospheric pressure was equal to that of a column of mercury 30 inches high, corresponding to a column of water 30 feet high, and that atmospheric pressure falls with increasing altitude. Torricelli postulated that a method of repeatedly creating a vacuum would enable atmospheric pressure to be a source of power and could be used in mine drainage. Steam at l00°C equals sea-level atmospheric pressure and so can raise water 30 feet. Tremendous pressure can be generated by superheating water to create high-pressure steam; at 200°C, pressure is 15 times greater than at l00°C, lifting water 450 feet.

The first steam engines were termed atmospheric engines. In 1680, Christian Huygens, a Dutch scientist, designed a system where gunpowder exploding in a cylinder created hot gases that were expelled through relief valves. On cooling, the valves closed and a partial vacuum existed within the cylinder. The gunpowder gas occupied a smaller volume than when heated; thus, atmosphere pressure drove a piston in the cylinder. In 1690, Huygens's assistant, Denis Papin, found that 1 volume of water yields 1300 volumes of steam. A vacuum could be achieved by converting steam back into water via condensation, propelling a piston up and down in a cylinder.

Prolific inventor Thomas Savery improved on this in 1698, designing a steam pump using heat to raise water, generating approximately 1 hp. Steam from a boiler passed through a valve-fitted pipe into a vessel full of water, expelling the water up through a second pipe. When steam filled the vessel, it was condensed by pouring cold water onto the outer surface. This created a partial vacuum. When the vessel was connected with another pipe with water at a lower level, atmospheric pressure forced the water up. Savery's engine pumped water for large buildings and waterwheels, but its maximum lift was inadequate for mine drainage.

Thomas Newcomen, an inventor and blacksmith, adopted Papin's cylinder and piston and built his own version of the steam pump, replacing costly horse-drawn pump engines. Newcomen's direct experience with drainage problems in Cornish tin mines led to his construction of an efficient engine using atmospheric pressure rather than high-pressure steam. The Newcomen system had a boiler produce steam at atmospheric pressure within a cylinder, where a pump rod hung from a beam so as to apply weight to drive a piston. When the cylinder was full of steam and closed by a valve, a jet of cold water condensed the steam and atmospheric pressure forced the pump rod to push the piston down. Generating approximately 5 hp, this engine was a success in draining coal mines, lifting 10 gallons of water 153 feet through a series of pumps. Its primary users were coal mine proprietors who ran their engines on low-grade coal.

With improved control of mine flooding, the depth of mines and the coal industry grew exponentially. Use of the steam engine spread throughout Europe and to the American colonies. Newcomen's design was so reliable that even as other fuel technologies were developed, the last engine of this type worked for more than a century in Yorkshire, England, without serious breakdown (it was finally dismantled in 1934). Steam power was also used to pump water for waterwheels in cotton mills, accommodating the growing energy needs of textile manufacture as well as a multitude of other industries.

Between 1769 and 1776, James Watt discovered that energy was lost in the process of cooling and reheating the Newcomen engine. The addition of a separate condenser cylinder permitted a steady injection of steam into the first cylinder without having to continuously reheat it. In 1774, Watt and Matthew Boulton, an English manufacturer in Soho, became partners, providing Watt with skilled engineers and workers.

An impediment to steam engine design was the shortage of precise cylinders; imprecise boring allowed steam to escape between the cylinder walls and piston. John Wilkinson designed a mill for boring iron cannons that was capable of making

precise cylinders for any purpose. His blast furnaces, with air from Watt's engine, produced consistent cylinders. Using this newfound precision in cylinder construction, the rotative Watt engine extracted four times as much energy, a minimum of 10 hp, from coal as the Newcomen model. By the turn of the 19th century, Watt's and Boulton's Soho factory had produced hundreds of engines powering industrial machinery.

Improvements in steam technology continued to be made during the 19th century. In 1802, a Cornish mining engineer, Richard Trevithick, built a small pumping engine with a cylinder 7 inches in diameter, a cast-iron boiler 1.5 inches thick, and steam pressure of 145 pounds per square inch—10 times atmospheric pressure. Two years later, Trevithick built 50 stationary engines and the first successful railway locomotive. By 1844, high-pressure steam engines averaged 68 million foot pounds per bushel of coal, compared with 6 million foot pounds capacity for the Newcomen engine. When Watt's engine was combined with Trevithick's design, a pressure of up to 150 pounds per square inch was achieved, referred to as "compounding." Trevithick's steam engine eliminated the huge rocking beam of Watt's design and became the new standard, suited to factories with limited space. His engines were unrivaled and remained in a variety of industrial purposes, including pumping, iron works, corn grinding, and sugar milling, until the end of the 19th century.

7. STEAM ENGINES AND TRANSPORTATION

Steam-powered engines were crucial in the development of transportation. Roads often were little more than deeply gouged tracks, slowing people, carriages, and carts in an energy-hindering quagmire. The growing demands for bulk fuel beyond what was locally available, with the high cost of transport added to the expense of energy resources, expedited innovation.

During the 1700s, British canals were improved, and tow paths allowed heavily burdened vessels to be pulled by teams of horses. Combining water and steam power, a paddlewheel steamboat ascended a river in 1783 near Lyons, France. William Symington, an English engineer, constructed an atmospheric steam engine to propel a small boat in 1788 using a horizontal double-acting cylinder with a connecting rod driving the paddlewheel's crankshaft. In the United States, Robert Fulton used a Boulton and Watt engine to operate a commercial steamer, and during the 1840s the U.S. Navy adapted this propulsion system in military craft, locating the engine below the waterline for protection.

In 1801, Trevithick built his first steam carriage (later driving one wildly through the streets of London). He combined the steam locomotive with railways, demonstrating its usefulness in conveying heavy goods and passengers. Rails had already been constructed for horses to tow carriages and coal carts more efficiently than on unreliable roads. The development of railway passenger services was a crucial formative factor in the phenomenon of the industrial revolution. Horsepower was replaced by the more powerful steam engine. By 1830, George Stephenson developed a locomotive railway line between Liverpool and Manchester without the need for stationary steam engines or horses in steep areas to supplement power. Railroad carriages were finally capable of hauling tons of coal and hundreds of passengers. Britain exported locomotives to Europe and America, where railway systems were rapidly established. Rail speeds exceeding 60 miles per hour were common, and engine efficiency increased, requiring only 23 pounds of coal per mile, although countries with abundant forests, such as the United States and Canada, still used wood fuel. Improved materials and methods of manufacture, as well as the steam turbine, resulted in higher power/weight ratios and increased fuel economy. During the 1880s, industrial steam power transformed networks of world communication, extending and unifying international economic systems.

8. PETROLEUM

Coal gas and petroleum energy share the property of having hydrocarbons as their principal constituents; coal gas is rich in the hydrocarbon methane, whereas petroleum consists of a complex mixture of liquid hydrocarbons. The use of petroleum products long antedates the use of coal gas. In Mesopotamia, concentrations of petroleum deposits provided commerce and production. Babylonians called inflammable oil "naphtha." For thousands of years, mixtures containing bitumen were used in roads, ship caulking, floor waterproofing, hard mortar, and medicines. Naphtha was militarily important as a weapon, although Romans derived their bitumen from wood pitch. Aztecs made chewing gum made with bitumen, and during the 16th century oil from seepages in

Havana was used to caulk ships. By the 15th and 16th centuries, there was an international trade in petroleum.

Distillation of crude oil revealed that its derivatives were suitable in axle grease, paints and varnishes, dressing leather, lamp fuel, and mineral turpentine. A pliable caulking for ships was made by thinning pitch thinned with turpentine, and hot asphalt pitch and powdered rock were used in flooring and steps. During the 19th century, asphalt mixed with mineral oil was used in pavements and roads, and oil cloth and linoleum became popular and inexpensive household items.

During the early 19th century, deep exploratory drilling for water and salt required sufficiently hard drills and mechanical power. Steam engines provided the energy, and the development of derricks aided in the manipulation of rapid-drilling machines. Prospecting for oil ceased to be dependent on surface seepages when hollow drills enabled drill samples to be removed, revealing the structure of underground formations. The compositions of crude oil varied; thus, methods of oil refinery were important. During the 1860s, the United States had a steady supply of 10 million barrels of petroleum annually. By 1901, Russian crude oil output reached 11 million tons, and petroleum-fueled railways connected world markets.

Kerosene was distilled from petroleum with sulfuric acid and lime, providing inexpensive and plentiful fuel for lamplight. Although gasoline remained a worthless and inflammable by-product of the industry, oil derivatives provided lubricants that became increasingly necessary with innovations in vehicles and machinery, and heavy machine oils were used on railways.

9. ELECTRICAL POWER

In early Greece, it was found that the *elektron* (amber), when rubbed, acquired the power of attracting low-density materials. The widespread use of electricity for heat, light, and power depended on the development of mechanical methods of generation. During the 17th and 18th centuries, static electricity was found to be distinct from electric currents. Electricity could be positive or negative as charged bodies repelled or attracted each other, distinguishing conductors from nonconductors.

In 1754, John Canton devised an instrument to measure electricity based on the repulsion of like-charged pith suspended by threads, and this was later standardized and redesigned as the gold leaf electroscope. Benjamin Franklin identified the electrical discharge of lightning, leading to the invention of the lightning conductor. In Italy, Allesandro Volta, a natural scientist, found that electricity was derived when alternate metal plates of silver or copper and zinc contacted each other within a solution. The importance of this discovery was that it provided a source of continuous electric current. The original voltaic energy battery gave stimulus to the experimental study of electricity. In a matter of months, laboratories produced electric batteries, converting the energy released in chemical reactions.

In 1820, Danish physicist H. C. Oersted described the magnetic field surrounding a conductor carrying an electric current. The relationship between the strength of a magnetic field and its electric current established that a continuous conductor in a magnetic field causes electric currents to flow. From 1834, rotating coil generators were made commercially in London. The earliest generators produced alternating currents. Converting alternating energy into direct electric currents was resolved via a mechanical commutator and rectangular coils that rotated in a magnetic field. Maximum voltage in each coil was generated in succession, alleviating the irregularities at a given speed of rotation providing constant voltage.

By 1825, electromagnets were used as an alternative to permanent magnets by the founder of the first English electrical journal, William Sturgeon. Electromagnets possessed enough residual magnetism in their iron cores to provide the necessary magnetic field to start output from an electric generator. The electric generator became a self-contained machine that needed only to be rotated to produce electrical energy. The application of a steam engine to rotate the armature generated enough electricity to supply arc lamps for lighthouses, bringing large-scale use of electricity a step closer.

An armature using a continuous winding of copper wire increased the possibilities of using arc lamps for lighting streets. Arc lamps developed after the discovery that a spark struck between two pieces of carbon creates brilliant light. Inventors Thomas A. Edison and Sir Joseph Swan developed filament lamps for domestic use during the 1870s, and an incandescent filament lamp used an electric current to heat its conductor.

The growing needs of industrial light required electric power generators to be substantial in size. In New York, Edison's electric-generating station was in

operation in 1882. Electric storage batteries were used for lighting railway carriages and propelling vehicles.

At Niagara Falls during the 1890s, George Westinghouse developed the first large-scale hydroelectric installation, with a capacity of 200,000 hp. Hydroelectric generators demanded a considerable capital outlay for successful operation, so coal-fired steam engines lingered as a favored energy source at the end of the 19th century. During the late 1800s, the electricity industry expanded, output per electric power stations tripled, and coal consumption per unit of electricity fell by nearly half.

Conductors consisting of concentric copper tubes were used with alternating currents because copper had a lower electrostatic capacity and the concentric cable had no inductive effect on neighboring telegraph, telephone, or other electrical installations. The electric telegraph required a reliable battery cell to provide constant voltage that was capable of prolonged output. Attendant construction needs for telegraph poles required the production of enormous quantities of timber, porcelain insulators, and rubber insulation for cables.

Local electrical generation evolved into large centralized distribution utilities, and surplus electricity was sold to local consumers. In 1889, the London Electricity Supply Corporation's power station provided high voltage by operating four 10,000-hp steam engines to fuel 10,000-volt alternators. The economic advantages of central power stations to generate electricity at high voltages for serving large areas brought new practical and economic problems of distribution and, thus, further innovations. By the end of the 19th century, underground distribution systems of electricity had color-coded cables. Each strand was identified in this manner, a major consideration given that the electrical network beneath city streets increased in complexity.

10. ENERGY FLOW AND INDUSTRIAL MOMENTUM

During the early industrial period, increases in scale and diversity of manufacturing and trade corresponded with a shortage of readily available consistent energy, and this pressure induced developments in fuel technology industries. Competition for dwindling resources spurred the expansion of international trade and exploration, and fuel efficiency became more crucial. The fusion between mechanized growth and economic fuel use created the momentum of energy exploitation and technological innovation, and socioeconomic systems became known as the industrial revolution. Transportation systems connected a myriad of worldwide energy sources, and improved communication expedited the process of efficient global fuel exploitation and industry. Global commerce and fuel exploitation decisively affected the flow of materials via worldwide transportation and trade systems. As technological innovations were applied to harvesting energy and the subsequent momentum of labor mechanization, production uniformity and the quantity of fuel used in mass processing vast quantities of goods coalesced into an enormous worldwide energy flow.

Glossary

aerosol Microscopic particles suspended in the atmosphere, originating from either a natural source (e.g., volcanoes) or human activity (e.g., coal burning).

albedo The reflectivity of the earth.

anthropogenic climate change Climate change due to human influences.

anticyclone A high-pressure weather system. The wind rotates around anticyclones in a clockwise direction in the Northern Hemisphere and counterclockwise in the Southern Hemisphere. They usually give rise to fine, settled weather.

convection In weather, the process of warm air rising rapidly while cooler air usually subsides more gradually over broader regions elsewhere to take its place. This process often produces cumulus clouds and may result in rain.

cyclone A low-pressure weather system. The wind rotates around cyclones in a counterclockwise direction in the Northern Hemisphere and clockwise in the Southern Hemisphere. Cyclones are usually associated with rainy, unsettled weather and may include warm and cold fronts.

dry static energy The sum of the atmospheric sensible heat and potential energy.

El Niño The occasional warming of the tropical Pacific Ocean from the west coast of South America to the central Pacific that typically lasts approximately 1 year and alters weather patterns throughout the world.

El Niño–Southern Oscillation (ENSO) El Niño and the Southern Oscillation together; the warm phase is El Niño and the cold phase is La Niña.

enthalpy The heat content of a substance per unit mass. Used to refer to sensible heat in atmospheric science (as opposed to latent heat).

greenhouse effect The effect produced as certain atmospheric gases allow incoming solar radiation to pass through to the earth's surface but reduce the outgoing (infrared) radiation, which is reradiated from Earth, escaping into outer space. The effect is responsible for warming the planet.

greenhouse gas Any gas that absorbs infrared radiation in the atmosphere.

Hadley circulation The large-scale meridional overturning in the atmosphere in the tropics.

La Niña A substantial cooling of the central and eastern tropical Pacific Ocean lasting 5 months or longer.

long-wave radiation Infrared radiation in the long wave part of the electromagnetic spectrum, corresponding to wavelengths of 0.8–1000 μm. For the earth, it also corresponds to the wavelengths of thermal-emitted radiation.

short-wave radiation Radiation from the sun, most of which occurs at wavelengths shorter than the infrared.

Southern Oscillation A global-scale variation in the atmosphere associated with El Niño and La Niña events.

thermocline The region of vertical temperature gradient in the oceans lying between the deep abyssal waters and the surface mixed layer.

total solar irradiance The solar radiation received at the top of the earth's atmosphere on a surface oriented perpendicular to the incoming radiation and at the mean distance of the earth from the sun.

troposphere The part of the atmosphere in which we live, ascending to approximately 15 km above the earth's surface, and in which temperatures generally decrease with height. The atmospheric dynamics we know as "weather" take place within the troposphere.

 © 2004 Elsevier Inc. All rights reserved.

urban heat island The region of warm air over built-up cities associated with the presence of city structures, roads, etc.

The distribution of solar radiation absorbed on Earth is very uneven and largely determined by the geometry of the sun–earth orbit and its variations. This incoming radiant energy is transformed into various forms (internal heat, potential energy, latent energy, and kinetic energy) moved around in various ways primarily by the atmosphere and oceans; stored and sequestered in the ocean, land, and ice components of the climate system; and ultimately radiated back to space as infrared radiation. The requirement for an equilibrium climate mandates a balance between the incoming and outgoing radiation and further mandates that the flows of energy are systematic. These drive the weather systems in the atmosphere and the currents in the ocean, and they fundamentally determine the climate. They can be perturbed, causing climate change. This article examines the processes involved and follows the flows, storage, and release of energy.

1. THE EARTH AND CLIMATE SYSTEM

Our planet orbits the sun at an average distance of 1.50×10^{11} m once per year. It receives from the sun an average radiation of 1368 W m^{-2} at this distance, and this value is referred to as the total solar irradiance. It used to be called the "solar constant" even though it does vary by small amounts with the sunspot cycle and related changes on the sun. The earth's shape is similar to that of an oblate spheroid, with an average radius of 6371 km. It rotates on an axis with a tilt relative to the ecliptic plane of 23.5° around the sun once per year in a slightly elliptical orbit that brings the earth closest to the sun on January 3 (called perihelion). Due to the shape of the earth, incoming solar radiation varies enormously with latitude. Moreover, tilt of the axis and the rotation of the earth around the sun give rise to the seasons, as the Northern Hemisphere points more toward the sun in June and the Southern Hemisphere points toward the sun in late December. The earth also turns on its axis once per day, resulting in the day–night cycle (Fig. 1). A consequence of the earth's roughly spherical shape and the rotation is that the average energy in the form of solar radiation received at the top of the earth's atmosphere is the total solar irradiance divided by 4, which is the ratio of the earth's surface area ($4\pi a^2$, where a is the mean radius) to that of the cross section (πa^2).

The earth system can be altered by effects or influences from outside the planet usually regarded as "externally" imposed. Most important are the sun and its output, the earth's rotation rate, the sun–earth geometry and the slowly changing orbit, the physical makeup of the earth system such as the distribution of land and ocean, the geographic features on the land, the ocean bottom topography and basin configurations, and the mass and basic composition of the atmosphere and ocean. These components affect the absorption and reflection of radiation, the storage of energy, and the movement of energy, all of which determine the mean climate, which may vary due to natural causes.

On timescales of tens of thousands of years, the earth's orbit slowly changes, the shape of the orbit is altered, the tilt changes, and the earth precesses on its axis like a rotating top, all of which combine to alter the annual distribution of solar radiation received on the earth. Similarly, a change in the average net radiation at the top of the atmosphere due to perturbations in the incident solar radiation from the changes internal to the sun or the emergent infrared radiation from changes in atmospheric composition leads to a change in heating. Changes in atmospheric composition arise from natural events such as erupting volcanoes, which can create a cloud of debris that blocks the sun. They may also arise from human activities such as the burning of fossil fuels, which creates visible particulate pollution and carbon dioxide, a greenhouse gas. The greatest variations in the composition of the atmosphere involve water in various phases, such as water vapor, clouds of liquid water, ice-crystal clouds, and hail, and these affect the radiative balance of the earth.

The climate system has several internal interactive components. The atmosphere does not have very much heat capacity but is very important—the most volatile component of the climate system with wind speeds in the jet stream often exceeding 50 m s^{-1}—in moving heat and energy around. The oceans have enormous heat capacity and, being fluid, can also move heat and energy around in important ways. Ocean currents may be >1 m s^{-1} in strong currents such as the Gulf Stream, but are more typically a few centimeters per second at the surface. Other major components of the climate system include sea ice, the land and its features [including the vegetation, *albedo* (reflective character), biomass, and ecosystems], snow cover, land ice (including the semipermanent ice sheets of Antarctica and Greenland, and glaciers),

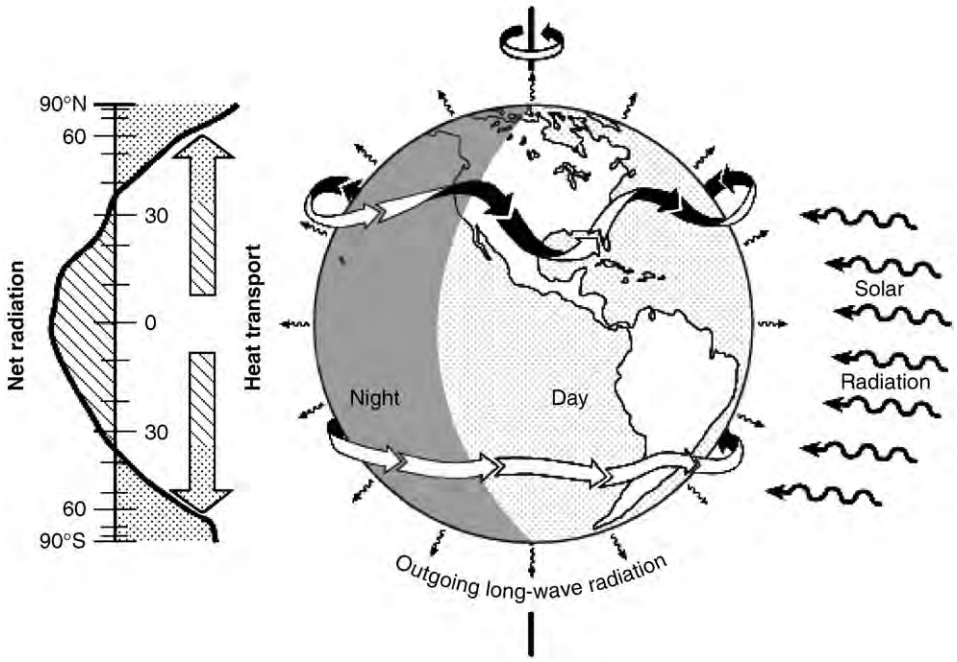

FIGURE 1 The incoming solar radiation (right) illuminates only part of the earth, whereas the outgoing long-wave radiation is distributed more evenly. On an annual mean basis, the result is an excess of absorbed solar radiation over the outgoing long-wave radiation in the tropics, whereas there is a deficit at middle to high latitudes (left) so that there is a requirement for a poleward heat transport in each hemisphere (arrows) by the atmosphere and the oceans. The radiation distribution results in warm conditions in the tropics but cold at high latitudes, and the temperature contrast results in a broad band of westerlies in the extratropics of each hemisphere in which there is an embedded jet stream (ribbon arrows) at approximately 10 km above the earth's surface. The flow of the jet stream over the different underlying surface (ocean, land, and mountains) produces waves in the atmosphere and geographic spatial structure to climate. [The excess of net radiation at the equator is 68 $W m^{-2}$ and the deficit peaks at -100 $W m^{-2}$ at the South Pole and -125 $W m^{-2}$ at the North Pole. From Trenberth *et al.* (1996).

and rivers, lakes, and surface and subsurface water. Their role in energy storage and the energy balance of the earth is discussed later.

Changes in any of the climate system components, whether internal and thus a part of the system or from external forcings, cause the climate to vary or to change. Thus, climate can vary because of alterations in the internal exchanges of energy or in the internal dynamics of the climate system. An example is El Niño–Southern Oscillation (ENSO) events, which arise from natural coupled interactions between the atmosphere and the ocean centered in the tropical Pacific. Such interactions are also discussed later from the standpoint of energy.

2. THE GLOBAL ENERGY BALANCE

The incoming energy to the earth system is in the form of solar radiation and roughly corresponds to that of a black body at the temperature of the sun of approximately 6000 K. The sun's emissions peak at a wavelength of approximately 0.6 μm and much of this energy is in the visible part of the electromagnetic spectrum, although some extends beyond the red into the infrared and some extends beyond the violet into the ultraviolet. As noted earlier, because of the roughly spherical shape of the earth, at any one time half the earth is in night (Fig. 1) and the average amount of energy incident on a level surface outside the atmosphere is one-fourth of the total solar irradiance or 342 $W m^{-2}$. Approximately 31% of this energy is scattered or reflected back to space by molecules, tiny airborne particles (known as aerosols), and clouds in the atmosphere or by the earth's surface, which leaves approximately 235 $W m^{-2}$ on average to warm the earth's surface and atmosphere (Fig. 2).

To balance the incoming energy, the earth must radiate on average the same amount of energy back to space (Fig. 2). The amount of thermal radiation

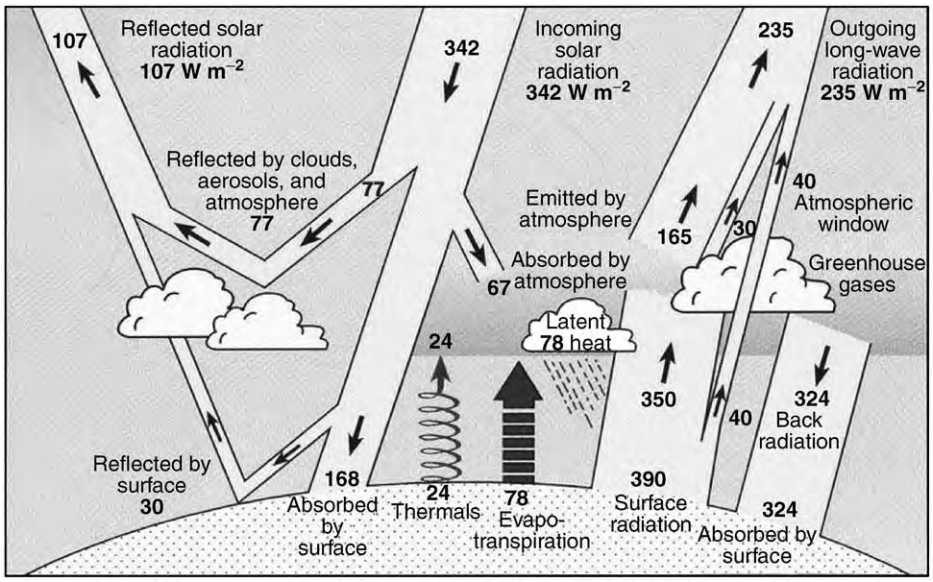

FIGURE 2 The earth's radiation balance. The net incoming solar radiation of 342 W m^{-2} is partially reflected by clouds and the atmosphere or at the surface, but 49% is absorbed by the surface. Some of this heat is returned to the atmosphere as sensible heating and most as evapotranspiration that is realized as latent heat in precipitation. The rest is radiated as thermal infrared radiation and most of this is absorbed by the atmosphere and reemitted both up and down, producing a greenhouse effect, since the radiation lost to space comes from cloud tops and parts of the atmosphere much colder than the surface. From Kiehl and Trenberth (1997).

emitted by a warm surface depends on its temperature and on how absorbing it is. For a completely absorbing surface to emit 235 W m^{-2} of thermal radiation, it would have a temperature of approximately −19°C (254 K). Therefore, the emitted thermal radiation occurs at approximately 10 μm, which is in the infrared part of the electromagnetic radiation spectrum. Near 4 μm, radiation from both the sun and the earth is very small, and hence there is a separation of wavelengths that has led to the solar radiation being referred to as short-wave radiation and the outgoing terrestrial radiation as long-wave radiation. Note that −19°C is much colder than the conditions that actually exist near the earth's surface, where the annual average global mean temperature is approximately 14°C. However, because the temperature in the lower atmosphere (troposphere) decreases quite rapidly with height, a temperature of −19°C is reached typically at an altitude of 5 km above the surface in midlatitudes. This provides a clue about the role of the atmosphere in making the surface climate hospitable.

2.1 The Greenhouse Effect

Some of the infrared radiation leaving the atmosphere originates near the earth's surface and is transmitted relatively unimpeded through the atmosphere; this is the radiation from areas where there are no clouds and which is present in the part of the spectrum known as the atmospheric "window" (Fig. 2). The bulk of the radiation, however, is intercepted and reemitted both up and down. The emissions to space occur either from the tops of clouds at different atmospheric levels (which are almost always colder than the surface) or by gases present in the atmosphere that absorb and emit infrared radiation. Most of the atmosphere consists of nitrogen and oxygen (99% of dry air), which are transparent to infrared radiation. It is the water vapor, which varies in amount from 0 to approximately 3%, carbon dioxide, and some other minor gases present in the atmosphere in much smaller quantities that absorb some of the thermal radiation leaving the surface and reemit radiation from much higher and colder levels out to space. These radiatively active gases are known as greenhouse gases because they act as a partial blanket for the thermal radiation from the surface and enable it to be substantially warmer than it would otherwise be, analogous to the effects of a greenhouse. Note that while a real greenhouse does work this way, the main heat retention in a greenhouse actually comes through protection from the wind. In the current climate, water vapor is estimated to account for approximately 60% of the greenhouse effect, carbon

dioxide 26%, ozone 8%, and other gases 6% for clear skies.

2.2 Effects of Clouds

Clouds also absorb and emit thermal radiation and have a blanketing effect similar to that of greenhouse gases. However, clouds are also bright reflectors of solar radiation and thus also act to cool the surface. Although on average there is strong cancellation between the two opposing effects of short-wave and long-wave cloud heating, the net global effect of clouds in our current climate, as determined by space-based measurements, is a small cooling of the surface. A key issue is how clouds will change as climate changes. This issue is complicated by the fact that clouds are also strongly influenced by particulate pollution, which tends to make more smaller cloud droplets, and thus makes clouds brighter and more reflective of solar radiation. These effects may also influence precipitation. If cloud tops become higher, the radiation to space from clouds is at a colder temperature and this produces a warming. However, more extensive low clouds would be likely to produce cooling because of the greater influence on solar radiation.

3. REGIONAL PATTERNS

The annual mean absorbed solar radiation (ASR) and outgoing long-wave radiation (OLR) are shown in Fig. 3. Most of the atmosphere is relatively transparent to solar radiation, with the most notable exception being clouds. At the surface, snow and ice have a high albedo and consequently absorb little incoming radiation. Therefore, the main departures in the ASR from what would be expected simply from the sun–earth geometry are the signatures of persistent clouds. Bright clouds occur over Indonesia and Malaysia, across the Pacific near 10°N, and over the Amazon in the southern summer, contributing to the relatively low values in these locations, whereas dark oceanic cloud-free regions along and south of the equator in the Pacific and Atlantic and in the subtropical anticyclones absorb most solar radiation.

The OLR, as noted previously, is greatly influenced by water vapor and clouds but is generally more uniform with latitude than ASR in Fig. 3. Nevertheless, the signature of high-top and therefore cold clouds is strongly evident in the OLR. Similarly, the dry, cloud-free regions are where the most surface radiation escapes to space. There is a remarkable cancellation between much of the effects of clouds on

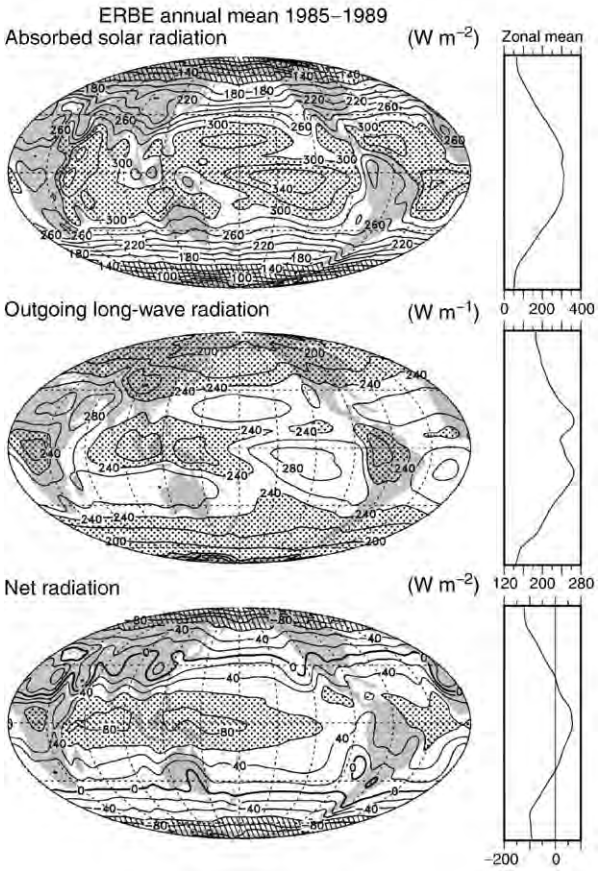

FIGURE 3 Maps of the annual mean absorbed solar radiation, outgoing long-wave radiation, and net radiation at the top of the atmosphere during the period between April 1985 and February 1989, when the Earth Radiation Budget Experiment was under way. From Trenberth and Stepaniak (2003).

the net radiation (Fig. 3). In particular, the high convective clouds are bright and reflect solar radiation but are also cold and hence reduce OLR. The main remaining signature of clouds in the net radiation from Earth is seen from the low stratocumulus cloud decks that persist above cold ocean waters, most notably off the west coasts of California and Peru. Such clouds are also bright, but because they have low tops they radiate at temperatures close to those at the surface, resulting in a cooling of the planet. Note that the Sahara desert has a high OLR, consistent with dry, cloud-free, and warm conditions, but it is also bright and reflects solar radiation, and it stands out as a region of net radiation deficit.

For the earth, on an annual mean basis there is an excess of solar over outgoing long-wave radiation in the tropics and a deficit at mid- to high latitudes (Fig. 1) that set up an equator-to-pole temperature gradient. These result, along with the earth's rotation,

in a broad band of westerlies and a jet stream in each hemisphere in the troposphere. Embedded within the midlatitude westerlies are large-scale weather systems that, along with the ocean, act to transport heat polewards to achieve an overall energy balance.

4. THE ATMOSPHERE

In the atmosphere, phenomena and events are loosely classified into the realms of "weather" and "climate." Climate is usually defined as average weather and thus is thought of as the prevailing weather, which includes not just average conditions but also the range of variations. Climate involves variations in which the atmosphere is influenced by and interacts with other parts of the climate system and the external forcings. The large fluctuations in the atmosphere from hour to hour or day to day constitute the weather but occur as part of much larger scale organized weather systems that arise mainly from atmospheric instabilities driven by heating patterns from the sun.

Much of the incoming solar radiation penetrates through the relatively transparent atmosphere to reach the surface, and so the atmosphere is mostly heated from below. The decreasing density of air with altitude also means that air expands as it rises, and consequently it cools. In the troposphere, this means that temperatures generally decrease with height, and warming from below causes convection that transports heat upwards. Convection gives rise to the clouds and thunderstorms, driven by solar heating at the earth's surface that produces buoyant thermals that rise, expand and cool, and produce rain and cloud.

Another example is the cyclones (low-pressure areas or systems) and anticyclones (high-pressure systems) and their associated cold and warm fronts, which arise from the equator-to-pole temperature differences and distribution of heating (Fig. 1). The atmosphere attempts to reduce these temperature gradients by producing these weather systems, which have, in the Northern Hemisphere, southerly winds to carry warm air polewards and cold northerly winds to reduce temperatures in lower latitudes. In the Southern Hemisphere, it is the southerlies that are cold and the northerly winds are warm. These weather systems migrate, develop, evolve, mature, and decay over periods of days to weeks and constitute a form of atmospheric turbulence.

Energy in the atmosphere comes in several forms. The incoming radiant energy is transformed when it is absorbed into sensible energy. On the surface of land, the heat may be manifested as increases in temperature or as increases in evaporation, and the partitioning depends on the available moisture and nature of vegetative ground cover. Increased evaporation adds moisture to the atmosphere, and this is often referred to as latent energy because it is realized as latent heating when the moisture is condensed in subsequent precipitation. Increases in temperature increase the internal energy of the atmosphere, which also causes it to expand. Consequently, it changes the altitude of the air and increases the potential energy. Therefore, there is a close relationship between internal and potential energy in the atmosphere, which are combined into the concept of enthalpy or sensible heat. Once air starts to move, usually because temperature gradients give rise to pressure gradients that in turn cause wind, some energy is converted into kinetic energy. The sum of the internal, potential, kinetic, and latent energies is a constant in the absence of a transfer of heat. However, the possibilities for conversions among all these forms of atmospheric energy are a key part of what provides the richness of atmospheric phenomena.

In terms of poleward transport of energy, the main transports at middle and higher latitudes occur in the form of sensible heat and potential energy, which are often combined as dry static energy, whereas at low to middle latitudes, latent energy also plays a major role. In the tropics, much of the movement of energy occurs through large-scale overturning of the atmosphere. The classic examples are the monsoon circulations and the Hadley circulation. At low levels, the moisture in the atmosphere is transported toward areas where it is forced to rise and hence cool, resulting in strong latent heating that drives the upward branch of the overturning cells and constitutes the monsoon rains. In the subtropics, the downward branch of the circulation suppresses clouds and is very dry as the "freeze-dried air" from aloft slowly descends, and the air warms as it descends and expands. Hence, in these regions the surface can radiate to space without much interference from clouds and water vapor greenhouse effects. This is what happens over the Sahara. However, another key part of the cooling in the subtropics that drives the monsoons is the link to midlatitude weather systems. The latter transport both sensible and latent heat polewards in the cyclones and anticyclones and hence cool the subtropics while warming the higher latitudes.

Thus, the atmosphere is primarily responsible for the energy transports (Fig. 1) that compensate for the

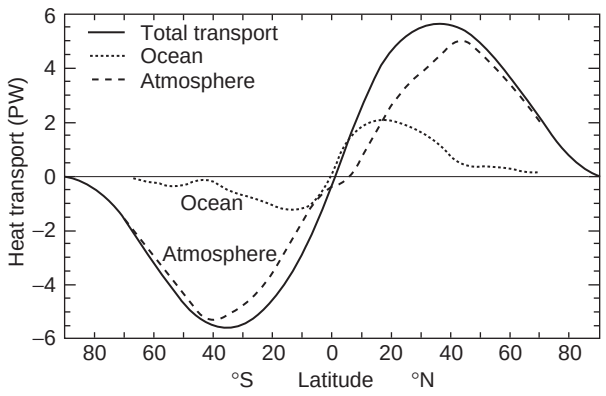

FIGURE 4 Poleward heat transports by the atmosphere and ocean and the total transport. From Trenberth and Caron (2001).

net radiation imbalances. Annual mean poleward transports of atmospheric energy of 5.0 PW peak at 43°N and with similar values near 40°S. Poleward ocean heat transports are dominant only between 0 and 17°N. At 35° latitude, where the peak total poleward transport in each hemisphere occurs, the atmospheric transport accounts for 78% of the total in the Northern Hemisphere and 92% in the Southern Hemisphere (Fig. 4).

5. THE HYDROLOGICAL CYCLE

Driven by exchanges of energy, the hydrological cycle involves the transfer of water from the oceans to the atmosphere, to the land, and back to the oceans both on top of and beneath the land surface. In the tropics in summer, land warms relative to the ocean and sets the stage for monsoon development. Water is evaporated from the ocean surface, cooling the ocean. As water vapor, it is transported perhaps thousands of kilometers before it is involved in clouds and weather systems and precipitated out as rain, snow, hail, or some other frozen pellet back to the earth's surface. During this process, it heats the atmosphere. Over land, soil moisture and surface waters can act through evaporative cooling to moderate temperatures. Some precipitation infiltrates or percolates into soils and some runs off into streams and rivers. Ponds and lakes or other surface water may evaporate moisture into the atmosphere and can also freeze so that water can become locked up for awhile. The surface water weathers rocks, erodes the landscape, and replenishes subterranean aquifers. Over land, plants transpire moisture into the atmosphere.

An estimate of the global hydrological cycle in units of $10^3\,km^3$ per year is that evaporation over the oceans (436) exceeds precipitation (399), leaving a net of 37 units of moisture transported onto land as water vapor. On average, this flow must be balanced by a return flow over and beneath the ground through river and stream flows and subsurface ground water flow. Consequently, precipitation over land exceeds evapotranspiration by this same amount (37). The average precipitation rate over the oceans exceeds that over land by 72% (allowing also for the differences in areas). It has been estimated that, on average, more than 80% of the moisture precipitated out comes from locations more than 1000 km distant, highlighting the important role of the winds in moving moisture.

6. THE OCEANS

The oceans cover 70.8% of the surface of the earth, although there is a much greater fraction in the Southern Hemisphere (80.9% of the area) than the Northern Hemisphere (60.7%), and through their fluid motions and high heat capacity they have a central role in shaping the earth's climate and its variability. The average depth of the ocean is 3795 m. The oceans are stratified opposite to the atmosphere, with warmest waters near the surface. Consequently, in the ocean, convection arises from cooling at the surface and transport of heat upwards occurs through colder and denser waters sinking and being replaced by lighter and more buoyant waters. Another vital factor in convection is the salinity of the water because this also affects density. Consequently, the densest waters are those that are cold and salty, and these are found at high latitudes where there is a deficit in radiation and atmospheric temperatures are low. The formation of sea ice also leads to a rejection of brine and increases the salinity of the surrounding waters. The cold, deep, abyssal ocean turns over only very slowly on timescales of hundreds to thousands of years.

The most important characteristic of the oceans is that they are wet. Water vapor, evaporated from the ocean surface, provides latent heat energy to the atmosphere when precipitated out. Wind blowing on the sea surface drives the large-scale ocean circulation in its upper layers. The ocean currents carry heat and salt along with fresh water around the globe (Fig. 4). The oceans therefore store heat, absorbed at the surface, for varying durations and release it in different places, thereby ameliorating temperature changes over nearby land and contributing substantially to variability of climate on many timescales.

Additionally, the ocean thermohaline circulation, which is the circulation driven by changes in seawater density arising from temperature (thermal) or salt (haline) effects, allows water from the surface to be carried into the deep ocean, where it is isolated from atmospheric influence and hence it may sequester heat for periods of 1000 years or more.

The main energy transports in the ocean are those of heat associated with overturning circulations as cold waters flow equatorwards at some depth while the return flow is warmer near the surface. There is a small poleward heat transport by gyre circulations whereby western boundary currents, such as the Gulf Stream in the north Atlantic or the Kuroshio in the north Pacific, move warm waters polewards while part of the return flow is of colder currents in the eastern oceans. However, a major part of the Gulf Stream return flow is at depth, and the most pronounced thermohaline circulation is in the Atlantic Ocean. In contrast, the Pacific Ocean is fresher and features shallower circulations. A key reason for the differences lies in salinity. Because there is a net atmospheric water vapor transport in the tropical easterly trade winds from the Atlantic to the Pacific across the central American isthmus, the north Atlantic is much saltier than the north Pacific.

7. THE LAND

The heat penetration into land is limited and slow, as it occurs mainly through conduction, except where water plays a role. Temperature profiles taken from bore holes into land or ice caps provide a coarse estimate of temperatures in years long past. Consequently, surface air temperature changes over land occur much faster and are much larger than those over the oceans for the same heating, and because we live on land, this directly affects human activities. The land surface encompasses an enormous variety of topographical features and soils, differing slopes (which influence runoff and radiation received), and water capacity. The highly heterogeneous vegetative cover is a mixture of natural and managed ecosystems that vary on very small spatial scales. Changes in soil moisture affect the disposition of heat at the surface and whether it results in increases in air temperature or increased evaporation of moisture. The latter is complicated by the presence of plants, which can act to pump moisture out of the root zone into the leaves, where it can be released into the atmosphere as the plants participate in photosynthesis; this process is called transpiration. The behavior of land ecosystems can be greatly influenced by changes in atmospheric composition and climate. The availability of surface water and the use of the sun's energy in photosynthesis and transpiration in plants influence the uptake of carbon dioxide from the atmosphere as plants transform the carbon and water into usable food. Changes in vegetation alter how much sunlight is reflected and how rough the surface is in creating drag on the winds, and the land surface and its ecosystems play an important role in the carbon cycle and fluxes of water vapor and other trace gases.

8. ICE

Major ice sheets, such as those over Antarctica and Greenland, have a large heat capacity but, like land, the penetration of heat occurs primarily through conduction so that the mass involved in changes from year to year is small. Temperature profiles can be taken directly from bore holes into ice and it is estimated that terrestrial heat flow is 51 mW/m^2. On century timescales, however, the ice sheet heat capacity becomes important. Unlike land, the ice can melt, which has major consequences through changes in sea level on longer timescales.

Sea ice is an active component of the climate system that is important because it has a high albedo. A warming that reduces sea ice, reduces the albedo and hence enhances the absorption of solar radiation, amplifying the original warming. This is known as the ice albedo feedback effect. Sea ice varies greatly in areal extent with the seasons, but only at higher latitudes. In the Arctic, where sea ice is confined by the surrounding continents, mean sea ice thickness is 3 or 4 m deep and multiyear ice can be present. Around Antarctica, the sea ice is unimpeded and spreads out extensively but, as a result, the mean thickness is typically 1 or 2 m.

9. THE ROLE OF HEAT STORAGE

The different components of the climate system contribute on different timescales to climate variations and change. The atmosphere and oceans are fluid systems and can move heat through convection and advection in which the heat is carried by the currents, whether small-scale short-lived eddies or large-scale atmospheric jet streams or ocean currents. Changes in phase of water, from ice to liquid to

water vapor, affect the storage of heat. However, even ignoring these complexities, many facets of the climate are determined simply by the heat capacity of the different components of the climate system. The total heat capacity considers the mass involved as well as its capacity for holding heat, as measured by the specific heat of each substance.

The atmosphere does not have much capability to store heat. The heat capacity of the global atmosphere corresponds to that of only 3.2 m of the ocean. However, the depth of ocean actively involved in climate is much greater. The specific heat of dry land is approximately a factor of $4\frac{1}{2}$ less than that of seawater (for moist land the factor is probably closer to 2). Moreover, heat penetration into land is limited and only approximately the top 2 m typically plays an active role (as a depth for most of the variations on annual timescales). Accordingly, land plays a much smaller role in the storage of heat and in providing a memory for the climate system. Similarly, the ice sheets and glaciers do not play a strong role, whereas sea ice is important where it forms.

The seasonal variations in heating penetrate into the ocean through a combination of radiation, convective overturning (in which cooled surface waters sink while warmer, more buoyant waters below rise), and mechanical stirring by winds through what is called the "mixed layer" and on average involve approximately 90 m of ocean. The thermal inertia of the 90-m layer would add a delay of approximately 6 years to the temperature response to an instantaneous change. This value corresponds to an exponential time constant in which there is a 63% response toward a new equilibrium value following an abrupt change. Thus, the actual change is gradual. The total ocean, however, with a mean depth of approximately 3800 m, if rapidly mixed would add a delay of 230 years to the response. Mixing is not a rapid process for most of the ocean, so in reality the response depends on the rate of ventilation of water between the mixed upper layers of the ocean and the deeper, more isolated layers through the thermocline (region of temperature gradient). Such mixing is not well-known and varies greatly geographically. An overall estimate of the delay in surface temperature response caused by the oceans is 10–100 years. The slowest response should be in high latitudes, where deep mixing and convection occur, and the fastest response is expected in the tropics. Consequently, the oceans are a great moderating effect on climate variations, especially changes such as those involved with the annual cycle of the seasons.

Generally, the observed variability of temperatures over land is a factor of two to six greater than that over the oceans. At high latitudes over land in winter, there is often a strong surface temperature inversion. In this situation, the temperature increases with altitude because of the cold land surface, and it makes for a very stable layer of air that can trap pollutants. The strength of an inversion is very sensitive to the amount of stirring in the atmosphere. Such wintertime inversions are greatly affected by human activities; for instance, an urban heat island effect exceeding 10°C has been observed during strong surface inversion conditions in Fairbanks, Alaska. Strong surface temperature inversions over midlatitude continents also occur in winter. In contrast, over the oceans, surface fluxes of heat into the atmosphere keep the air temperature within a narrow range. Thus, it is not surprising that over land, month-to-month persistence in surface temperature anomalies is greatest near bodies of water. Consequently, for a given heating perturbation, the response over land should be much greater than that over the oceans; the atmospheric winds are the reason why the observed factor is only in the two to six range.

Another example is the contrast between the Northern Hemisphere (NH) (60.7% water) and Southern Hemisphere (SH) (80.9% water) mean annual cycle of surface temperature. The amplitude of the 12-month cycle between 40 and 60° latitude ranges from <3°C in the SH to ~ 12°C in the NH. Similarly, in midlatitudes, the average lag in temperature response relative to the sun for the annual cycle is 33 days in the NH versus 44 days in the SH, again reflecting the difference in thermal inertia.

10. ATMOSPHERE–OCEAN INTERACTION: EL NIÑO

The climate system becomes more involved as the components interact. A striking example is a phenomenon that would not occur without interactions between the atmosphere and ocean, El Niño, which consists of a warming of the surface waters of the tropical Pacific Ocean. It takes place from the International Dateline to the west coast of South America and results in changes in the local and regional ecology. Historically, El Niños have occurred approximately every 3–7 years and alternated with the opposite phases of below average temperatures in the tropical Pacific, called La Niña. In the atmosphere, a pattern of change called the Southern

Oscillation is closely linked with these ocean changes so that scientists refer to the total phenomenon as ENSO. El Niño is the warm phase of ENSO and La Niña is the cold phase.

El Niño develops as a coupled ocean–atmosphere phenomenon, and the amount of warm water in the tropics is redistributed and depleted during El Niño and restored during La Niña. There is often a mini global warming following an El Niño as a consequence of heat from the ocean affecting the atmospheric circulation and changing temperatures throughout the world. Consequently, interannual variations occur in the energy balance of the combined atmosphere–ocean system and are manifested as important changes in weather regimes and climate throughout the world.

11. ANTHROPOGENIC CLIMATE CHANGE

11.1 Human Influences

Climate can vary for many reasons, and in particular, human activities can lead to changes in several ways. However, to place human influences in perspective, it is worthwhile to compare the output from a power plant with that from the sun. The largest power plants that exist are on the order of 1000 MW, and these service human needs for electricity in appliances and heating that use power in units of kilowatts. Figure 2 shows that the energy received at the top of the atmosphere is $342\,\mathrm{W\,m^{-2}}$ on an annual mean basis averaged over the globe. This is equivalent to 175 PW, although only approximately 120 PW is absorbed. One petawatt is 1 billion MW or 1 million huge power plants. Consequently, it is easily recognized that human generation of heat is only a tiny fraction of the energy available from the sun. This also highlights the fact that the main way in which human activities can compete with nature is if they somehow interfere with the natural flow of energy from the sun, through the climate system, and back out to space.

There have been major changes in land use during the past two centuries. Conversion of forest to cropland, in particular, has led to a higher albedo in places such as the eastern and central United States and changes in evapotranspiration, both of which have probably cooled the region in summer by perhaps 1°C and in autumn by more than 2°C, although global effects are less clear. In cities, the building of "concrete jungles" allows heat to be soaked up and stored during the day and released at night, moderating nighttime temperatures and contributing to an urban heat island. Space heating also contributes to this effect. Urbanization changes also affect runoff of water, leading to drier conditions unless compensated by water usage and irrigation, which can cool the area. However, these influences, although real changes in climate, are quite local. Widespread irrigation on farms can have more regional effects.

Combustion of fossil fuels not only generates heat but also generates particulate pollution (e.g., soot and smoke) as well as gaseous pollution that can become particulates (e.g., sulfur dioxide and nitrogen dioxide, which get oxidized to form tiny sulfate and nitrate particles). Other gases are also formed in burning, such as carbon dioxide; thus, the composition of the atmosphere is changing. Several other gases, notably methane, nitrous oxide, the chlorofluorocarbons (CFCs), and tropospheric ozone, are also observed to have increased due to human activities (especially from biomass burning, landfills, rice paddies, agriculture, animal husbandry, fossil fuel use, leaky fuel lines, and industry), and these are all greenhouse gases. However, the observed decreases in lower stratospheric ozone since the 1970s, caused principally by human-introduced CFCs and halons, contribute to a small cooling.

11.2 The Enhanced Greenhouse Effect

The amount of carbon dioxide in the atmosphere has increased by more than 30% in the past two centuries since the beginning of the industrial revolution, an increase that is known to be in part due to combustion of fossil fuels and the removal of forests. Most of this increase has occurred since World War II. Because carbon dioxide is recycled through the atmosphere many times before it is finally removed, it has a long lifetime exceeding 100 years. Thus, emissions lead to a buildup in concentrations in the atmosphere. In the absence of controls, it is projected that the rate of increase in carbon dioxide may accelerate and concentrations could double from pre-industrial values within approximately the next 60 years.

If the amount of carbon dioxide in the atmosphere were suddenly doubled, with other things remaining the same, the outgoing long-wave radiation would be reduced by approximately $4\,\mathrm{W\,m^{-2}}$ and instead trapped in the atmosphere, resulting in an enhanced greenhouse effect. To restore the radiative balance, the atmosphere must warm up and, in the absence of

other changes, the warming at the surface and throughout the troposphere would be approximately 1.2°C. In reality, many other factors will change, and various feedbacks come into play, so that the best estimate of the average global warming for doubled carbon dioxide is 2.5°C. In other words, the net effect of the feedbacks is positive and approximately doubles the response otherwise expected.

Increased heating therefore increases global mean temperatures and also enhances evaporation of surface moisture. It follows that naturally occurring droughts are likely to be exacerbated by enhanced drying. After the land is dry, all the solar radiation goes into increasing temperature, causing heat waves. Temperature increases signify that the water-holding capacity of the atmosphere increases and, with enhanced evaporation, the atmospheric moisture increases, as is currently observed in many areas. The presence of increased moisture in the atmosphere implies stronger moisture flow converging into all precipitating weather systems, whether they are thunderstorms, extratropical rain, or snow storms. This leads to the expectation of enhanced rainfall or snowfall events, which are also observed to be happening. Globally, there must be an increase in precipitation to balance the enhanced evaporation and hence there is an enhanced hydrological cycle.

The main positive feedback comes from water vapor. As the amount of water vapor in the atmosphere increases as the earth warms, and because water vapor is an important greenhouse gas, it amplifies the warming. However, increases in clouds may act either to amplify the warming through the greenhouse effect of clouds or reduce it by the increase in albedo; which effect dominates depends on the height and type of clouds and varies greatly with geographic location and time of year. Decreases in sea ice and snow cover, which have high albedo, decrease the radiation reflected back to space and thus produce warming, which may further decrease the sea ice and snow cover, known as ice albedo feedback. However, increased open water may lead to more evaporation and atmospheric water vapor, thereby increasing fog and low clouds, offsetting the change in surface albedo.

Other, more complicated feedbacks may involve the atmosphere and ocean. For example, cold waters off the western coasts of continents (such as California or Peru) encourage development of extensive low stratocumulus cloud decks that block the sun and this helps keep the ocean cold. A warming of the waters, such as during El Niño, eliminates the cloud deck and leads to further sea surface warming through solar radiation.

11.3 Effects of Aerosols

Aerosols occur in the atmosphere from natural causes; for instance, they are blown off the surface of deserts or dry regions. As a result of the eruption of Mt. Pinatubo in the Philippines in June 1991, considerable amounts of aerosol were added to the stratosphere that, for approximately 2 years, scattered solar radiation leading to a loss of radiation and a cooling at the surface.

As noted previously, human activities also affect the amount of aerosol in the atmosphere. The main direct effect of aerosols, such as sulfate particles, is the scattering of some solar radiation back to space, which tends to cool the earth's surface. Aerosols can also influence the radiation budget by directly absorbing solar radiation, leading to local heating of the atmosphere, and, to a lesser extent, by absorbing and emitting thermal radiation. A further influence of aerosols is that many of them act as nuclei on which cloud droplets condense. A changed concentration therefore affects the number and size of droplets in a cloud and hence alters the reflection and the absorption of solar radiation by the cloud.

Because man-made aerosols typically remain in the atmosphere for only a few days before they are washed out by precipitation, they tend to be concentrated near their sources, such as industrial regions, adding complexity to climate change because they can help mask, at least temporarily, any global warming arising from increased greenhouse gases.

12. OBSERVED AND PROJECTED TEMPERATURES

Changes in climate have occurred in the distant past as the distribution of continents and their landscapes have changed, as the so-called Milankovitch changes in the orbit of the earth and the earth's tilt relative to the ecliptic plane have varied the insolation received on earth, and as the composition of the atmosphere has changed, all through natural processes. Recent evidence obtained from ice cores drilled through the Greenland ice sheet indicates that changes in climate may often have been quite rapid and major and not associated with any known external forces.

Observations of surface temperature show a global mean warming of approximately 0.7°C during the past 100 years. The warming became noticeable from the 1920s to the 1940s, leveled off from the 1950s to the 1970s, and increased again in the late 1970s. The calendar year 1998 is the warmest on record. The 1990s are the warmest decade on record. Information from paleodata further indicates that these years are the warmest in at least the past 1000 years, which is as far back as a hemispheric estimate of temperatures can be made. The melting of glaciers throughout most of the world and rising sea levels confirm the reality of the global temperature increases.

Climate modeling suggests that solar variability has contributed to some of the warming of the 20th century, perhaps 0.2°C, up to approximately 1950. Changes in aerosols in the atmosphere, both from volcanic eruptions and from visible pollutants and their effects on clouds, have also contributed to reduced warming, perhaps by a couple of tenths of a degree. A temporary cooling in 1991 and 1992 followed the eruption of Mount Pinatubo in June 1991. Heavy industrialization and associated pollution following World War II may have contributed to the plateau in global temperatures from approximately 1950 to 1970. Interactions between the atmosphere and the oceans, including El Niño, have contributed to natural fluctuations of perhaps two-tenths of a degree. It is only after the late 1970s that global warming from increases in greenhouse gases has emerged as a clear signal in global temperatures.

Projections have been made of future global warming effects based on model results. Because the actions of humans are not predictable in any deterministic sense, future projections necessarily contain a "what if" emissions scenario. In addition, for a given scenario, the rate of temperature increase depends on the model and features such as how clouds are depicted so that there is a range of possible outcomes. Various projections in which the concentrations of carbon dioxide double 1990 values by the year 2100 indicate global mean temperature increases ranging from 2 to 4°C higher than 1990 values. Uncertainties in the projections of carbon dioxide and aerosols in the atmosphere add to this range. However, a major concern is that the rates of climate change as projected exceed anything seen in nature in the past 10,000 years.

Glossary

core sample A specimen obtained in a long cylinder, taken from a physical site for subsequent study; used in many fields, including oil exploration and archaeology. In archaeology, elements in the core sample can be carbon dated, allowing a reconstruction of the implicit historical record.

Malthusian population dynamics A demographic theory originated by Thomas Malthus, suggesting that the human population has a natural tendency to grow sufficiently rapidly to offset and perhaps even overshoot productivity gains in food production. Malthus also made the related assertion that population growth will therefore be sensitive to per capita consumption—tending to increase when consumption rises and to decrease when consumption falls. Hence, the term refers to a situation in which population growth is positively related to per capita consumption. It is noteworthy that the term does not describe societies that have gone through the so-called demographic transition in which fertility tends to fall at sufficiently high income levels, it does seem to describe societies at the level of development of Easter Island prior to European contact.

market failure A situation in which markets fail to achieve economic efficiency. Open-access resources and, more broadly, difficulty in establishing property rights constitute an important source of market failure.

open-access resource A resource to which any potential user can gain access. Various communities have sometimes had land to which everyone had access, e.g., a "common," consisting of grazing land. It was commonly observed that such common land was often overgrazed. The tendency to overuse open-access resources is sometimes referred to as the "open-access" problem, which is an extreme version of "incomplete property rights," arising when the owner or controller of an economic resource can exclude other users only at significant cost.

predator–prey system A system in which a "prey" forms an important part of the consumption for a "predator." It has often been observed that predators and prey (such as lynx and rabbits) sometimes go through dramatic population cycles. In the early 20th century, Lotka and Volterra independently studied the formal properties of simple linear two-equation dynamic systems in an effort to shed light on predator–prey systems. They discovered that population cycles are a natural outcome of such systems for particular parameter values. Extinction and monotonic convergence to a steady state are also possible dynamic trajectories in predator–prey models.

Easter island (or rapa nui) is remarkable for being a small geographic entity that has generated enormous academic and popular interest. This interest arose primarily from the enormous stone statues, or moai, positioned at various locations around the island. These moai are sometimes referred to as "the mystery of Easter Island." The mystery of the moai remained unsolved until the last decade of the 20th century, when it became clear that the statues were intimately connected to a story of resource depletion and collapse.

1. THE MYSTERY OF EASTER ISLAND

1.1 Early European Contact

First European contact with Easter Island occurred on Easter Day of 1722, when three Dutch ships under the command of Jacob Rogaveen stopped for a 1-day visit at the very isolated South Pacific island, just over 3000 km west of Chile. The visitors observed a small, treeless island populated by what they thought were about 3000 islanders and, to their surprise, by a large number of giant statues. The outside world had no previous knowledge of Easter Island and the islanders apparently had no awareness of the outside world. The visit must have been a shock to the Easter Islanders, but no systematic account of their reaction survives and no further contact with Europeans occurred until 1770, when a Spanish vessel made a brief stop.

The first systematic study of Easter Island dates from the 1774 visit of James Cook. At least one member of Cook's crew could understand the Polynesian dialect spoken by the Easter Islanders. This allowed Cook to infer that the Easter Island population was in fact Polynesian. In addition, Cook learned that the islanders believed that the statues had been built and moved to their then-current locations by some supernatural force. Certainly the islanders of 1774 had no concept of how to carve or move the statues. Cook estimated that the island's population was about 2000, which would have been insufficient to move the statues using any technology available on the island.

1.2 Explanations of the Moai

The mystery of how the statues came into existence remained a topic of increasingly fanciful speculation from Cook's day forward. Among the more striking theories advanced to explain the mystery include Thor Heyerdahl's view that the statues had been built by an advanced South American civilization that had discovered and colonized Easter Island before somehow being displaced by a less advanced Polynesian society. In an effort to support his theory, Heyerdahl undertook a famous voyage to Easter Island, in a reed boat named the Kon Tiki, starting from off the coast of Chile. An alternative and even more exotic theory was that Easter Island was the remnant of the hypothesized archipelago civilization of "Mu" that, similar in concept to Atlantis, had sunk beneath the ocean due to geological events. Perhaps the most remarkable theory was that of Eric von Daniken, who wrote a best-selling book (*Chariots of the Gods*) and produced a popular 1970s television series, which proposed that the statues had been built by extraterrestrials.

These imaginative explanations have been displaced by scientific evidence, including carbon dating of core samples taken from Easter Island and a genetic study of skeletal remains on Easter Island. This evidence has allowed the development of a rather different understanding of Easter Island's past. This understanding, based on resource depletion and collapse, explains both the statues and the decline of the Easter Island civilization.

2. FIRST DISCOVERY AND EARLY HISTORY

2.1 The Virgin Forest

Although there is some uncertainty about dates, it now seems that Easter Island was first discovered by a small group of Polynesians sometime between 400 and 700 AD. The striking surprise that emerged from analysis of core samples is that Easter Island was at this time covered by a dense forest of *Jubaea chilensis* (the Chilean wine palm). This particular palm is a large, slow-growing tree that grows in temperate climates.

2.2 The Easter Island Economy

Following first discovery of Easter Island, the new inhabitants developed an economy based on the wine palm. Harvested trees were the raw material for canoes that could be used for fishing, leading to an early diet that depended very heavily on fish, gradually supplemented from other sources, including yams grown on deforested sections of the island, and domestic fowl. The population grew steadily and the civilization grew more sophisticated, allowing a substantial diversion of labor into ceremonial and other nonsubsistence activity. However, as time progressed, the forest stock gradually diminished. At first, liberation of forested land for agricultural uses, for dwelling space, and for other purposes would have been seen as a benefit. The rate of forest decline was slow. In a typical lifetime (somewhere between 30 and 40 years for those who survived early childhood), it would have been hard to notice a dramatic change in the forest cover because the stock would not have declined by more than about 5 or 6% over a 30- to 40-year period, until relatively near the end of viable forest.

3. RESOURCE DEPLETION AND COLLAPSE

3.1 An End to the Golden Age

By the turn of the millennium in 1000 AD, the population was still rising and a statue-carving culture had developed. The statues were carved in Easter Island's lone quarry and then transported to desired locations using logs as rollers. The forest stock would have been down to perhaps two-thirds of its original level and the islanders probably would have regarded as apocryphal any claims that the island was once fully forested. However, this much loss of forest cover would have begun to reduce rainfall (because low clouds could pass overhead more easily) and would also have reduced the capacity of the soil to retain water. These trends continued for the next several hundred years. The peak population (of probably between 10,000 and 14,000), the greatest intensity of statue carving, and the virtual elimination of the forest stock all occurred in the neighborhood of 1400 AD.

3.2 Collapse of a Civilization

The subsequent 100 years on Easter Island must have been very difficult. Statue carving declined and soon ceased entirely. A new weapon, almost certainly used for hand-to-hand combat, enters the archaeological record at this time. Chickens were moved into fortified enclosures, much of the population moved into caves, and there is evidence of cannibalism from this period. The population began to decline steadily. The population was apparently still decreasing in the 18th century, because the 1774 population estimate by Cook was significantly less than Rogaveen's estimate of 50 years earlier. In addition, Cook noted that many of the statues had been pushed over on their faces, but no such phenomenon was observed by Rogaveen. It seems likely that the middle of the 18th century was a turbulent time on Easter Island. As has been frequently observed, the Easter Island civilization temporarily surpassed its limits and crashed devastatingly.

4. MALTHUSIAN POPULATION DYNAMICS

4.1 A Cautionary Tale?

The basic facts regarding Easter Island are no longer in serious dispute. It is, however, important to understand why Easter Island suffered an internally generated collapse based on resource overuse. The real question is whether Easter Island is an unusual and isolated case or whether it is a cautionary tale for the modern world. It is therefore important to uncover any general principles that might be inferred from the Easter Island experience.

4.2 Malthusian Population Dynamics and Overshooting

One important idea that might shed light on Easter Island derives from Malthusian population dynamics. Polynesian societies (along with virtually all other societies at comparable stages of development) were Malthusian in the sense that fertility was positively related to consumption (or real income) and mortality was negatively related to consumption. Correspondingly, in times of increasing hardship, fertility would decrease and mortality would increase. Depending on the precise responsiveness of fertility and mortality to real income (or food supply), and on other aspects of the environment, it is possible for Malthusian populations to "overshoot." Such populations would tend to increase too rapidly to be sustained, leading to an ultimate population "crash" enforced by some of the more unpleasant instruments of mortality, such as disease, starvation, and violent conflict. This possible feature of Malthusian models led subsequent readers of economist Thomas Malthus to refer to economics as the "dismal science."

4.3 Mitigating Factors and Reinforcing Factors

Various factors can mitigate Malthusian population dynamics (as Malthus recognized), including technological progress and the possibility of a "demographic transition" under which fertility declines at sufficiently high incomes. (The combination of technological progress and a demographic transition has, of course, allowed most of the modern world to avoid the Malthusian trap over the two centuries that have passed since the time of Malthus.) On the other hand, as Malthus also realized, there are factors that tend to exacerbate Malthusian dynamics, including reliance on open-access resources and lack of property rights more generally.

4.4 Easter Island and Malthusian Overshooting

At a superficial level, Easter Island might look like a simple example of Malthusian population

overshooting. The mitigating factors were not present, in that little technological progress occurred and the level of income was never high enough for a demographic transition to be relevant. In addition, the Easter Island economy did suffer from heavy reliance on a renewable resource that very likely was characterized by open-access problems or at least by incomplete property rights. However, Malthusian overshooting cannot be the whole story, for most Polynesian societies did not experience the boom-and-bust pattern exhibited by Easter Island, even though these societies were similar to the Easter Island culture in most important respects. Thus, for example, islands such as Tahiti and New Zealand's North Island appeared to be in something approaching a long-run steady state at the time of first European contact. Therefore, there must be more to the story than simple Malthusian overshooting.

5. A PREDATOR–PREY SYSTEM WITH UNFORTUNATE PARAMETER VALUES

5.1 Easter Island as a Predator–Prey System

As reported in 1998 by Brander and Taylor, the understanding of Easter Island can be greatly advanced by using formal mathematical analysis. The formal description provided here relies on that analysis. One key point is that the Easter Island economy can be viewed as a "predator–prey" system. The forest resource can be considered as the prey and the Easter Islanders as the predators. One important aspect of even relatively simple predator–prey systems is that small to moderate changes in one or more key parameters can give rise to major qualitative changes in the dynamic pattern of population growth and decline. In particular, depending on parameter values, it is possible for a given model structure to give rise to smooth, or "monotonic," movement toward a steady state or, alternatively, to a boom-and-bust cycle. One possible behavior is long-run stability of the type apparently observed in Tahiti. Another possible behavior is the rise and fall that characterizes Easter Island. More broadly, it is quite possible that the same general model might describe a variety of Polynesian societies, with plausible variations in parameter values giving rise to the observed differences in demographic and economic experience.

5.2 Modeling the Renewable Resource Stock

The economy and ecology of Easter Island were relatively simple, but obtaining a tractable mathematical representation still requires significant abstraction and approximation. At a minimum, it is necessary to model the behavior of two "stocks" or "state variables": the forest stock and the population. In fact, it is an oversimplification to focus just on the forest stock. Even in the absence of the forest stock, grass, shrubs, and certain vegetables could be grown and this biomass was sufficient to support a diminished but significant population. Rather than introduce a third "stock" representing other biomass, it is simpler to aggregate the renewable resource base growing on the land into a single resource stock, denoted as S. For simplicity, sometimes just the term "forest" is used, but it should be kept in mind that other components of the flora biomass are also relevant.

5.3 Logistic Growth

The starting point for describing the evolution of a renewable resource stock is the logistic growth function. Using t to denote time, a simple logistic growth function has the form $G(t) = rS(1-S/K)$. The variable r is the intrinsic growth rate and K is the environmental carrying capacity, or maximum possible size of the resource stock. $G(t)$ is the growth rate defined in biomass units and G/S is the proportional growth rate (i.e., a number such as 0.1 or 10%). If the forest stock S reaches a level equal to carrying capacity K, then $G = 0$ and no further growth occurs. Similarly, if there is no forest stock, then $S = 0$ and no growth occurs. If the forest stock is small relative to carrying capacity (but positive), then S/K is negligible and $G = rS$. In this case, proportional growth G/S approaches r. Thus, we can think of r as the proportional growth rate in the absence of congestion effects. As the forest stock increases, there is congestion (competition for space, rainfall, sunlight, etc.), with the result that the proportional growth rate tends to decline. However, the base to which that growth rate is applied increases as S increases. Therefore, the absolute growth rate in biomass units increases with S up to a critical point beyond which the congestion effect dominates the increasing base effect and the absolute growth rate declines. A logistic growth function is illustrated in Fig. 1. It is clear from Fig. 1 that the maximum sustainable yield occurs at the maximum

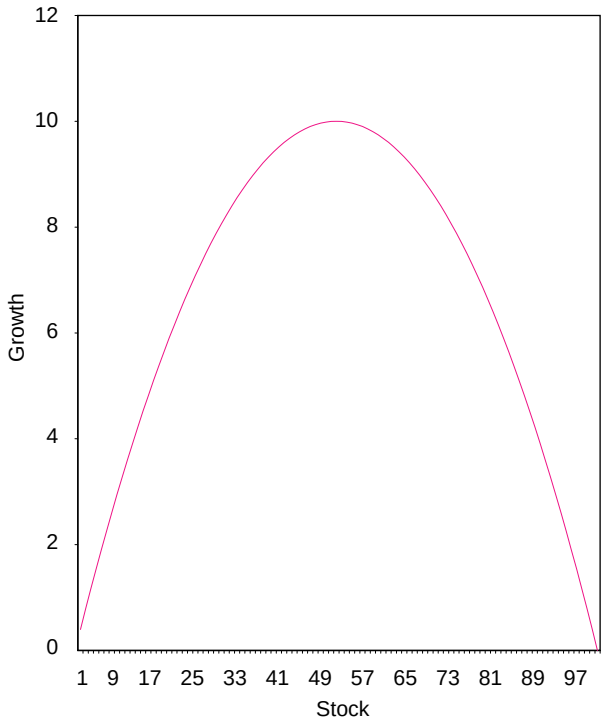

FIGURE 1 Logistic growth.

growth rate. In other words, it would be possible to maintain a stock of $K/2$ and harvest at this maximum growth rate in steady state.

5.4 Other Growth Functions

The logistic growth function is no doubt far from being a perfect approximation to the growth of the *Jubaea chilensis* forest on Easter Island. Various extensions to the logistic growth function are possible. For example, it is quite possible that at very low values of the stock, the proportional growth rate actually tends to decline. This is referred to as "depensation" or the "Allee effect." The logistic growth function can be augmented to allow for depensation, but that will not be pursued here. The basic logistic growth function does allow for the critical elements of biological renewable resource growth that are needed to capture at least the qualitative experience of Easter Island.

5.5 Open Access, Property Rights, and Harvesting Behavior

The natural growth of the forest stock provides part of the story in characterizing the evolution of the forest stock. The other part of the story depends on the harvesting behavior of the Easter Islanders. The key economic point is that under conditions of incomplete property rights, it is natural to expect that, for any given stock, the amount harvested at any given time period, $H(t)$, is increasing with population size. In other words, for any given set of external conditions and any given forest stock, we expect more harvesting to occur if there is a larger population seeking to use the forest stock. Similarly, for a given population, harvesting is easier if the stock is larger, and therefore more harvesting would be likely to occur. In the case of pure open access (no enforceable property rights) and standard demand and production functions, the harvesting function can be shown to take on the form $H = aSP$, where a is a parameter reflecting demand conditions and the harvesting technology and P is the population. This functional form is used here for concreteness, although other related functional forms would have similar properties. The differential equation that governs the evolution of the forest stock can therefore be written as

$$dS/dt = G(t) - H(t) = rS(1 - S/K) - aSP, \quad (1)$$

where state variables S and P are functions to time t.

5.6 Population Growth

To describe population growth, we adopt the linear form used by Lotka and Volterra in their original predator–prey formulations. The first component is a base net fertility rate, n, that would apply in the absence of a resource stock (and would presumably be negative in our environment). In addition, there is a second term that, from our point of view, captures the Malthusian idea that net fertility rises when per capita consumption rises. This implies that proportional net fertility should rise when, other things equal, the resource stock is larger. The effect follows because a higher stock (for a given population) would normally give rise to higher per capita consumption. This reasoning leads to the following population growth function:

$$dP/dt = nP + bPS, \quad (2)$$

where b is a parameter that reflects economic conditions. It can be seen from Eq. (2) that proportional population growth rate $(dP/dt)/P$ equals the base rate plus some increment related to the per capita resource stock. The functional form could be changed to include a "congestion effect," similar to the congestion effect that arises in the logistic growth function that is used for the resource stock, but

Eq. (2) should allow a reasonable approximation to actual events.

5.7 A Dynamic System

Equations (1) and (2) form an interdependent dynamic system similar to the Lotka–Volterra predator–prey model. Equation (1) shows the evolution of prey (the forest stock) and has the key property that the prey tends to diminish more quickly when there are more predators (humans). Equation (2) shows the evolution of the predator and has the property that the predator increases more rapidly when prey are more numerous. Figure 2 illustrates the relationship between the principal "stocks" and "flows" in the model using a formal flow diagram.

It is possible to examine the properties of this model analytically. Solutions for steady states can be determined and the dynamic path leading from any initial conditions can be characterized. Depending on parameter values, three steady states are possible, one with no humans and the forest at environmental carrying capacity, one with no humans and no resource stock, and one "interior" steady state with positive stocks of humans and forest biomass. The dynamic evolution of the model can be either monotonic or cyclical, once again depending on parameter values.

5.8 Simulation of Easter Island

Perhaps the most revealing method of analysis of this dynamic system is through simulation. It is possible to estimate plausible values for the parameters in Eqs. (1) and (2) and simulate the evolution of Easter Island. The necessary parameters are a, b, n, r, and environmental carrying capacity K. It is also necessary to specify the size $P(0)$ of the initial founding population.

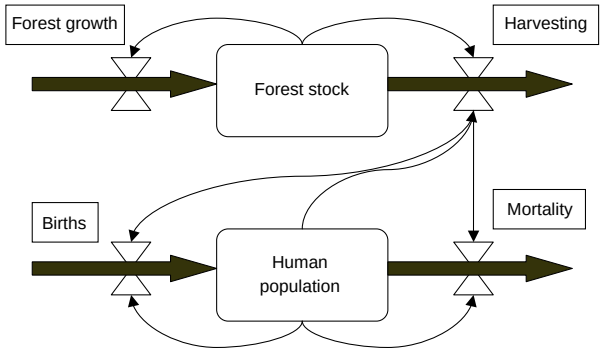

FIGURE 2 A flow diagram of stocks and flows.

The environmental carrying capacity and the initial forest stock are taken to be the same. Of course, the size of this stock can be normalized to any value. For scaling purposes, it is convenient if the resource stock is normalized to be of approximately the same magnitude as the maximum population, so we assume the initial resource stock (and environmental carrying capacity) is 12,000 biomass units. The initial population probably arrived in one or a few large ocean-going canoes that had traveled a considerable distance in search of new land. Take the founding population to be 40, although it makes very little difference if the founding population were taken to be twice or three times as large or, for that matter, if it were smaller. The net fertility rate, n, is the proportional (or percentage) rate of growth in the absence of the resource stock. In the simulation, discrete periods of 10 years will be used. Using a value of -0.1 for n indicates that, without the biomass in place, the population would tend to decline at a rate of 10% per decade. Parameters a and b reflect particular underlying economic conditions related to harvesting technology and to the preferences of the Easter Islanders. Because Eqs. (1) and (2) are being used as the starting points for the formal analysis here, parameters a and b could be viewed as essentially arbitrary parameters that we choose appropriately to "fit" the model to the experience of Easter Island. However, Eqs. (1) and (2) can be derived from more fundamental economic structures that suggest plausible magnitudes for a and b. A plausible magnitude for a is 4×10^{-5} and a plausible magnitude for b is 1.6×10^{-4}.

The key parameter of interest is the intrinsic growth rate, r. As it happens, *Jubaea chilensis* is a well-known species. It prefers temperate climate and grows slowly, normally requiring 40 to 60 years from first planting to the time it bears its first fruit. An intrinsic growth rate on the order of 4% per decade would be plausible. The Easter Island flora biomass consisted of more than just *J. chilensis*, but the forest was by far the most important part of the resource stock, so 4% (or 0.04) is used in the base case simulation for Easter Island.

To obtain simulations for Easter Island, Eqs. (1) and (2) are converted to discrete format. Thus, the two simulated equations are as follows:

$$S_{t+1} = S_t + rS_t(1 - St/K) - aS_tP_t, \qquad (1A)$$

$$P_{t+1} = nP_t + bP_tS_t. \qquad (2A)$$

The units of time are decades and the model is run for about 1200 years. The results are shown in Fig. 3.

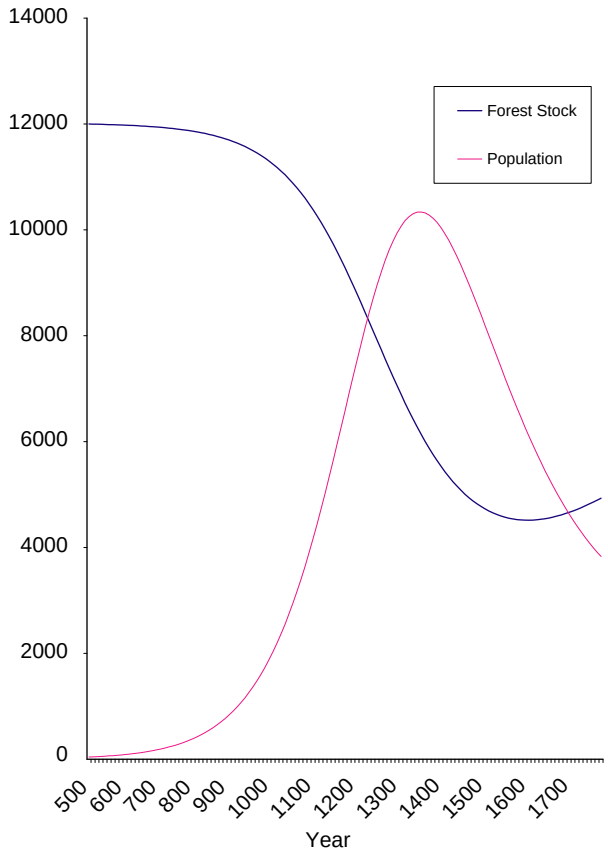

FIGURE 3 Easter Island simulation.

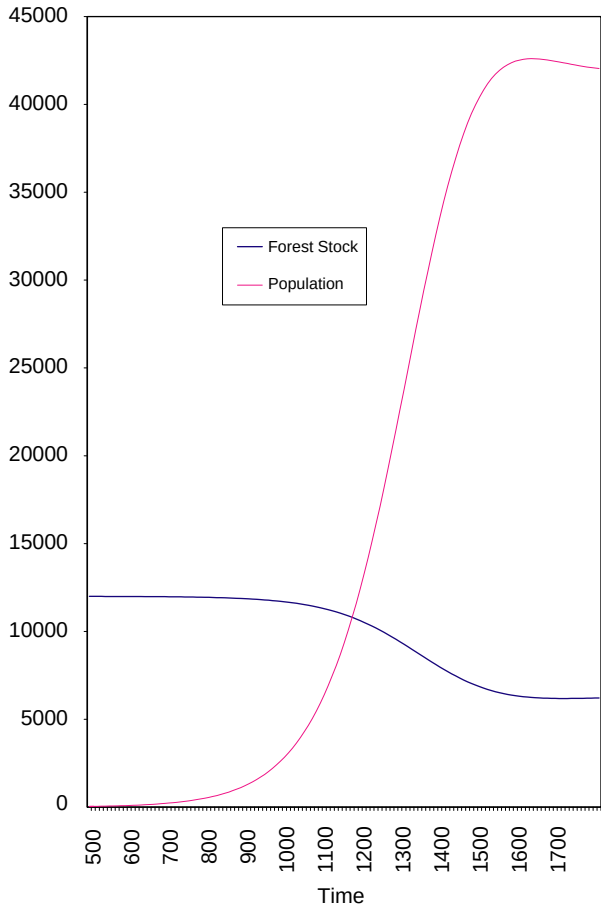

FIGURE 4 A fast-growing resource.

As can be seen in Fig. 3, this relatively simply model tracks the known facts about Easter Island quite well. If it is assumed that first colonization occurred in 500 AD, then peak population occurs in the 14th century at just over 10,000. From there, the population decreases and is down to a little over 4000 by the time of first European contact in 1722—a little high relative to actual estimates, but quite close. The resource stock is down to less than half its initial level by 1400 AD. On the actual Easter Island, this was about the time the wine palm forest completely disappeared, so for this to be accurate it would need to be the case that the flora biomass in the absence of the palm forest was about half of the biomass with the forest. This is certainly high, because the original palm forest had far more than twice the biomass of whatever shrubs, grass, and other vegetation was left after the forest was gone. Still, the general qualitative pattern shown in Fig. 3 is a reasonable representation of the Easter Island experience.

A particularly interesting variation of this simulation arises from making one change in a model parameter. Most of Polynesia did have palm forests. However, the palms growing on other islands grew much faster than the Chilean wine palm. The two most common large palms are the *Cocos* (coconut palm) and the *Pritchardia* (Fijian fan palm). These palms reach the fruit-growing stage after 7 to 10 years (much less than the 40- to 60-year period for the wine palm) and would have an intrinsic growth rate on the order of 35% per decade (rather than 4%). The resulting simulation is shown in Fig. 4, which illustrates a dynamic pattern strikingly different from that of Fig. 3. No boom-and-bust pattern is discernible. In fact, there is a very slight cycle that would not disappear entirely unless the intrinsic growth rate exceeded 71% per decade, but, even at 35%, the very gentle cycle would be much too damped to be evident to archaeologists and the approach to steady state is virtually monotonic. The forest stock declines smoothly to a new steady state that would correspond to having some standing forest in steady state. Low intrinsic growth rates, on the other hand, produce sharp cyclical fluctuations.

Therefore, in the predator–prey model described here, an island with a slow-growing resource base will exhibit overshooting and collapse. An otherwise identical island with a more rapidly growing resource base will exhibit a near-monotonic adjustment of population and resource stocks toward steady-state values. This fact alone can explain the sharp difference in experience between Easter Island and other Polynesian islands.

There are 12 so-called mystery islands in Polynesia that had been settled by Polynesians but were unoccupied at the time of first European contact. All these islands but one had relatively small carrying capacities. Applying our model, we see that if K (carrying capacity) is too small, then there is no interior steady state, implying that a colonizing population might arrive and expand but would eventually be driven to extinction.

6. THE ROLE OF PROPERTY RIGHTS AND OPEN ACCESS

A presumption underlying the analysis here is that property rights were incomplete, perhaps not to the point of full open access, but at least to the point where it was hard to prevent increased harvesting as the population increased. Specifically, in Eq. (1) harvesting is assumed to be increasing with population size for any given stock. This need not be the case if property rights are complete, because an efficient owner or manager of the resource would restrict access beyond some optimal point.

It is unlikely that Easter Island was characterized by complete open access, but it is very likely that property rights were incomplete in the sense that different competing harvesters probably had access to some common part of the forest. Incomplete property rights give rise to market failure, with the result that overharvesting occurs. In other words, the individual incentives faced by individual harvesters (or by small kinship groups) would lead to overharvesting from the collective point of view. As shown in Fig. 4, even with incomplete property rights, it is still possible to have monotonic adjustment to a steady state if parameter values are suitable. However, it would be even better if the society could enforce strict property rights. If a dictator or "social planner" could impose strict property rights, that person could, for example, set harvesting at the level of maximum sustainable yield and keep harvesting at that level independent of population size. However, by all accounts, that level of control was very difficult to impose and maintain in Polynesian and in most other societies.

In addition to the property rights problem, there was also a significant intertemporal market failure problem. Specifically, no one who planted or nurtured a young wine palm could expect to make personal use of that tree in his or lifetime, because life expectancy was short relative to the time taken for trees to reach maturity. Even the planter's children would be unlikely to benefit from the such activity. It would be the generation of one's grandchildren who would benefit from current planting activity. Thus, the incentives to undertake investments in planting and growing were weak. In modern societies, someone who plants a stand of trees can sell the stand at any time to someone else willing to hold the tree lot for some period of time—secure in the knowledge that it can be sold to still another person in the future. This mechanism of overlapping ownership connected through markets allows, in effect, future generations to "pay" for current investments. This is necessary for economic efficiency. However, in the Easter Island context, there would be no such markets. Thus, there would be a "market failure" leading to under investment in planting and growing trees. In primitive societies, social norms often take the place of market transactions in enforcing particular economic investments, but social norms are highly unreliable. In the Easter Island case, it is quite possible that the statue-carving norm dominated any conservation norms and worsened rather than mitigated the overharvesting problem.

7. AFTERMATH

It is useful to consider the history of Easter Island after the 18th century. The story is a very sad one—much worse than the endogenous boom-and-bust cycle that had already occurred on Easter Island. From the time of James Cook in the late 18th century through the mid-19th century, conditions on Easter Island gradually improved and the population increased gradually. Population was reliably estimated at something exceeding 3000 in 1862. In 1862 and 1863, slave traders from the Spanish community in Peru invaded the island and took about one-third of the islanders as slaves. Most of these slaves died of smallpox and other infectious diseases within a few years. A few returned to Easter Island, inadvertently causing a smallpox epidemic that killed most of the remaining Islanders.

By 1877, the population reached its low point of 111. Some of the deaths would have been due to causes other than smallpox, but, even allowing for these other causes, these numbers imply that the death rate from smallpox exceeded 90% of the base population—probably the highest death rate ever observed from an infectious disease invading a population of significant size. Although this has nothing to do with the pattern of resource overuse and collapse, it illustrates an important force in human history: the devastating effect that a new infectious disease can have on a long-isolated population.

From 1877, the population gradually increased through natural increase, immigration from other Polynesian islands (especially Tahiti), and immigration from the South American mainland. In 1888, the island was annexed by Chile, which maintains possession of the island at present. Population on the island has risen to something approaching 3000 and is devoted primarily to agriculture and to tourism. There is some mild tension between the predominantly Polynesian traditional or indigenous peoples and the South American population in Easter Island, but, on the whole, Easter Island is a peaceful and pleasant island that has become a major tourist destination of particular interest to "cultural tourists" who wish to see the now carefully maintained and protected moai.

8. LESSONS OF EASTER ISLAND

Some observers like to see Easter Island as a metaphor for the modern world. However, it is important to be aware of the differences. The first point, as has been emphasized already, is that societies of the Easter Island type do not necessarily have a dramatic decline. In the case of Easter Island, the civilization was "unlucky" to be on an island where the main resource was very slow growing. If the resource had been faster growing, then the boom-and-bust cycle probably would have been avoided, as it was in most of Polynesia. Therefore, even if Earth as a whole could be viewed as Easter Island writ large, there would no presumption about any inevitability of the imminent decline and fall of modern civilization.

On the other hand, Easter Island should not be viewed as an isolated case. As modern archaeology has made increasing use of sophisticated scientific methods, it has become increasingly clear that resource degradation has played an important role in the rise and fall of many civilizations. The truly unique feature of Easter Island was its isolation, which prevented migration as a response to resource degradation. In other parts of the world, overshooting population and resource degradation have led to substantial out-migration that mitigated, but did not eliminate, the population losses and the cultural losses associated with the boom-and-bust cycle. The lesson here is that resource management is very difficult, especially in conditions approaching open access, and overshooting is a genuine concern. This applies to the modern world just as it did to Easter Island. Thus, for example, major fisheries, major wildlife resources, and major forest resources around the world have been significantly compromised already. It is quite possible that various populations around the world, especially in areas with high population growth, such as Africa and parts of the Middle East, are on an overshooting trajectory.

Another lesson to be drawn from Easter Island concerns the danger of making simple linear projections based on a short time series. If an Easter Islander had, in the year 1300, extrapolated trends in population and real income based on the previous few centuries, that person would have failed to anticipate the "turning point" in population and real income that was coming. It is a characteristic of resource systems and predator–prey systems more broadly that cyclical patterns are common.

Even the two centuries of remarkable economic performance that have occurred in the time since Malthus should not encourage complacency about avoiding future Malthusian adjustment, especially if major renewable resource stocks (fish, forests, and soil) continue to decline. The world's current population growth rate is about 1.3% per year, significantly lower than its peak of 2.2% (reached in 1963), but still high by historical standards. Current population growth rates imply a population doubling in just over 50 years. Current resource stocks, even if degradation could be slowed or halted, would have a hard time supporting such a population at anything like current levels of real income, even adjusting for likely technological improvements over the next 50 years. A subsequent doubling in the latter half of the 21st century would seem completely infeasible. Therefore, it seems that population growth will have to fall dramatically from current levels over the next 100 years. Whether this is achieved through a benign demographic transition or through the more unpleasant Malthusian mechanisms of disease, famine, and violent conflict is still very much an open question at this stage.

Glossary

biocapacity The potential productivity of the biologically productive space within a specified country, region, or territory.

biologically productive space Areas of land and water capable of supporting photosynthesis at sufficient rates to provide economically useful concentrations of biomass. Marginal and unproductive regions, such as deserts, tundra, and the deep oceans, are excluded. The global biologically productive space totals 11.4 billion ha.

ecological deficit The amount by which the ecological footprint of a population (e.g., a country or region) exceeds the biocapacity of the space available to that population.

ecological footprint A measure of how much biocapacity a population, organization, or process requires to produce its resources and absorb its waste using prevailing technology.

ecological overshoot Ecological deficit met through the overexploitation of resources or accumulation of waste. William Catton defines the term as "growth beyond an area's carrying capacity, leading to crash."

embodied energy The energy used during a product's entire life cycle for manufacture, transport, operation, and/or disposal.

global hectare One hectare of biologically productive space with world-average productivity.

productivity A measurement of the potential rate of biological production of a given area. Various indicators can be used to weight productivity, including agricultural suitability, potential net primary production, and useful biomass extraction.

The ecological footprint is a measurement that compares rates of human resource consumption and waste generation with the biosphere's rates of resource regeneration and waste assimilation, expressed in terms of the area necessary to maintain these flows. Ecological footprints represent the biologically productive space required to produce the resources and absorb the wastes of a given population, organization, or product using prevailing management and technology.

1. ECOLOGICAL OVERSHOOT

The nature of ecological limits may be one of the most influential misconceptions of the sustainability debate. A former executive director of the United Nations (UN) Population Fund stated that "many environmentalists think [that the carrying capacity of Earth] is 4 billion, maximum. But now we have 6 billion people." The continued growth of the human population and resource consumption, however, is only an apparent contradiction. In reality, ecological limits can be exceeded for a period of time because nature reacts with inertia. More precisely, natural capital can be harvested faster than it regenerates, thereby depleting the natural capital stock. Ecologists call this state overshoot.

The concept of overshoot reconciles the apparently contradictory assertions that standards of living are waxing while ecological capacity is waning. Nevertheless, uncertainties remain regarding the possible impacts of prolonged overshoot. Some fear that unsustainable harvests will trigger the sudden collapse of ecosystems, leaving fisheries and other dynamic resource stocks irreversibly damaged.

 © 2004 Elsevier Inc. All rights reserved.

Others hope that the contraction of ecosystem services will be slower and more forgiving.

The delayed effects of overshoot and difficulty of valuing ecosystem services prevent markets and uninformed policy from forming corrective feedback mechanisms. Without adequate feedback mechanisms, such as systematic accounting that compares human demands on nature with nature's capacity to regenerate, overshoot can go unnoticed, thereby undermining humanity's future. Industrial economies in particular can exceed "sustainable limits" by masking resource depletion and decreasing energy returns on investment with technological advances, inexpensive energy, and easy access to distant resources. Particularly on the waste side, feedback is weak: CO_2 from fossil fuel burning leaves tailpipes with ease, independent of the increasing CO_2 concentration in the atmosphere.

No national government or UN agency operates a comprehensive accounting system to document the extent to which human demands fit within the capacity of existing ecosystems. The ecological footprint is one of the few tools that attempts integrated resource accounting.

The purpose of ecological footprints is not only to illustrate the possibility of overshoot but also to offer a robust tool to demonstrate its occurrence. As a resource accounting tool, it can help determine who is contributing, and how much, to the overall impact of humanity. Most important, it can evaluate potential strategies for avoiding overshoot.

2. CONCEPTUAL PREDECESSORS OF THE ECOLOGICAL FOOTPRINT

Biophysical assessments of human dependence on nature date back thousands of years to tales about the relationship between people and land. Records on the concept of carrying capacity trace at least as far back as Plato's "Laws," Book V, which states that a "suitable total for the number of citizens cannot be fixed without considering the land and the neighboring states. The land must be extensive enough to support a given number of people in modest comfort, and not a foot more is needed."

The first scholarly book in English on sustainable resource use may have been John Evelyn's 1664 "Sylva: A Discourse of Forest Trees and the Propagation of Timber." In North America, George Perkins Marsh's widely read 1864 study, "Man and Nature," was influential in increasing the awareness of nature's limited capacity to provide for human demands. Formal ecological accounting dates to 1758, when François Quesnay published "Tableau Economique," which captures the relationship between land productivity and wealth creation. Intellectual groundwork for more recent studies was laid in the 1960s and 1970s, particularly through George Borgstrom's concept of "ghost acreage," Howard Odum's energy analyses, and Jay Forrester's model on world resource dynamics presented in Donella Meadows *et al*.'s "Limits to Growth" report to the Club of Rome in 1972.

Natural capital accounts focused on regional and global limits are increasingly prominent in the political debate. Peter Vitousek's 1986 landmark study, "Human Appropriation of the Products of Photosynthesis," compiled consumption data to determine the human economy's draw on terrestrial net primary productivity. Based on 1980s data, the study estimates that humanity co-opts 40% of the photosynthetic materials produced by terrestrial ecosystems, excluding the photosynthesis that assimilates fossil fuel emissions and other anthropogenic waste. Fischer-Kowalski and Hüttler used material flow analysis to advance measurements of societal metabolism, a macroindicator of the environmental performance of societies. The World Resources Institute's biennial "World Resources" report and the United Nations Environment Programme's (UNEP) "Global Environmental Outlook" provide detailed documentation of pressures facing global ecosystems but do not contain aggregated impact assessments.

3. COMPONENT- AND COMPOUND-BASED APPROACHES

There are two basic ecological footprinting methods: component- and compound-based. The first calculates the footprint of individual goods or organizations. This bottom-up, component-based method first identifies all relevant items and then assesses the ecological footprint of each item using life-cycle data. The overall accuracy of the final result depends on the completeness of the component list as well as the reliability of the life-cycle assessment (LCA) of each identified component. This approach provides a high level of detail but has limitations due to LCAs' frequent inaccuracies, incompleteness, and poorly defined boundaries. The component-based method also has difficulty with data gaps and indirect expenditures outside of an organization's inventories, such as public infrastructure and military.

The compound-based method uses a top-down approach to aggregate economic and environmental statistics into national ecological footprints. Compound footprinting, which underlies the national results presented in this article, calculates the ecological footprint using aggregate national data. This information is more complete than subnational sources and LCAs and captures both direct and indirect consumption. For instance, to calculate the paper footprint of a country, information about the total amount consumed is typically available and sufficient for the task. In contrast to the component method, there is no need to know which portions of the overall paper consumption were used for which purposes, aspects that are poorly documented in statistical data collections.

4. METHOD OF NATIONAL ECOLOGICAL FOOTPRINT ACCOUNTING

National ecological footprint accounts consist of two measurements. The footprint aggregates the total area a given population, organization, or process requires to produce food, fiber, and timber; provide space for infrastructure; and sustain energy consumption. The biocapacity aggregates the total area available to supply these demands.

The ecological footprint focuses on six potentially renewable demands: cropland, pasture, forests, built-up land, fisheries, and energy. Activities in these components are deemed sustainable if rates of resource use and waste generation do not exceed a defined limit that the biosphere can support without degrading the resource stock. By including a core set of potentially sustainable activities, the ecological footprint defines minimum conditions for sustainability.

The results underestimate human impact and overestimate the available biocapacity by counting each footprint component only once if multiple demands come from the same area; choosing the more conservative footprint estimates and more optimistic biocapacity estimates when in doubt; and including agricultural practices as if they would not cause long-term damage to soil productivity. The accounts also exclude activities for which there is insufficient data or understanding, such as acid deposition. Activities that systematically erode nature's capacity to regenerate are also excluded, including aquifer depletion, soil erosion, and the release of chlorofluorocarbons.

In order to provide a quantitative answer to the research question of how much regenerative capacity is required to maintain a given resource flow, ecological footprint accounts use a methodology grounded on six assumptions:

1. It is possible to use annual national statistics to track resource consumption and waste generation for most countries.
2. Resource flows can be measured in terms of the bioproductive area necessary for their regeneration and the assimilation of their waste. (Resource and waste flows that cannot be measured are excluded from the assessment.)
3. Bioproductive areas of different productivity can be expressed in a common unit of standardized usable biological productivity. Usable refers to the portion of biomass used by humans, reflecting the anthropocentric assumptions of the footprint measurement.
4. The sum of mutually exclusive areas needed to maintain resource flows expressed in a common unit represents aggregate demand; the sum of mutually exclusive bioproductive areas expressed in a common unit represents aggregate supply.
5. Human demand (footprint) and nature's supply (biocapacity) are directly comparable.
6. Area demand can exceed area supply, meaning that activities can stress natural capital beyond its regenerative capacity. For example, the products from a forest harvested at twice its regeneration rate have a footprint twice the size of the forest. A footprint greater than biocapacity indicates ecological deficit. Ecological deficits are compensated in two ways: Either the deficit is balanced through imports (ecological trade deficit) or the deficit is met through overuse of domestic resources, leading to natural capital depletion (ecological overshoot).

Cropland, forests, pastures, and fisheries vary in biological productivity, or their capacity to provide ecological goods and services through photosynthesis. One hectare of arid rangeland, for example, has less capacity to recycle nutrients, produce food, and support diverse land-use patterns than one hectare of temperate forest. The ecological footprint therefore normalizes each bioproductive area—cropland, pasture, forests, built-up land, and fisheries—into common units of "global hectares" (gha).

Current accounts weight productivity according to agricultural suitability—a function of numerous factors, including temperature, precipitation, soils, and slope. The Food and Agriculture Organization and International Institute for Applied Systems

TABLE I

Global Biocapacity[a]

Area	Equivalence factor (gha/ha)	Global area (billion ha)	Biocapacity (billion gha)
Cropland	2.1	1.5	3.2
Pasture	0.5	3.5	1.6
Forest	1.3	3.8	5.2
Built-up land	2.2	0.3	0.6
Fisheries	0.4	2.3	0.8
Total	1.0	11.4	11.4

[a] The relative productivities of major global bioproductive areas, expressed in actual area (hectares) and productivity-weighted area (global-hectares). Equivalence factors are based on the suitability index of Global Agro-Ecological Zones 2000 (FAO/IIASA). Data are rounded.

Analysis have created a spatially explicit distribution of these variables in the "suitability index" of Global Agro-Ecological Zones 2000. Recent ecological footprint accounts use this index to translate unweighted hectares into global hectares (Table I). Other possibilities for weighting productivity include potential primary production and the rate of economically useful biomass production.

5. BIOPRODUCTIVE AREAS OF THE ECOLOGICAL FOOTPRINT

Earth has a surface area of 51.0 billion ha, of which 36.6 billion ha is ocean and inland waters and 14.4 billion is land. Ecological footprint accounts estimate that less than one-fourth of Earth's surface—9.1 billion ha of land and 2.3 billion ha of water—provides sufficient concentrations of economically useful biomass to be considered biologically productive. The 11.4 billion ha of bioproductive area is differentiated into five components: cropland, pastures, forests, built-up land, and fisheries. The remaining 39.6 billion ha is marginally productive or unproductive for human use because it consists of the deep oceans, is covered by ice, or lacks fertile soils and fresh water.

Cropland occupies approximately 1.5 billion ha of the most productive land worldwide. Current accounts include 74 crops and 15 secondary products and report details on how food crops are used (waste, seeds, feed, food, and processing), traded, and stored. These numbers document the area dedicated to cultivation and omit impacts from unsustainable agricultural practices, such as long-term damage from topsoil erosion, salinization, and contamination of aquifers with agrochemicals.

Pastures, which cover 3.5 billion ha, supply a substantial part, perhaps half, of the metabolic needs of livestock worldwide. Differing definitions of what constitutes pasture, poorly documented temporal and spatial variations in forage production and quality, and difficulties in separating metabolic needs supplied through concentrate feeds, crop residues, and other nonpasture sources make the pasture footprint difficult to determine. Healthy pastures are a critical component of food security, and even a preliminary assessment of their global capacity to support livestock would improve the current dearth of data.

Forests provide lumber, pulp, and fuelwood and include both natural forests and plantations. The Food and Agriculture Organization's "Forest Resource Assessment 2000" places the total area at 3.8 billion ha. Estimates of timber productivity are derived from the UN's Economic Commission for Europe's "Temperate and Boreal Forest Resource Assessment 2000" and data from the Intergovernmental Panel on Climate Change. These sources also provide information on plantation type, coverage, timber yield, and areas of protected and economically inaccessible forest.

Fisheries are concentrated on a relatively narrow portion of the ocean located on continental shelves. Excluding inaccessible or unproductive waters, these include an estimated 2.0 billion ha. Although a mere fraction of the ocean's 36.3 billion ha, this 2.0 billion ha provides 95% of the marine fish catch. Inland waters comprise an additional 0.3 billion ha.

Higher trophic-level fish—species high on the food chain—consume a proportionally greater portion of the ocean's primary productivity than lower trophic-level fish. It is estimated that each level up in the food chain translates into a 10-fold increase in demand for photosynthetic production per unit of biomass. Thus, 1 ton of cod at trophic level 4 has a footprint 10 times larger than 1 ton of sardines at trophic level 3. (Trophic level 1 corresponds to photosynthetic species at the base of the food chain—the primary producers.)

Built-up land for housing, transportation, industrial production, and capturing hydroelectric power occupies approximately 0.3 billion ha. Built-up land is poorly documented at a global level, partially due to different definitions used in various studies and the difficulty of satellites to view smaller objects and linear developments such as roads. However, some

countries, such as those in the European Union, have more reliable data sets. Current accounts assume that built-up land replaces cropland because most human settlements favor fertile regions well suited for agriculture. Hence, urban expansion encroaches typically on cropland.

6. FOSSIL ENERGY

The footprint of fossil fuels can be assessed by a number of approaches. The question of how much regenerative capacity is required to maintain the throughput of fossil fuel through the human economy can be addressed from three perspectives: absorbing the waste, maintaining the energy supply, and maintaining the resource. While locally significant, the area required for extraction, solid waste disposal, and power production is comparatively small at 3.2 ha/MW. In contrast, the waste assimilation method places the footprint for carbon emissions from the operation, construction, and maintenance of a typical coal-fired facility at 1900 gha/MW and the footprint of a similar-sized natural gas plant at 1050 gha/MW.

6.1 Waste Assimilation Method

The most common method for determining the ecological footprint of fossil fuels is based on the assumption that the primary limitation for fossil fuel use is the biosphere's ability to absorb CO_2 waste emissions. Following the dictum of the 1992 UN Framework Convention on Climate Change that calls for CO_2 stabilization in the atmosphere, the waste assimilation approach estimates how much larger the biosphere would need to be to provide the absorptive services to remove excess carbon emissions. Most accounts calculate this area by estimating the additional forest area required to fully sequester CO_2 emitted from the burning of fossil fuels.

Of the average annual 6.3 Gt of anthropogenic carbon emitted from fossil fuel combustion and cement production during the 1990s, the ocean absorbed an estimated 1.7 Gt and the land another 1.4 Gt. This imbalance has led to an increase in the atmospheric concentration of CO_2 from a preindustrial level of 280 parts per million (ppm) in 1750 to 370 ppm at the end of the 20th century. Given that carbon has a much shorter residence time in the terrestrial sink than in the oceanic sink, reflects prior biomass removal, and is susceptible to re-release from land-use and climate changes, current accounts only deduct the emissions sequestered in the ocean from the footprint.

Although possibilities for carbon sequestration include the fertilization of oceans and the pumping of carbon emissions underground, the reversion to forests from human-altered landscapes—cropland, pastures, and settlements—is used to calculate the footprint because it best reflects the biosphere's sequestration potential without human management. Reforestation measures have been implemented on a small scale and actively debated as a legitimate source of carbon credits in international climate negotiations. However, this approach does not suggest that the problem of increasing CO_2 concentration in the atmosphere can be solved through sequestration alone. Rather, it shows that the biosphere does not provide sufficient biological capacity for sequestration, and that it is highly unlikely that the CO_2 concentration in the atmosphere can be stabilized without reducing carbon emissions.

According to this method, the ecological footprint of fossil fuels equals the area that would be needed to assimilate carbon emissions through reforestation. Although sequestration rates vary with the temporal and spatial scales involved, and global average rates cannot be determined with great precision, sequestration would decrease significantly after 30–50 years as replanted forests mature. Although some studies have found that mature forests have retained their sink capacity, others have found that they loose their capacity or even become net carbon sources. Using the waste assimilation approach, the ecological footprint of fossil fuels provides a conservative estimate of the bioproductive area needed to assimilate carbon emissions. Assuming a generous sequestration rate of 0.95 tons C/ha/year and deducting the oceanic sink, a reforested area of more than 6 billion gha would be needed to balance current emissions. The total bioproductive land mass amounts to only 9.1 billion ha, equivalent to 10.6 billion gha.

6.2 Renewable Substitution Method

This approach builds on the idea of maintaining the energy stock. This means that depleted fossil fuel would be compensated with equivalent amounts of energy stocks. The most common long-term energy stock the biosphere accumulates is in wood. Hence, this method for calculating the ecological footprint of fossil fuels, and nonrenewable fuels in general, estimates the area required to supply their energy equivalent in fuelwood.

The ecological footprint of fossil fuels thus becomes the area needed to renew the energy equivalent of fossil fuel combustion. Unlike large-scale hydropower or geothermal energy, the energy stored in fuelwood is available in unmanaged systems and has been the mainstay of most pre-industrial societies (although many have managed fuelwood stocks). The ecological footprint expressed in fuelwood compares societies' nonrenewable energy demands with the biosphere's unmanaged renewable supply. On average, forests produce approximately 40 GJ of fuelwood/gha/year. Harvesting young, quickly growing trees may increase this capacity to 60 GJ/gha/year. Much of the energy captured by forests through net primary production is lost to decomposition and herbivory, and a portion of the remaining biomass energy, or net ecosystem productivity, is in foliage, roots, or other sources less suitable as fuel.

Variations of this technique describe the area needed to derive the energy equivalent of fossil carriers not in fuelwood but in cultivated biomass such as switchgrass, ethanol, or methanol derived from agriculture or forestry. Converting biomass fuels into liquid and gaseous mediums for use in prevailing infrastructure would net less energy than the total captured in unconverted biomass.

Andrew Ferguson of Optimum Population Trust promotes a slightly different approach by estimating an appropriate mix of renewable energy sources—photovoltaic arrays, offshore and onshore wind turbines, biomass-based ethanol, etc. The composition of the mix reflects the limitations of wind power due to its irregular availability and the cost barriers of photovoltaic arrays. He estimates that this mix could generate the current energy demand at approximately 95 GJ/ha/year. This would most likely occupy above-average-quality land, indicating an energy yield less than 95 GJ/gha/year.

6.3 Fossil Carrier Regeneration

This method treats fossil fuels like a renewable resource. The waste assimilation and renewable substitution approaches give the areas needed to balance emissions and energy stocks, not the area required to renew fossil fuels per se. This approach considers fossil fuels as a very slowly renewable resource limited by sedimentation and accumulation rates, and it defines their use as sustainable only when the fossil fuel stocks in the lithosphere are neither diminished nor transferred to the atmosphere (Table II). This method provides an assessment of the area needed to continue fossil fuel consumption indefinitely. With a global footprint of 100 gha/capita—50 times greater than global biocapacity and 100 times greater than the footprint from carbon sequestration and fuelwood substitution—it also demonstrates that the continued disparity between rates of fossil fuel consumption and creation will lead to the stock's depletion.

TABLE II

Regeneration Rates of Fossil Energy[a]

Fossil energy carriers	Yield (MJ/m^2/year)
Coal	0.05
Fuels	0.08
Natural gas	0.01

[a] Annual accumulation rates of fossil energy carriers based on estimated rates of carbon sedimentation. The data are presented in unweighted hectares. The ecological footprint typically weighs hectares by their productivity. From Ströglehner (2003).

7. NUCLEAR ENERGY

As with fossil fuels, the area occupied through extraction, production, and waste disposal of nuclear energy is relatively minor, amounting to 0.4 ha/MW. The embodied energy of nuclear infrastructure is small relative to the energy output because of the high energy density of nuclear fuel. By itself, nuclear fuel makes relatively few demands on biological productivity when contained, but intentional and accidental releases of radioactive materials have compromised human and environmental health. Failures of nuclear power plants can appropriate large bioproductive areas by making them unsuitable for human use for extended periods of time. The meltdown of Chernobyl has completely removed a 170,000-ha "zone of alienation" from economic turnover and restricted activities on hundreds of thousands of additional hectares since the 1986 accident and possibly for thousands of years into the future. Fallout contaminated larger areas extending from nearby Ukraine, Belarus, and southwestern Russia to distant Poland, Norway, and Sweden. The actual biocapacity occupied by nuclear energy is uncertain and speculative. Some studies treat the nuclear footprint as negligible or subsume these demands within national built-up areas and fossil fuel expenditures. Most nuclear footprints use the footprint of the fossil fuel energy equivalent.

8. RENEWABLE ENERGY

Some studies have examined the ecological footprint of renewable energy sources but more work is needed (Table III). This inattention is partly due to the fact that renewable sources provide an insignificant fraction of all commercial energy. Moreover, rapidly developing technologies make generalizations about conversion efficiencies, embodied energies, and life spans difficult. Although the energy embodied within the fossil fuel infrastructure is miniscule when compared with the energy expended in the fuels' extraction, transportation, and combustion, the energy embodied in most renewables' infrastructure dominates an essentially free energy source.

8.1 Hydropower

Hydropower is the largest renewable source of commercial energy. In 1995, it provided 7% of all commercial energy and 20% of electricity globally. The ecological footprint of hydropower is based on the area inundated by the reservoir created by the dam, the energy embodied in the dam, and the biological productivity lost because of the dam, primarily through depleted fish stocks. Sergio Pacca and Arpad Horvath assessed the carbon emissions released in the construction, maintenance, and operation of various electricity facilities. Basing the hydropower analysis on the Glen Canyon Dam, which generated 5.55 TWh of electricity in 1999, they determined these processes would release 25,000 tons of CO_2 per year averaged over a 20-year life cycle. The associated carbon footprint is 10.5 gha/MW.

The ratio of energy output to inundated area and the productivity of inundated land are highly variable. Energy output fluctuates with power demand and reservoir levels, although typical outputs for hydropower facilities in the United States are 40% of maximum capacity. A random survey of 24 hydropower dams in the Pacific Northwest of the United States found that the inundated areas produce an average of 3200 GJ/ha/year (10 ha/MW), varying widely between 15 GJ/ha/year (lower-course dams) and 11,000 GJ/ha/year (upper-course dams in mountain areas). A similar survey of 28 dams in 17 countries suggests an annual production of 900 GJ/ha/year (35 ha/MW), ranging from a minimum of 12 GJ/ha/year for Ghana's 833-MW Akosombo Dam to a maximum of 15,300 GJ/ha/year for Chile's 500-MW Pehuenche Dam. These values are highly variable and underestimate energy output per hectare by including the original river area as part of the inundated area. Hydroelectric plants located far from populated centers have long-distance transmission inefficiencies that increase the footprint of useful electricity to reach homes and commercial facilities.

TABLE III

Energy Yield of Renewable Sources[a]

Renewable sources	Yield (MJ/m^2/year)
Electricity, photovoltaic	450
Electricity, wind	900
Electricity, water power	100
Solar heating	1200
Wood extensive	7
Wood intensive	190
Straw as by-product	4
Miscanthus	25
Rape oil	6
Methyl ester of rapeseed	5
Organic ethanol from sugarcane	9
Organic ethanol from sugar beet	8
Organic ethanol from wood	5
Organic ethanol from wheat	5
Organic ethanol from maize	2
Organic methanol from wood	12
Organic biogas, digestor gas, and landfill gas	5

[a] The data are presented in unadjusted hectares that do not reflect differences in biological productivity. The ecological footprint weighs hectares by their productivity. These data may differ from other estimates depending on technology or other factors. For instance, sources indicate slightly higher ethanol yields in Brazil of 12 MJ/m^2/year. From Stöglehner (2003).

8.2 Wind Power

The most attractive sites for wind power are often offshore or in remote regions, potentially limiting demands for biocapacity. Moreover, the actual area occupied by turbines and other infrastructure is only 5% of the total area of wind farms, leaving the remainder available for pasture, fisheries, or other dual uses. At an average output of 8200 GJ/ha/year, the built-up footprint of a wind power plant on average-quality pasture is 1.8 gha/MW.

The energy embodied in the extensive infrastructure needed to capture a diffuse and intermittent energy source forms a large part of the footprint of wind power. Pacca and Horvath estimate that the CO_2 embodied in the construction and materials of a wind farm capable of generating 5.55 TWh/year

would total 800,000 tons over 20 years—approximately 10 times greater than the embodied emissions of a similarly sized coal-powered facility (excluding operational emissions). Assuming a 20-year life span, the carbon sequestration footprint is 16.9 gha/MW, one order of magnitude greater than the built-up area of the wind farm. If wind or another renewable carrier supplied the construction energy, the footprint of embodied energy would be greatly reduced.

8.3 Photovoltaic

Like other renewable energy technologies, photovoltaic (PV) arrays contend with low power densities. Nevertheless, annual energy output can be impressive. Assuming an annual power density of 15 W/m^2 typical in commercial systems and allowing additional space for shading and access within large-scale installations, PV systems occupy 10 ha/MW. One hectare of PV panels can deliver the thermal energy contained in 100 tons of oil annually. Without including the excess capacity required in a working infrastructure, PV arrays covering a square 160 km on each side could supply the electricity demand of the United States. With a population of 280 million people, this amounts to 0.01 ha/capita. The global area amounts to .002 ha/capita, covering a square 310 km on each side. The complete replacement of fossil fuels with a hydrogen fuel cell-based economy may require an additional area manyfold larger. PV installations atop buildings or in arid regions can mitigate competition for bioproductive areas, an advantage shared with wind power. Also, although potential PV sites may be more widespread than those for wind power, the embodied energy is also greater. Pacca and Horvath estimate the CO_2 emissions embodied in a PV system producing 5.55 TWh/year to be 10 million tons over 20 years, or 211 gha/MW.

9. ENERGY FOOTPRINT OF PREINDUSTRIAL SOCIETY

Historically, renewable energy captured chemically through photosynthesis drove nearly every aspect of society. Renewable kinetic sources—wind and water—held much less global prominence, although they expanded rapidly in the 18th and 19th centuries, when wind mills spurred the colonization of the American frontier and waterwheels became increasingly important in industrialization. In most areas, however, fuelwood supplied the majority of heat energy for small-scale activities, such as domestic heating and cooking, and larger scale enterprises such as metal smelting.

In many areas, fuelwood limitations were one factor restricting the size of preindustrial cities. According to Vaclav Smil, 12th-century Paris, then a large city of 100,000 people, may have required 1.5 tons of fuelwood per person annually, amounting to 3 PJ/year. Even if half of this demand was met through wood grown on cropland or other nonforest sources, as in some low-income countries today, the fuelwood footprint would have approached 0.4 gha/capita. The forest area required for energy demands alone equaled 50–200 times the urban area. Overland transport of fuelwood was prohibitively expensive at distances of more than 30 km, and cities with river access drew resources from great distances. Preindustrial Beijing, for example, imported huge rafts of wood from as far as Szechwan province more than 1000 km away. Fuelwood limits halted economic activities in less fortunate cities, where villages and industry competed for energy sources. According to one estimate, in 17th-century Europe fuelwood shortages halted production every other year in a typical ironworks furnace, which in 1 year of operation consumed 4000 ha of forest. Assuming a typical European growth rate of 5 tons/ha/year, this would equal a footprint of approximately 10,000 gha. Fuelwood demands increased severalfold during industrialization. By the mid-19th century, the United States fuelwood demand was 5 tons/capita, with a possible fuelwood footprint of 2.5 gha/capita—a national total of 60 million gha.

Crop residues and other cultivated biomass have played a significant but limited role in providing heat since their value as food and fertilizer introduced competing demands. David Pimentel estimates that currently fuelwood supplies half of all the world's biomass fuel by weight, whereas crop residues supply one-third. The higher energy density of fuelwood, however, means that the actual contribution of crop residues to biomass energy is smaller. More important, the chemical energy of cultivated biomass fed people and livestock, the predominant source of mechanical energy for transportation and labor. Powerful draft horses, for example, provided the labor of 10 men but could reach peak performance only when well nourished. Such an animal would eat the daily equivalent of 5 kg of oats, matching the food needs of 6 people. Nevertheless, the mechanical energy available in draft animals retained its advantage well into industrialization, and in the

United States, the demand for horses reached its height in the second decade of the 20th century. At an average yield of just over 1100 kg of oats/ha/year, a working horse may have had a cropland footprint of 3.5 gha. Some estimates place horse feed as constituting 20% of cultivated cropland in the United States at that time—amounting to approximately 60 million gha or 0.55 gha/capita.

The ecological footprint of energy obtained through fuelwood and agriculture faced local limits. Transgression of these constraints leads to an ecological deficit, a state in which ecological demands exceed local capacity. An ecological deficit signifies either imports of ecological capacity from abroad or ecological overshoot of local resources. Although ecological imports may contribute to overshoot abroad, local overshoot has immediate domestic implications. In the case of renaissance England, an escalation in charcoal demands for metal smelting led to widespread deforestation. Abundant coal supplies yielded a ready charcoal replacement and weaned England from fuelwood by the late 17th century, ushering in an early industrialization and the dawn of the first fossil fuel-dependent society.

10. ENERGY FOOTPRINT OF INDUSTRIAL SOCIETY

Tapping fossil fuel reservoirs accumulated over hundreds of millions of years exceeds local rates of fossil fuel formation, leading to local overshoot. The widespread transition to fossil fuels, however, has resulted in global overshoot and a qualitative shift in humanity's relation to the biosphere (Table IV; Fig. 1). Despite radical local and regional ecological changes from preindustrial societies, the human economy only surpassed global limits when fossil fuel use exceeded ecologically sustainable rates and induced the expansion and intensification of extractive industries such as agriculture and forestry. Although local overshoot portends immediate domestic resource constraints, global overshoot from fossil fuels externalizes costs, diffusing the feedback needed to adjust behavior.

Renewable energy sources bounded the growth of preindustrial economies, but the switch to fossil fuels curtails photosynthetic limitations. Energy production from biomass equaled that from coal and oil at the end of the 19th century. Fifty years later, however, biomass energy amounted to only one-fourth of global energy production, and its contribution to useful work was far smaller. Meanwhile, oil has increased in global prominence to become the largest primary energy source (Table V). The magnitude of this transformation has been immense. At more than 320 EJ/year, the global production of fossil fuels, for example, dwarfs the energy captured in food production by an order of magnitude.

With the advent of industrial civilization, nonrenewable sources became the prime economic drivers, supplanting not only fuelwood for heat but also livestock for transportation and labor. Fertile areas freed by the shift from biomass energy to fossil energy, decreasing transportation costs, global markets, and the diffusion of burdens from fossil fuel combustion helped spark an enormous expansion,

TABLE IV

Global Ecological Footprint and Biocapacity, 1999

Area	Footprint (gha/cap)	Biocapacity (gha/cap)
Cropland	0.5	0.5
Pasture	0.1	0.3
Forest	0.3	0.9
Fisheries	0.1	0.1
Built-up land	0.1	0.1
Fossil fuels and nuclear energy	1.2	0.0
Total	2.3	1.9

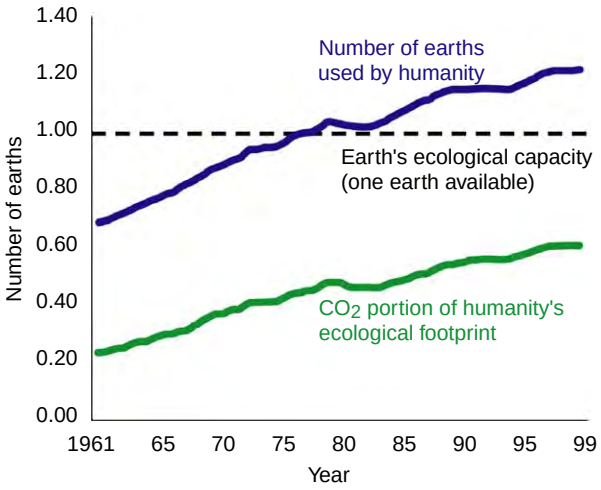

FIGURE 1 Global ecological footprint versus biocapacity, 1961–1999. Human demand exceeded the biosphere's supply during this time period, most clearly manifest in increasing CO_2 concentrations and overexploited fisheries.

TABLE V

Global Ecological Footprint of Energy, 1999

Energy source	Footprint (gha/cap)
Oil	0.5
Coal	0.4
Natural gas	0.2
Nuclear	0.1
Fuelwood	0.05
Hydro	0.002
Total	1.2

Data are rounded.

beginning with the human population in the mid-19th century and soon followed by the global economy. Today, the footprint of timber products in high-income countries is 0.7 gha/capita. Mechanized forestry boosted labor productivity with modern mills, harvesters, and chainsaws—Canadian timber extraction, for example, was 3.1 gha per Canadian in 1999. In contrast, the biocapacity of global forests approaches 0.9 gha/capita, of which only 0.4 gha/capita is exploitable. The fossil fuel transition also enables industrial fishing fleets to harvest previously inaccessible stocks, raising the footprint of the global marine catch to its estimated biocapacity of 0.1 gha/capita. The footprint of marine fish consumption averages at least triple this rate in high-income countries.

The mechanization of agriculture relieved the 20% of cropland used to feed work horses in the early 20th-century United States. The freed area became a source of meat and milk production, and in 1999 meat- and milk-producing livestock consumed 60% of U.S. maize. At the same time, the intensification of agriculture, along with new breeding techniques, initiated dramatic increases in crop yields and the human population. A substantial portion of the food energy consumed by people relies on fertilizers and agricultural chemicals synthesized through fossil fuels.

Fossil fuels have created a transitory carrying capacity of significant proportions. The ecological footprint accounts make this "phantom planet" visible. As the coiner of this term, William Catton, points out, this extra capacity gives humanity the illusion of living on a larger planet and encourages human expansion beyond the regenerative capacity of the biosphere. Consider the following comparison: 0.7 TW of human food produced today occupies more than 40% of the biosphere's regenerative capacity; in comparison, fossil fuel consumption exceeds 10 TW. From this perspective, the fossil fuel provides humanity with a temporary income that corresponds to the capacity of more than five biospheres (0.4% biospheres $\times$ 10 TW/0.7 TW = 5.7 biospheres). Therefore, some biologists liken humanity's aggregate behavior to that of species who come in contact with a large but finite food stock. Examples are deer introduced to an island or yeast cells placed in a cup full of sugar. Such an abundance of food typically leads to population growth beyond the habitat's carrying capacity, resulting in a population crash. So far, the growth curves of the fossil fuel economy have resembled the yeast cells in a finite cup of sugar. The difference is that people have choice. Like financial budgeting, ecological footprint accounts help society choose the most desirable allocation of the limited budget nature provides. The alternative is to continue liquidating natural capital.

2. **Application to Specific Energy-Development Activities**
3. **Conclusions**

Glossary

analysis The second phase of the ecological risk assessment. It consists of the characterization of exposure, which is the measurement of the temporal and spatial distribution of a stressor, and characterization of effects, which is the identification and quantification of adverse effects elicited by the stressor.

assessment endpoint An explicit written expression of an environmental value that is to be protected in an ecological risk assessment. The environmental value consists of an entity (e.g., fish-eating birds) and a property of that entity (e.g., abundance). For example, sustaining the population of fish-eating birds in the vicinity of a water body.

conceptual site model A written description or visual representation of predicted relationships regarding how a stressor may affect the ecological components (ranging from an individual organism to a specific population, communities of populations, etc.) of the natural environment.

ecological risk assessment A process that evaluates the likelihood that adverse ecological effects may occur or are occurring as a result of the exposure of terrestrial, avian, and aquatic receptors to one or more stressors. As currently practiced in the United States, the process consists of three steps: problem formulation, analysis, and risk characterization.

measurement endpoint A concentration-dependent measurable response (typically an adverse effect such as lowered reproduction) to a stressor that is used to evaluate potential adverse effects to the environmental value specified in the assessment endpoint. For example, a comparison of the number of kingfisher (a fish-eating bird) young produced per nest at an impacted water body with the number of kingfisher young produced per nest at a nonimpacted water body.

problem formulation The first step in the ecological risk assessment, which includes a preliminary characterization of exposure; examination of available data and data needs, policy, and regulatory issues; and an evaluation of site-specific factors to define the feasibility, scope, and objectives of the ecological risk assessment. The outcome of the problem-formulation step is the selection of assessment and measurement endpoints and the development of a conceptual site model.

receptor A biotic component (from an individual organism to a population, a species to a community, etc.) of the ecosystem that is, or may be, adversely affected by a stressor.

risk characterization The third and final phase of the ecological risk assessment. It uses the results of the exposure and effects analyses to evaluate the likelihood of adverse ecological effects associated with exposure to a stressor.

stressor Any physical, chemical, or biological entity that can induce an adverse effect on a receptor.

Since the mid-1970s, public concern regarding the effects of chemicals released into the environment has increased, leading state and federal regulatory agencies to develop and adopt procedures for assessing both potential and actual ecological impacts that occur as the result of these releases. These effects are evaluated through a process called an ecological risk assessment (ERA). The requirement for ERAs was brought about by the Comprehensive Environmental Response Compensation and Liability Act (also

 © 2004 Elsevier Inc. All rights reserved.

known as Superfund), Resource Conservation and Recovery Act, and other environmental statutes. However, it was not until the late 1980s when the Science Advisory Board, the research arm of the U.S. Environmental Protection Agency, recommended that the agency place as much emphasis on evaluating ecological risks as on human health risks. Efforts to then standardize the ERA process began.

The existence of a well-established process to evaluate potential human health risks has had an important effect on the ERA process. In human health risk assessment, humans are the receptor of concern (unlike in ecological risk assessment, in which many receptors can be exposed and can potentially be at risk). Society also places a great deal of value on each individual human and on the prevention of very subtle adverse effects. In human health risk assessment, for example, an increase in mortality of 1% caused by a chemical release would be unacceptable. In ecological risk assessment, an increase in mortality of more than 1% may be acceptable if it occurs in a common and abundant species. In order to ensure that unacceptable levels of risk do not occur in humans, human health risk assessment uses numerous conservative assumptions. A conservative assumption is one that leads to overprotection rather that underprotection. Because society generally places more value on humans than on ecological receptors, and also places a unique value on different groups of ecological receptors, practitioners and users of ecological risk assessment need to be cognizant of the degree of conservatism contained in an ERA, that it is appropriate, and that it is consistent with societal norms. There is a tendency to allow the conservatism found in human health risk assessments to creep into ecological risk assessments and for ecological relevance to be lost.

With regard to the development of energy, ERAs are typically used to evaluate the effects of chemicals released into the environment, although the process has been developed to deal with "stressors" in general. The development of energy presents special challenges to evaluating impacts to environmental quality because exploration, development, refining, distribution, and use of energy from different types of energy systems have the potential for releasing a variety of chemicals into the environment over scales ranging from the small and local to regional and global levels. This article outlines concerns and issues to be considered during the preparation of ERAs for energy systems with examples from associated activities. This articles focuses on the potential effects of chemicals released during energy development and use and not on other stressors, such as nuclear radiation, heat, or the habitat disturbance that may occur during mining or oil drilling. A brief discussion of other stressors (e.g., physical effects to habitats from hydropower) associated with energy development is presented.

1. COMPONENTS OF AN ECOLOGICAL RISK ASSESSMENT

Ecological risk assessments (ERAs) typically consist of three steps: problem formulation, analysis, and risk characterization. Problem formulation provides the overall rationale and justification for the subsequent steps in the ERA. Problem formulation summarizes available information and uses it to develop clearly defined goals for the ERA as well as unambiguous criteria for evaluating potential risks. Endpoints that are ambiguous or difficult to define and measure (such as "ecosystem health") will only result in disagreement about what was intended (e.g., protection of individual receptors versus protection of a population of receptors versus protection of certain ecosystem processes such as providing a food source). The results of the problem-formulation step are a conceptual site model (CSM) and the selection of assessment and measurement endpoints. The CSM considers the dominant physical, chemical, and biological characteristics of a system; identifies relevant receptors; and identifies potentially complete pathways by which relevant receptors can be exposed to stressors. It is common for a CSM to identify 5–10 receptors to evaluate in an ERA. Typically, 1 receptor is evaluated in each assessment endpoint. For example, for a release of chemicals to a water body, one assessment endpoint may be the protection of fish-eating birds relying on that water body as a food source. The selected receptor for this endpoint might be a kingfisher (a fish-eating bird species) that has been observed feeding at the water body.

The CSM provides the basis for the selection of assessment endpoints and the measurement endpoints used to evaluate them. Site-specific assessment endpoints should be identified that address stressor-specific potential adverse effects to individual organisms (in the case of threatened or endangered species) or to local populations or communities of plants and animals. Typically, several assessment endpoints are selected to evaluate potential ecological effects based on the potentially complete pathways between the source of the chemicals and the receptors that might

be affected. For the example of a chemical release to a water body (discussed previously), an additional assessment endpoint might be the continued survival of the largemouth bass population. A third assessment endpoint would be the evaluation of the potential adverse effects to a terrestrial mammal such as a mink or raccoon that uses the water body for food and drinking water.

Measurement endpoints represent observations, measurements, or analyses that evaluate an assessment endpoint. One to several measurement endpoints are used to evaluate each assessment endpoint. For the kingfisher described previously, one set of measurement endpoints might focus on whether the aquatic community in the pond can still provide enough food to sustain the kingfisher population living near the pond. Measurement endpoints may include direct comparison of water body chemical concentrations to ambient water quality criteria; laboratory bioassays of site water with standard aquatic organisms; and field surveys of aquatic communities comparing the site to a reference area that has the same features as the site water body, except for the presence of site-related chemicals.

For measurement (and assessment) endpoints evaluating ecological communities, the distinction between structure and function of the endpoints is important. For the example of a chemical release to surface water, historically many ecological risk assessments have included the structure of the benthic community (e.g., diversity) as an assessment endpoint. It may be more appropriate to focus on the functional aspects of the benthic community (e.g., its function as a prey base for higher trophic-level predators). A change in the structure (i.e., the diversity of organisms present) of a lower trophic-level community that serves as a prey base for higher trophic-level predators may be less important than a change in the biomass of prey produced (i.e., the weight of prey available to be eaten by predators) by the community.

A second important distinction is between chemicals that can be directly toxic but do not bioaccumulate and chemicals that are directly toxic and also bioaccumulate. For chemicals that can bioaccumulate (e.g., PCBs and mercury), assessment endpoints generally include higher trophic-level predators that may accumulate these chemicals from the food chain. For these compounds and receptors, endpoints evaluating indirect toxicity through food chain exposures may be more relevant than endpoints evaluating direct toxicity. Conversely, for chemicals with low potential for bioaccumulation, selection of assessment endpoints may concentrate on lower trophic-level receptors that may have higher direct exposures to the chemicals. For these compounds and receptors, assessment endpoints evaluating direct toxicity to fish or benthic invertebrates (e.g., reduced growth, reduced reproduction, or even mortality) may be more relevant than those evaluating indirect toxicity from food chain exposures.

Analysis is the second step in the ERA process. In this step, exposures of receptors to stressors are evaluated and the relationship between stressor levels and ecological effects is documented. Exposure characterization describes potential or actual contact or cooccurrence of stressors with receptors.

In large and complex ERAs, exposures of ecological receptors to chemicals may vary over time and space depending on the characteristics of the selected receptors. Migratory species will spend less time being exposed to site-specific chemical concentrations than resident species. For species with large home ranges that forage over large areas that do not contain site-related chemicals, exposures will be lower than those for species with smaller home ranges that may be exposed to site-related chemicals for their entire lifetimes. Exposures may be measured directly by sampling receptors or the organisms that comprise their diet, but more commonly exposures are estimated using a series of standard equations. The equations require information about the concentration of chemicals in food, foraging areas and habits, food consumption rates, body weight, water consumption rates, and incidental media-specific ingestion rates (e.g., the amount of soil ingested by robins feeding on worms). This information is obtained from sources ranging from literature summary values to species-specific literature values and results from experimental studies conducted in the field.

Ecological effects characterization identifies the effects (e.g., mortality and reduced reproductive success) elicited by a stressor, the relationship between these effects and the assessment endpoints (e.g., sustaining the population of fish-eating birds in the vicinity of a water body), and provides an evaluation of how these effects change with varying stressor levels. The characterization begins by evaluating available effects data to specify (i) the effects that are elicited by the stressor, (ii) the plausibility that effects may occur or are occurring as a result of exposure to the stressor consistent with the conceptual site model, and (iii) the links between measurable ecological effects and assessment endpoints when the latter cannot be directly measured.

Effects data may consist of chemical-specific literature values from laboratory studies on the selected receptor species, results of chemical-specific studies on taxonomically related species, and results of studies on structurally similar chemicals. Site-specific field studies may also be evaluated as part of the effects characterization, depending on the selected assessment endpoints (e.g., sustaining the population of fish-eating birds in the vicinity of a water body) and measurement endpoints (e.g., field studies of reproductive success). Data typically collected from laboratory studies include effects ranging from the molecular level (e.g., enzyme induction) to the organ level (e.g., liver or kidney toxicity) and the organism level (e.g., mortality). Data typically collected from field studies include population-level effects (e.g., reduced numbers or reduced reproduction).

The selection of the appropriate study to use in the ecological effects characterization requires linking the study to the selected assessment endpoint. If the assessment endpoint includes a threatened or endangered species, then the effects characterization may focus on effects to an individual. However, if the assessment endpoint is sustaining the population of fish-eating birds in the vicinity of a water body and one measurement endpoint is sustaining the food supply for the fish-eating birds, then the effects characterization may focus on population-level effects to prey fish species.

The last step of the ERA process is risk characterization. This step combines the results of the analysis phase to develop estimates of the potential risks posed to the ecological receptors included in the assessment endpoints identified in the problem-formulation step. Risk characterization evaluates whether the doses measured or estimated in the exposure assessment are higher than the doses (identified in the effects assessment) that cause adverse effects and whether the estimated exposures are likely to cause adverse effects to the selected assessment endpoint. Because ERAs generally contain conservative assumptions, it is possible that an estimated exposure exceeds the allowable exposure but that an adverse effect is not expected to the assessment endpoint. Risk estimates developed from measurement endpoints are evaluated in the context of the significance of any adverse effects and lines of evidence supporting their likelihood of occurrence. For the assessment endpoint of a threatened or endangered species, this may include an evaluation of whether individual-level effects are likely to occur.

For assessment endpoints that are being evaluated using multiple measurement endpoints, a weight of evidence approach is typically used. In this approach, the weight conferred on each measurement endpoint, the magnitude of the response to each endpoint, and the concurrence among measurement endpoints are used to evaluate whether significant ecological effects are likely to occur. The weight of each measurement endpoint is a function of the degree of association between the measurement and assessment endpoints, the study design, and the quality of the data supporting the measurement endpoint. In the second component, strong unambiguous responses provide greater weight than weak responses. Finally, when a number of different measurement endpoints indicate similar responses, this provides additional weight. For example, one measurement endpoint [e.g., comparison of the number of kingfisher (a fish-eating bird) young produced per nest at an impacted water body with the number of kingfisher young produced per nest at a nonimpacted water body] may indicate no adverse effects to the assessment endpoint (e.g., sustaining the population of fish-eating birds), but an additional assessment endpoint including an evaluation of the potential for adverse effects to the aquatic community that serves as the food source for the kingfisher may indicate the potential for an adverse effect. A weight of evidence approach is used to evaluate whether the estimated effects to the food supply are sufficient to cause adverse effects to the selected assessment endpoint. Considerations in this evaluation also include the presence of alternative sources of food and the likelihood of their use by the kingfishers.

2. APPLICATION TO SPECIFIC ENERGY-DEVELOPMENT ACTIVITIES

The development of energy, although providing a benefit to society, can adversely affect the environment. ERAs can be used to assess the magnitude or severity of the perturbation and in determining cleanup levels in circumstances in which a cleanup is required. As previously mentioned, the focus of this article is on the evaluation of potential ecological effects associated with chemical releases from energy development.

The ERA process can be used to evaluate other nonchemical stressors, such as physical disturbance, radiation, and thermal changes in an environment. For example, nuclear power-generating stations have

the potential to release radioactive materials into the environment. As a stressor, radionuclides can be examined via the same ERA process as that used for chemical stressors. This process includes identification of appropriate potential receptors and endpoints, determination of levels of radionuclides in the environment, analysis of the levels of existing radiation versus benchmarks levels for organisms of concern or the endpoints that are being assessed, followed by the characterization of the risks to populations of various organisms in the release area. As with other energy-development activities, the critical step in the process is a thorough and appropriate problem-formulation step, including the development of a conceptual site model that emphasizes the circumstances of the release area and takes into consideration the movement and ultimate effects of radiation on natural ecosystems.

Although the ERA process evaluates the potential for chemicals to affect biological organisms, it is important to understand the impact that physical disturbance and habitat alteration may have on the ecosystem versus the release of development-related chemicals. Hydroelectric power, which releases few chemicals to the environment, may block the movement of fish up and downstream; may reduce large fluctuations in hydrologic regimes that may hinder plant and animal species that are competitively more adapted to living in flood-prone areas; or may change nesting areas, resulting in the modification of faunal communities in an area. Nuclear and fossil fuel power plants may impinge or entrain large quantities of fish and aquatic life through water intake for cooling purposes. These facilities may discharge heated water into the environment that may kill fish, block fish migrations, or result in the encroachment of nuisance species. Mining for coal can result in the stripping of mountaintops and the resulting loss of habitat used by terrestrial wildlife. All these are "nonchemical" stressors with the potential to pose ecological risk that can be evaluated using ERAs.

The point is that an ERA is a tool used to evaluate the effects of stressors on the environment. Its results must be placed in a realistic context of the breadth of stressors that result from a given energy-development activity. As discussed previously, and discussed throughout much of this section, the problem formulation stage is the critical first step in identifying what potential issues must be evaluated in the ERA and how they relate to other stressors in the environment. The following sections discuss issues related to the use of ERAs for specific energy-development activities.

2.1 Ecological Risk Assessment Applied to Oil and Gas Activities

Because energy development is dominated by the use of oil and gas as fuel sources (approximately 40% of the world's energy supply is from crude oil), this article focuses on the ecological effects associated with the various stages of energy development from oil and gas. Oil- and gas-related activities have the potential to adversely affect ecological receptors through the release of a variety of chemicals to the environment. Glen W. Suter outlines a general framework for conducting ecological risk assessments at sites at which petroleum hydrocarbons are the dominant chemicals that may potentially pose an ecological concern.

2.1.1 Petroleum Hydrocarbons in the Environment

In 1989, the U.S. Environmental Protection Agency (EPA) reported that 20.9 million barrels of production waste and 361 million barrels of drilling waste were generated from approximately 835,000 oil and gas wells nationwide. Additionally, they reported that on average approximately 9000 oil spills occurred each year, releasing approximately 11 million barrels of oil into the environment. Ecological impacts associated with these releases ranged from short-term effects such as fish kills to long-term impacts such as chronic changes in benthic macroinvertebrate community structure (e.g., the number and diversity of invertebrates living in sediments).

The ecological impacts produced by these releases occurred as a result of physical actions, such as smothering and fouling, and the direct toxicity of the various chemicals in the petroleum mixtures. Key organic compounds in such releases include polycyclic aromatic hydrocarbons [e.g., phenanthrene and benzo(*a*)pyrene] and volatile organic compounds (e.g., benzene). Although the potential effects from inorganics (e.g., metals) are generally not of concern where petroleum mixtures are spilled in the environment, metals such as arsenic, barium, cadmium, chromium, copper, lead, mercury, and selenium can be released at levels that are toxic to terrestrial and aquatic receptors during oil and gas production activities.

Petroleum is a mixture of hydrocarbons that can be classified into two broad categories: aliphatic hydrocarbons, which can be further divided into alkanes, alkenes, and cycloalkanes, and the aromatic hydrocarbons. The percentage of each group present varies with both the source of crude oil and the

refined product. The compounds within these two chemical groups exhibit a range of toxicity, with some being extremely toxic, whereas others are relatively benign. In general, the toxicity of hydrocarbons is related to their chemical structure and their affinity for water, with more soluble compounds being relatively less toxic. Although this is a general relationship and can be affected by chemical structures, compounds that are more soluble in water are less soluble in fat. As the solubility in fat or lipids increases, solubility in water decreases and the ability of the hydrocarbon to cross the cell membrane and produce biological damage increases. This relationship also suggests that as lipid solubility increases, the potential for the chemical to be passed up through the food chain (from an original food source to a lower level predator and then to ever higher levels of predators) increases.

Understanding these toxicological properties is important because of the general manner in which many regulatory agencies evaluate the presence of petroleum at sites. As opposed to measuring the concentration of each chemical in a hydrocarbon mixture, many states regulate and evaluate petroleum sites based on the quantification of total petroleum hydrocarbons (TPHs) in surface water, sediments, and soil. The EPA defines TPH as "a measure of the concentration or mass of petroleum hydrocarbon constituents present in a given amount of air, soil, or water" and further notes that

> *the term total is a misnomer, in that few, if any, of the procedures for quantifying hydrocarbons are capable of measuring all fractions of petroleum hydrocarbons present in the sample. Volatile hydrocarbons are usually lost in the process and not quantified. Additionally, some nonpetroleum hydrocarbons may be included in the analysis.*

To the extent that the hydrocarbon extraction efficiency is not identical for each method, the same sample analyzed by different TPH methods will produce different TPH concentrations. TPH analytical procedures use a variety of techniques, such as gas chromatography (GC), infrared spectroscopy (IR), gravimetric techniques, and immunoassays. Because of different technical processes, each technique detects a different range of hydrocarbons. GC techniques normally measure the broadest range of hydrocarbons, whereas IR techniques measure most hydrocarbons with the exception of volatiles and compounds with high numbers of carbon atoms. Gravimetric methods measure anything that is extractable except volatiles, and immunoassays measure only aromatic hydrocarbons, such as polycyclic aromatic hydrocarbons and benzene, toluene, ethylbenzene, and xylenes compounds. Interference with the analytical procedure of some of the methods can result from the presence of natural oils, humic substances, and peat moss. TPH measurements have been made of grass (14,000 mg/kg of TPH), pine needles (16,000 mg/kg of TPH), and oak leaves (18,000 mg/kg of TPH). Assessing risk based only on TPH is difficult because the analytical procedures identify all hydrocarbons and not specific ones, regardless of the source. As such, TPH analysis does not adequately characterize a petroleum mixture and provides little basis for characterizing the fate, transport, and toxicological properties of the mixture.

Under these conditions, using TPH leads to overestimates of ecological risk if, for example, the allowable TPH concentration was based on a "toxic" petroleum mixture and the petroleum being assessed was from a relatively "inert" source. Conversely, ecological risk may be underestimated if the reverse were true—the TPH in the field was from a petroleum source that was more toxic than that used to establish the allowable TPH level. The more appropriate manner for characterizing site conditions related to petroleum releases is the use of analytical procedures that evaluate the semivolatile and volatile organic compounds using standard EPA protocols. This is supported by guidance documents from Oak Ridge National Laboratory that state that TPH analysis provides little basis for performing an ERA because it supplies limited information about the composition and, therefore, the properties that determine the potential fate and toxicity of the material. However, TPH may be useful for determining the extent of contamination or the locations of the greatest contamination.

In addition to the shortcomings in adequately characterizing differences in toxicity in different petroleum hydrocarbons, TPH analyses also fail to consider the processes that cause petroleum hydrocarbons to partition into the environment. Mixtures of petroleum hydrocarbons change once released into the environment because weathering, the process by which natural chemical and physical processes alter the composition of the mixture, changes the bioavailability of the remaining hydrocarbons and hence their toxicity. Weathering is primarily driven by dissolution in water, biodegradation, and volatilization.

Because weathering affects each class of hydrocarbons differently, the toxicity of a particular mixture changes as it weathers. The solubility and volatility of all compounds generally decrease with

an increase in molecular weight. Aromatic hydrocarbons, those hydrocarbons with one or more benzene rings, are more soluble in water, whereas low-molecular-weight aliphatic hydrocarbons, characterized by a straight chain of carbon atoms, are more volatile. Low-molecular-weight compounds, which are more soluble and volatile, tend to migrate from contaminated soil at a much faster rate than high-molecular-weight compounds. Residual compounds left in highly weathered hydrocarbons tend to be the higher molecular-weight compounds that are less mobile and generally less toxic.

2.1.2 Oil and Gas Production

Potential ecological impacts from releases of chemicals during oil production activities are generally small in scale, although they can produce severe effects to locally affected communities. Compounds of ecological concern can occur in drilling mud and fluids, which when released into the environment can produce fish kills, smother benthic invertebrate communities, and destroy vegetation. Such compounds include arsenic, chromium, copper, iron, and other metals as well as oil, grease, chlorides, nitrates, and other substances. These substances tend to be directly toxic to fish, wildlife, and other biological receptors but generally do not bioaccumulate at successively higher trophic levels of the food chain.

As a result of the small scale of individual production activities at a single well, ERAs may overestimate risks to populations if they used conservative assumptions and focused on individuals rather than having the problem-formulation phase consider the issue of scale in the context of appropriate receptors and endpoints. In examining a single drilling site or release via the standard three-step ERA process, consideration must be given to applying realistic exposure parameters to the typical receptors found in a given area. Because the focus of the ERA must be on evaluating the potential for ecological impacts to local populations, care must be taken to ensure that the inference of impacts to local organisms is not considered as a significant impact to the population. A drill rig located on a $\frac{1}{2}$-acre site in a 1000-acre tract that supports a population of the meadow vole *Microtus pennsylvanicus* might only affect 4–6 animals based solely on the territory that the animals occupy. Out of the greater population of animals, in which an individual female may bear as many as 150 young per year, this would place into question the ecological relevance of a risk assessment that is not focused in the problem formulation on population issues. However, if the 1000-acre tract were covered with a large number of drilling sites, the cumulative effect of many sites, all releasing approximately the same quantity of compounds, could result in ecological impacts to populations of animals and plants.

2.1.3 Petroleum Refining, Storage, and Processing

From an ecological standpoint, evaluating the ecological impacts associated with residual petroleum releases at major oil-production facilities can be difficult because of the complexity of the sites, the large number of chemicals involved, and the ongoing production practices. An examination of many of the large refineries or terminals shows that these facilities are often located adjacent to sensitive environments, such as coastal waterways, rivers, and harbors. In New Jersey, the largest refineries can be found at locations along the Delaware River in the south and adjacent to Raritan Bay, Arthur Kill, and Newark Bay in the New York/New Jersey Harbor area. These locations present ample opportunity for the discharge of petroleum and petroleum-related products into productive ecosystems containing receptors that will be in close contact with the released materials.

Part of the complexity in dealing with such facilities is their size, the diversity of habitats and the variety of ecological receptors that can be exposed, and the age of the facilities. Refineries can be very large, in excess of 150 acres, and contain freshwater and coastal wetlands, ponds, and forests. Although production activities within refineries and terminals dominate land use, most refineries also contain land that is undisturbed, fallow, or covered with storage tank fields, landfills, and waste management units. Many of the areas supporting seemingly natural habitats may have historically been used for storage or production. At several refineries in New Jersey, forests and shrublands have grown on parts of the property that previously contained storage tanks that were removed from service and dismantled. These areas of terrestrial vegetation support a number of wildlife species, including white-tailed deer (*Odocoileus virginianus*) and avian predators such as red-tailed hawks (*Buteo jamaicensis*). However, these habitats have developed in areas created by fill and often contain residual levels of petroleum hydrocarbons. From a gross standpoint, the fact that these areas have revegetated substantiates the limited effects of residual hydrocarbons in the environment. Nevertheless, ERAs are generally required in such circumstances to evaluate any potential risks associated with residual levels.

In preparing an ERA for a refinery or large production facility, great care must be given to the problem-formulation step. As opposed to ERAs conducted under production or drilling scenarios, refinery ERAs must consider three complex issues. First, refineries often contain hundreds of existing or former discharge sources. These sources can include crude oil or basic petroleum products as well as more refined petrochemical products that may potentially be more toxic than crude oil. Second, the pathways associated with a refinery ERA often include both aquatic and terrestrial environments, with numerous assessment endpoints in each of these environments that may need to be evaluated. Typical assessment endpoints include the maintenance of viable terrestrial plant communities; maintenance of viable aquatic and wetland plant communities; maintenance of aquatic wildlife, fish, and benthic invertebrate communities; and maintenance of both resident and migratory terrestrial wildlife populations. Third, developing a conceptual site model for a refinery or terminal is often complicated by the age and location of these facilities. In industrial sections of the northeastern United States, some refineries began operations in the late 1800s or early 1900s, whereas general industrialization extends back to the late 1700s. In these settings, it is often difficult to distinguish impacts associated with refinery operations from those that occurred as a result of general urbanization and to isolate site-related ecological impacts from impacts that may have occurred as a result of neighboring facilities that may also be releasing constituents of concern to the environment.

In settings in which refineries have residual concentrations of chemicals but still support viable populations of terrestrial and aquatic flora and fauna, comparison to background chemical data can be an important indicator of site-related effects. In this case, it is essential to collect background chemical data from locations similar in habitat but still subject to the same level of historic disturbance as the refinery. Refineries are typically located adjacent to, or close to, major harbors, with more than 60 petroleum facilities located in the Newark Bay estuary alone. Between 1982 and 1991, a total of 1453 accidental incidents released more than 18 million gallons of hazardous materials and petroleum products into Newark Bay. Thus, identification of background locations can be a contentious issue in industrialized settings because chemical concentrations can be quite high—high enough that they would require cleanup if the site were in a pristine setting.

The EPA has issued guidance on use of background data in ERAs. Although the agency recognizes that sources other than the facility being investigated may release chemicals into the environment, the expectation is that the effect of background concentrations will be included in risk estimates, even if background is the primary source of risk, and be qualitatively discussed in the risk characterization section of the ERA. The importance of the background concentrations of chemicals of concern is applicable in the risk management phase following the completion of the risk assessment. The assumption is that even if the background chemical concentrations were anthropogenically produced, taking action to address their presence at a particular site would be neither practical nor cost-effective if the background levels are widespread. Furthermore, remediated sites, which receive a constant stream of off-site contamination, will only be recontaminated from upstream sources. Particularly in aquatic sediments, a remediated area can be recontaminated by the movement of contaminated sediments from upstream areas through the action of currents or by the release of pollutants from upstream facilities.

2.1.4 Distribution

Distribution of oil and gas through pipelines can cause large-scale effects that are not related to chemical releases (e.g., alteration of many miles of habitat during construction) and relatively local effects from releases of oil during a pipeline failure or releases of other chemicals associated with transport of oil and gas. The most well-known of these was the release of PCBs at gas pipeline compressor stations. Unlike most petroleum constituents, PCBs have the potential to bioaccumulate. Consequently, assessments of ecological risks associated with PCB releases required food web modeling to predict ecological risks to upper trophic-level predators.

The other common mode of oil distribution is via ships. The release of oil in aquatic ecosystems has two primary modes of impact. One is physical fouling or impairment of biological organisms, such as birds, fish, and plants. The other is the toxic effect of the chemicals in the oil or refined product or any residual compounds. Physical fouling can be the most destructive action, but its effects are short term and mitigated by the dilution and degradation of the released oil. The toxic effects are often longer term and are assessed through the ERA process.

2.1.5 Retail Service Stations

Typically, individual gasoline service stations do not pose a significant threat to ecological resources. Service stations are small in relation to the surrounding environment and most are located in developed, urban areas or along paved roadways. These areas generally do not support large communities of native plants or animals that can be exposed to petroleum-related products nor are they generally located near sensitive habitats. Additionally, the major contamination sources at service stations are leaking underground storage tanks used to store gasoline and other products. Because the tanks are located in the ground, exposure pathways to ecological receptors in the surface environment are generally not complete. Without a complete exposure pathway, there can be no risk. However, exposure can occur if a leaking tank contaminates groundwater, which in turn is discharged to a surface water body or a wetland. In such instances, chemicals to which ecological receptors may be exposed include volatile organic compounds such as benzene, toluene, xylene, ethylbenzene, and methyl *tert*-butyl ether (MTBE) and, depending on the age of the release, inorganic constituents such as lead.

In evaluating the ecological risks associated with groundwater contamination originating from a service station located in the Pine Barrens Management Area of southern New Jersey, environmental sampling indicated that ethylbenzene, xylenes, MTBE, and lead were being released over a 50-ft stretch of a small steam flowing through a mixed hardwood forested wetland. The problem formulation indicated that the release had the potential to affect invertebrates within the stream sediments, fish living in the stream, and wildlife that either used the stream as a water source or fed on plants growing adjacent to the stream. Investigation of the release found maximum concentrations in sediments of 34 μg/kg of xylenes, 50 μg/kg of MTBE, and 24 mg/kg of lead. The only chemicals identified in surface water were MTBE (0.5 μg/liter) and lead (26.5 μg/liter). To characterize potential risk, chemical concentrations in surface water and sediments were compared to values for specific chemicals that are meant to be protective of the environment under most conditions. Slight exceedances existed, so a site-specific biological survey of benthic invertebrates in sediments was conducted. Benthic invertebrate surveys conducted at reference locations and site-sampling locations found no difference between the two areas in the kinds of species present, indicating that the aquatic community in the affected stream was similar in all respects to the aquatic community in unaffected streams. The ERA concluded that no adverse ecological impacts were associated with the discharge of contaminated groundwater. Although remedial actions to address groundwater contamination and potential human health risks were implemented, no actions were necessary within the stream or wetlands to protect ecological resources.

2.2 Ecological Risk Assessments Associated with Coal Mining

Whereas ecological risk issues complicated by industrial development and background contamination dominate some aspects of the petroleum industry, coal mining is generally an activity that occurs in more natural settings. The obvious ecological impact associated with coal mining is the destruction of habitat. However, chemicals can be released into the environment from the development of ore piles, mine tailings, and spoil heaps.

The chemical release of greatest ecological concern is acid mine drainage (AMD). In certain circumstances, surface water and shallow groundwater will react with rocks containing sulfur-bearing minerals to create sulfuric acid. This acidified water then leaches metals such as aluminum, iron, and manganese from rocks that come in contact with the water. Aluminum concentrations of 57 mg/liter have been measured in AMD from mining in Appalachia. The EPA chronic water quality criterion for aluminum is 87 μg/liter under alkaline conditions (the potential for aluminum toxicity increases with increasing acidity), which is approximately 1000 times lower than the aluminum concentration in AMD. The EPA chronic water quality criteria for acidity (pH) ranges between 6.5 and 9 standard units, whereas pH in AMD from Appalachia has been reported to be as low as 2.7. AMD has caused the complete elimination of fish from some lakes and streams in the Appalachians or the presence of only a few acid-tolerant fish species in other waters.

2.3 Ecological Risk Assessment Procedures Applied to Power Generation

Power generation through the burning of fossil fuels can lead to a variety of chemical-related impacts to the environment. Also, direct habitat loss can occur as a result of facility construction, tank storage, or coal pile maintenance. Chemical impacts can occur as the result of catastrophic releases of oil or waste materials

such as caustic soda, the generation of AMD (from coal piles), or the improper storage or mishandling of waste sludges and fly ash wastes. Fly ash wastes from coal-fired power plants contain metals, such as aluminum, arsenic, cadmium, chromium, copper, mercury, and selenium, that can be discharged at concentrations sufficient to significantly impact benthic invertebrate populations and fish communities as well as terrestrial plant and animal communities.

The most wide-ranging ecological issue associated with power plants is the release of chemicals through stacks into the atmosphere. Conceptual site models for air-dispersion ERAs must take into account the numerous potentially complete exposure pathways that can spread hundreds of miles from the site and affect many receptors. In such instances, ERAs must focus on select indicator organisms that are used as the most likely impacted organisms as well as sensitive receptors that could be most adversely impacted by the stack emissions. Particularly important issues related to air emissions, mercury, and acid rain are discussed in detail in the following sections.

2.3.1 Potential Ecological Impacts from Mercury Emissions

The EPA completed an assessment of the potential impacts of mercury emissions, part of which consisted of an ERA. It estimated that approximately 87% of the estimated 144 Mg (158 tons) of mercury emitted annually into the atmosphere by anthropogenic sources in the United States is from combustion point sources, 10% is from manufacturing point sources, 2% is from area sources, and 1% is from miscellaneous sources. Four specific source categories account for approximately 80% of the total anthropogenic emissions: coal-fired utility boilers (33%), municipal waste combustion (19%), commercial/industrial boilers (18%), and medical waste incinerators (10%). These sources represent high-temperature waste combustion or fossil fuel processes. For each of these operations, mercury is present as a trace chemical in the fuel or feedstock. Because of its relatively low boiling point, mercury is volatilized during high-temperature operations and discharged to the atmosphere with the exhaust gas.

Mercury is emitted from stacks primarily in its elemental or inorganic (combined with other inorganics, such as sulfide or chloride) form. Mercury is transported and deposited onto soils and surface waters, where some is converted to organic mercury (e.g., methylmercury). Inorganic and elemental mercury are directly toxic through ingestion and inhalation, but organic mercury tends to bioaccumulate and toxicity is expected through the food chain in higher trophic-level organisms, not in directly exposed lower trophic-level organisms. That is, because mercury accumulates through the food chain, exposures experienced by higher trophic-level organisms to bioaccumulated levels of mercury can cause direct toxicity, whereas exposures experienced by lower trophic-level organisms to nonbioaccumulated levels may not be sufficient to cause toxicity.

The EPA's risk assessment evaluated the fate and transport of mercury emissions and used estimated atmospheric mercury concentrations and deposition rates as inputs in a model to derive concentrations of mercury in soils and surface waters over the drainage basis for an entire water body. These soil and water concentrations were used to estimate mercury (as methylmercury) concentrations in the associated biota and fish, which humans and other animals were assumed to consume. Methylmercury intake (on a per body weight basis) was estimated for six wildlife species: kingfisher, river otter, loon, mink, osprey, and bald eagle. Methylmercury exposures for the most exposed wildlife species (the kingfisher) were estimated to be up to two orders of magnitude higher than human exposures from contaminated freshwater fish. For wildlife, the importance of site-specific effects of mercury exposure is anticipated to be greater than that for humans in the general population because fish-eating wildlife obtain their fish from a much more limited geographic area than do people, and the diet of some wildlife species is composed almost entirely of fish.

The broad ecosystem effects of mercury are not completely understood. No applicable studies of the effects of mercury on intact ecosystems were found. Consequently, characterization of risk for nonhuman species did not attempt to quantify effects of mercury on ecosystems, communities, or species diversity. The characterization focused on quantities of mercury that may adversely affect the health of sensitive subpopulations of wildlife species and on the collocation of these populations with areas of elevated mercury exposures from anthropogenic emissions of mercury.

The results of the EPA's assessment suggest that ecosystems most at risk from airborne releases of mercury exhibit one or more of the following characteristics:

1. They are located in areas where atmospheric deposition of mercury is high.
2. They include surface waters already impacted by acid deposition.

3. They possess characteristics other than low pH that result in high levels of bioaccumulation.
4. They include sensitive species.

2.3.2 Ecological Impacts Associated with Acid Rain

Acid rain is the generic term for the wet deposition of substances that make the rain more acidic than the normal pH 5.6 of carbon dioxide in equilibrium with distilled water. Acidic deposition includes both wet and dry deposition of material more acidic than normal based on the concentrations of sulfates and oxides of nitrogen. In 1997, the major sources of sulfur dioxide emissions were electric utilities (60%), industrial combustion (17%), and industrial processes (8%). Transportation sources (including cars, trucks, and nonroad vehicles such as construction equipment) accounted for more than 50% of all nitrogen oxide emissions. Other major sources of nitrogen oxides include electric utilities (26%) and industrial combustion (14%). According to regional studies conducted by the EPA since 1990, agricultural activities, particularly manure handling, constitute the largest source of ammonia emissions. Motor vehicles and industrial processes also contribute to ammonia emissions.

Although regulatory controls in the 1970s and 1990s resulted in decreased sulfur dioxide emissions, levels remained high compared to background conditions. From 1995 to 1997, wet deposition of sulfate in the northeast was approximately 20% lower than levels in the preceding 3 years with implementation of the 1990 Clean Air Act Amendments. Controls on nitrogen oxides and ammonia were not fully addressed during the same period; consequently, emissions of these compounds have remained largely unchanged.

The 1990 National Acid Precipitation Assessment Program report to Congress concluded that there was insubstantial evidence that acid deposition had caused the decline of trees, other than red spruce, growing at high elevations. Research has shown that acid deposition contributes to the decline of red spruce trees throughout the eastern United States and sugar maple trees in central and western Pennsylvania. Reported symptoms of tree decline include poor crown condition, reduced tree growth, and unusually high levels of tree mortality.

Acid deposition degrades water quality by lowering pH levels (i.e., increasing acidity), decreasing acid-neutralizing capacity, and increasing aluminum concentrations. Although sulfate concentrations in lakes and streams have decreased during the past 20 years, they remain high compared to background conditions. Moreover, improvement in the acidity of lakes and streams in the northeast has been limited. For example, many Adirondack region lakes are still acidic or subject to short-term pulses in acidity associated with precipitation events.

3. CONCLUSIONS

The ERA process consists of three steps: problem formulation (including developing a CSM and selecting assessment and measurement endpoints), analysis (exposure and effects), and risk characterization. Problem formulation (including selection of the ecological values to be protected) is the most important step because it identifies the ecological values that need to be protected and evaluated. Although scientific considerations play a role in identifying these values, value judgments (subjectivity or professional judgment) have an equal if not more important role, for example, in selecting which species to use as an indicator, whether to examine individual or population effects, or whether to consider structure or function of a plant or benthic invertebrate community. Problem formulation also involves the evaluation of complete versus incomplete exposure pathways. The analysis phase includes the evaluation of potential exposures of receptors to chemicals and the evaluation of the potential toxicity of these chemicals to the receptors.

The last step of the ERA process is risk characterization, which evaluates whether the doses measured or estimated in the exposure assessment are higher than the doses (identified in the effects assessment) that cause adverse effects and whether the estimated exposures are likely to cause adverse effects to the selected assessment endpoint. Because ERAs generally contain conservative assumptions, it is important to evaluate the contribution of background concentrations.

In the development of energy and energy sources, wherever release of chemicals to the environment occurs, an ERA may be needed to evaluate the potential for ecological impacts associated with that release. ERAs must be tailored to meet the technical requirements and challenges of the energy-development industry.

1. Eight Basic Problems
2. Fossil Fuels
3. Nuclear Power
4. Renewable Energy
5. International Comparisons of Energy Consumption

Glossary

energy reserves The portion of the total resource base that has been located with certainty that can be economically recovered and used with present technology. This quantity is not fixed.

energy resources The portion of the total resource base that has been estimated with at least a small degree of certainty, and which might be recovered in the future.

location theory Spatial theory developed to solve optimization problems for selecting a preferred zone or location for a facility, which involves trading off transportation costs with production and processing costs, production balances, and market delivery levels.

Organization of Petroleum Exporting Countries (OPEC) Members include Algeria, Indonesia, Iran, Iraq, Kuwait, Libya, Nigeria, Qatar, Saudi Arabia, United Arab Emirates, and Venezuela.

resource/production ratio The ratio of total oil or gas resources to the current production level; provides a rough estimate of the scarcity of fossil fuels in a country, region, or the world.

The economic geography of energy involves quantitative and qualitative study of the spatial patterns of energy production, transportation, and use at a variety of geographic scales, and analysis of the determinants of those patterns. It is a surprisingly diverse subject area, encompassing everything from locational and transportation models, to economic impact studies of energy development and use, to international, national, regional, and site-specific problems associated with particular energy sectors. Site-specific sector problems include transportation constraints associated with natural gas in various countries, the growing scarcity of oil and gas, emergency planning at nuclear power plants and radioactive waste disposal, environmental impacts, and factors influencing the international rate of diffusion of wind power technology. Given this diversity of subject matter, the discussion here provides a broad overview of the economic geography of energy.

1. EIGHT BASIC PROBLEMS

Eight broad research problems are representative of the rich range of energy subjects that are investigated in the field of economic geography: supply and demand location, fossil fuel scarcity, environmental impacts, nuclear proliferation, renewable energy development, electric utility deregulation, geopolitics, and technological changes and energy efficiency.

1.1 Separation between Supply and Demand Centers

From prehistory until the Industrial Revolution, most energy sources used by humans were localized (i.e., available within 5–10 miles of end users). Energy sources included draft animals, human slaves, and renewable sources such as biomass (wood and wastes), water mills, and wind power. Following the onset of the Industrial Revolution, with advancements in transportation technology and increased rates of deforestation in many regions, societies increasingly relied on long-distance shipments of coal, wood, and eventually oil, natural gas, and electric power. With increased separation between the location of energy resources and demand centers came a need to investigate the optimal transportation modes, production rates, inventories, and scheduling of energy production and delivery systems. Industrial location theory and mathematical programming techniques

 © 2004 Elsevier Inc. All rights reserved.

have been used by geographers to analyze the trade-off between energy development and production costs, and shipment costs to market centers to explain the siting pattern of energy facilities. A major factor determining the economic value of an energy source or carrier to its consumers is whether it can be economically stored or controlled for later use, which in turn is a function of the demand at a particular location. This interplays with other determinants of the desirability of a specific energy source or carrier, such as pecuniary cost, convenience of access and use, energy efficiency, steadiness of flow and renewability, safety, quality and other environmental properties, and end-use technology.

1.2 The Growing Scarcity of Fossil Fuels

Policy concerns have been raised about the scarcity of fossil fuels, especially oil and natural gas, since the 1970s. The important distinction between oil and gas reserves and resources leads to different prognoses in different parts of the world (see the Glossary). A useful indicator of scarcity is the resource/production ratio, which can be instructive to calculate for various nations. For instance, Indonesia had 7.4 billion barrels of oil resources in the ground in 2000 and produced 515 million barrels in 2001, leading to a ratio of 14.4, an indicator of the number of years of production left before its supply is exhausted, *ceteris paribus*. The same ratio for the United States in 2001 was 62.1. These ratios will not change with shifts in production technology or in the availability and cost of alternative energy sources.

1.3 Environmental Impact

The production and use of all energy sources results in undesirable environmental effects, which vary based on the health of the existing ecosystem, the size and health of the human population, energy production and consumption technology, and chemical properties of the energy source or conversion device. A shorthand equation for the environmental impact of energy production and use is $I = P \cdot A \cdot T$, where I is environmental impact, P is the size of the human population, A is the affluence of the population (e.g., per capita income), and T is technology (e.g., energy efficiency, emission rate of air and water pollution). Such impacts have been operationalized by geographers in case studies around the world. In some cases, regional econometric and input–output models have been used in these studies.

1.4 Nuclear Proliferation

Geographers researching the development of nuclear power have shifted emphasis from commercialization, cost, risk, public acceptance, and power plant siting in the 1950s through the early 1980s to reactor decommissioning and radioactive waste disposal since then. With nuclear power development on hold in most countries, attention has also been given to nuclear weapons facilities and weapons proliferation in an increasingly dangerous world. With the distinction, shaky at best, between civil and military nuclear programs made by the United States and United Kingdom under the Nonproliferation Treaty of 1970, nuclear programs or policies of nations with unofficial nuclear weapons programs (i.e., South Africa, Israel, Argentina, Brazil, Taiwan, and perhaps Iran, among others) will come under increased scrutiny. This is in addition to the eight or more nations with official nuclear weapons (and power) programs by 2003: the United States, Russia (and perhaps other former Soviet republics), United Kingdom, France, China, India, Pakistan, and North Korea.

1.5 Development of Renewable Energy Sources

Amid growing concern in the international scientific community concerning the scarcity of fossil fuels, greenhouse gas emissions, and global climate change, analytical interest in renewable energy development has grown. Because renewable energy sources are widely yet unevenly available, geographic analysis of development potential and policies is important. Biomass energies and hydroelectric power are the traditional sources of renewable energy; development policy has focused on wind, solar, geothermal, and hydrogen power technologies. Wind energy development in the United States has been slow but steady since the 1990s, whereas Germany became the world leader in installed capacity in 1997. Other nations with significant programs in renewable energy development include Spain (wind), Italy (geothermal), Denmark (wind), Iceland (hydrogen and geothermal), Israel (solar), Japan (solar and geothermal), Philippines (geothermal), India (wind and solar), Indonesia (geothermal), Brazil (biomass and hydrogen), Mexico (geothermal), and South Africa (solar).

1.6 Electric Utility Deregulation

Electric utility deregulation offers the great promise of market forces leading to lower electric rates, lower

air pollution, greater energy (and economic) efficiency, and perhaps greater use of renewable energy sources. Ideally, deregulation involves the restructuring of a previously monopolized or nationalized electric utility into separate generation, transmission, distribution, and marketing companies, and allowing wholesale and retail choice of generation company or power marketer. Deregulation has occurred to varying degrees since 1989 in the United Kingdom, Norway, Australia, New Zealand, Chile, Argentina, and about 20 states in the United States. There have been promising results in a few countries and in some U.S. states in some respects, especially lower rates and lower air pollution. In most cases, competitive markets have yet to be realized and lower rates can be attributed to other causes, such as previously planned amortization or retirement of expensive power plants, unexpected surplus in natural gas, rate caps, etc. In addition, deregulation has had only a slight beneficial effect on the use of renewable electricity sources. The promise of electric utility deregulation is thus unfulfilled and deserves further study.

1.7 Role of Geopolitics

Geopolitical considerations have played a major role in many energy policy decisions, e.g., in domestic debates over gasoline taxes, pipeline construction, radioactive waste disposal, and acid rain control legislation in the United States, and in petroleum-related violence in Nigeria. The most prominent role for geopolitics in energy policy has probably involved international discussions on controlling greenhouse gas emissions, and in oil markets. In the cases of the Kyoto Protocol of 1997 and the 1992 Framework Convention on Climate Change, nations carefully considered their national economic interests, domestic politics, and international trade during the negotiations. European countries, with the lowest rates of population and economic growth along with strong domestic environmental lobbies, have pursued a greater rate of greenhouse gas reduction. The United States, in contrast, has been stubbornly cautious and backed out of the treaty in 2001 (arguing it is not in its economic best interests), and the oil-rich nations of the Middle East have been least supportive of any emissions controls. In the case of oil markets, with the United States now dependent on imports for over half its supply, energy policy and trade strategy have played major roles in the pursuit of new oil discoveries in Alaska and in warfare in Kuwait, Iraq, and perhaps Afghanistan.

1.8 Technological Change and Energy Efficiency

Although technological change (usually involving an improvement in energy efficiency) is not inherently a geographic process, it does not occur uniformly over geographic space. Consequently, mathematical modeling and behavioral and innovation diffusion studies by geographers have improved our understanding of the pervasive phenomenon of technological change in energy markets. Similarly, creative government policies in Germany since 1990 have led to a faster rate of adoption of renewable energy sources, compared to the United States. Other studies have helped to explain why Japan, Italy, Germany, and Scandinavian countries have lower levels of energy consumption per capita or per unit of gross domestic product (GDP) than is the case in the United States and Canada. The answer to this question is a complex mix of price, government incentives and standards, economic structure, education, and lifestyle factors.

2. FOSSIL FUELS

2.1 Oil

The economic geography of the world oil industry has been studied in detail since the 1963 seminal study by Peter Odell. This study provided an analysis of the factors that contributed to the spatial distribution of the production, refining, transport, distribution, and consumption of oil. One interesting comparison is that although the share of proved crude oil reserves located in the Middle East at the time of the study was 60%, the share has risen only slightly since then, to about 65% by 2002. The top five nations of the world in terms of crude oil reserves are all in the Middle East, with the United States a distant eighth (Table I). Given these patterns, it is not surprising that the Organization of Petroleum Exporting Countries (OPEC) accounted for 39% of the world's crude oil production in 2002, with 26% coming out of the Persian Gulf. Saudi Arabia was the leading producer at 8.4 million barrels/day, followed by Russia and the United States. Before the rise of OPEC in the 1960s, the majority of global production was controlled by multinational oil companies. Although OPEC's production share peaked at 55% in 1973 and steadily declined following the OPEC oil embargo of that year to a low of 29% in 1985, it has gradually risen again since then to the current 39%

TABLE I

Proved Reserves of Fossil Fuels in Selected Countries in 2002[a]

Nation	Oil (10^9 barrels)	Gas (10^{12} m^3)	Coal (10^6 short tons)
Saudi Arabia	261.8	6.36	0
Iraq	112.5	3.11	0
United Arab Emirates	97.8	6.01	0
Kuwait	96.5	1.49	0
Iran	89.7	23.00	1885
Venezuela	77.8	4.19	479
Russia	60.0	47.57	157,010
United States	30.4	5.19	249,994
Libya	29.5	1.31	0
Mexico	12.6	0.25	1211
China	18.3	1.51	114,500
Qatar	15.2	14.40	0
India	5.4	0.76	84,396
Australia	3.5	2.55	82,090
Germany	0.3	0.34	66,000

[a]Data from the British Petroleum Company (2003) and the Energy Information Administration (2003).

level. Oil prices have been remarkably stable since 1974, except for the period from 1980 to 1986 following the Iranian Revolution and during the Iran–Iraq War.

The global patterns in crude oil refining, consumption, and trade illustrate how integrated the oil markets have become in recent decades. In the case of refining, the United States is by far the global leader. It refined more than 15 million barrels/day in 2001, accounting for 21.6% of the world total. Europe as a whole (not counting the European portion of the former Soviet Union) was not far behind at 21.2%, though capacity is split widely among Germany, Italy, France, the United Kingdom, Netherlands, Spain, and others. The Middle East accounted for 8% of the global refining throughput in 2001, led by Saudi Arabia and Iran. South America and Central America were next at 7.9%, led by Brazil and Venezuela. The next largest refiner was the former Soviet Union at 7% (mostly Russia), though its capacity has fallen by about 30% since 1991. Other leading oil refiners include China and Japan. Global patterns of oil consumption are more geographically concentrated than is refining, with the United States, Europe (except for the former Soviet Union), Russia, Japan, and China accounting for 64% of the total.

The global trade pattern in crude oil and refined petroleum products is show in Fig. 1. The large production coming out of the Middle East, which accounts for more than 40% of the total trade flow, is marketed to Japan, the Asia Pacific region, Europe, and the United States. The United States made a concerted effort after the 1973 OPEC embargo to be less dependent on the OPEC supply, but it actually increased its foreign crude oil and refined product import dependence over this period, going from 36% in 1973 to over 60% in 2002. The former Soviet Union is also a major oil trader, with most of its exports destined for refineries in western Europe.

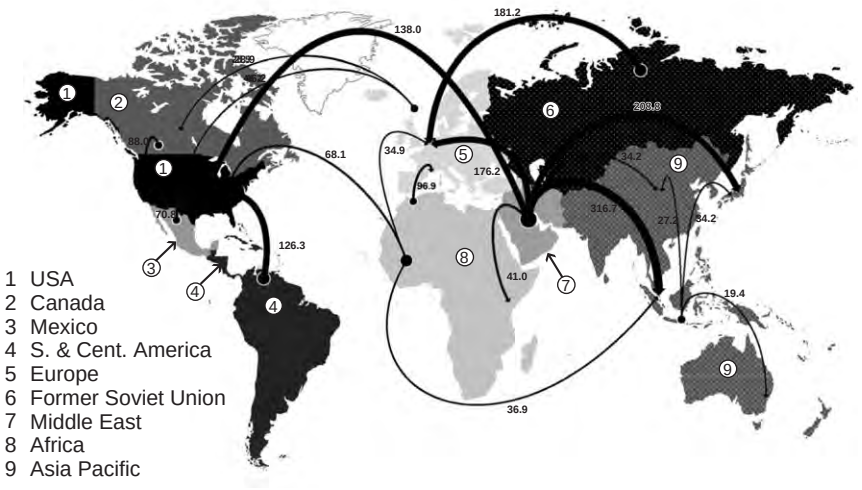

FIGURE 1 Major trade movements of oil (million tonnes). From the British Petroleum Company (2002), with permission.

Other significant oil shipment routes include Venezuela to the United States, Algeria and Libya to southern Europe, and Nigeria to the United States and the Asia Pacific region (Fig. 1).

Synthetic forms of oil supplies also can be developed. Although the vast technical potentials of tar sands and shale oil have been known for decades, these resources are beset by economic, environmental, and political problems and the industries are only in their infancy. Tar sands reserves, which are more properly known as bitumen or petroleum with very high viscosity, low resource quality, and low energy content, are concentrated in northern Alberta, Canada, where total production through surface and *in situ* mining amounted to just 30 million tonnes in 1999; an additional 3.3 million tonnes was produced in Venezuela. Canada has 979 million tonnes of proved recoverable reserves of synthetic crude oil or raw bitumen; Venezuela has 373 million tonnes. This compares with an additional 4231 million tonnes of additional reserves of foreseeable economic interest in the United States (half of the total is located in Utah and Alaska). The tar sands reserves of the United States and Canada are slightly larger than their oil reserves, whereas the tar sands reserves are much smaller than oil reserves in Venezuela.

The ultimate development potential of oil shales, if development proves to be economically and environmentally sound, is much greater than that of tar sands. The term "shale oil" is commonly used, although it is a misnomer because the organic material is chiefly kerogen and the hard rock it is usually found in is marl. This alternative oil resource can also be mined by conventional or *in situ* methods. The United States has by far the largest quantity of proved recoverable reserves of shale oil, at 60,000–80,000 million tonnes of oil equivalent. A small commercial facility was founded in Autun, France in 1839. Other nations that have produced shale oil include Canada, Scotland, Russia, China, Brazil (195 thousand tonnes in 1999), Estonia (151 thousand tonnes in 1999), and Australia (5 thousand tonnes in 1999, though production has grown since then).

2.2 Natural Gas

The spatial patterns of the world natural gas industry are somewhat different than those for oil, because gas has not been explored for and developed with the same vigor, is much less convenient to store, and is much more expensive to ship because of its low energy density (especially internationally). Geographic studies of this industry have concentrated on its production potential and have modeled its expanded development, transport via pipeline, and trade, especially in North America, Russia, and the rest of Europe.

The gas reserve base is geographically concentrated, with Russia, Iran, and Qatar accounting for 55% of the world total in 2002 (Table I). Other leading holders of gas reserves are Saudi Arabia, United Arab Emirates, the United States, Algeria, and Venezuela. The gas reserve base does not include coal bed methane, the reserve of which may be equal to or greater than that of conventional world gas in Canada and Russia alone. The United States and Russia are the only countries that account for more than 10% of the share of global gas production, each at about 22%. United States production totaled 555 billion m^3 in 2001; Russia produced 542 billion m^3. Canada was a distant third, at 172 billion m^3/yr. Although Russia used to dominate global output, it has alternated places with the United States as global leader since 1997.

Gas production figures, of course, reflect a nation's consumption level and involvement in international trade. The United States, the world's leading gas consumer, accounts for more than one-fourth of global consumption and is thus a slight importer, mostly from Canada (Fig. 2). Russia, conversely, only uses 15.5% of the world's gas output, and is a net exporter, to Europe and Turkey. European gas consumption, led by the United Kingdom, accounts for nearly 20% of global output. The total volume of liquefied natural gas (LNG) in world trade was 143 billion m^3 in 2001, or one-third the level of movement by pipeline in gaseous form. The leading shippers of LNG in recent years have been Indonesia, Algeria, Malaysia, and Qatar. About half of this LNG is sold to Japan, with another seventh of the total going to South Korea.

2.3 Coal

Economic geography studies of the coal industry began in the 1930s. The early work focused on the location of coal seams, local economic development, and transportation to markets in the United States and Europe. Geographic research since the 1970s has been more analytical and has often used mathematical programming models, because such studies have emphasized optimal coal development and shipment patterns, power plant siting, the response of the industry to technological change, growing environmental constraints, and electric utility deregulation. In the United States, e.g., coal mining has gradually

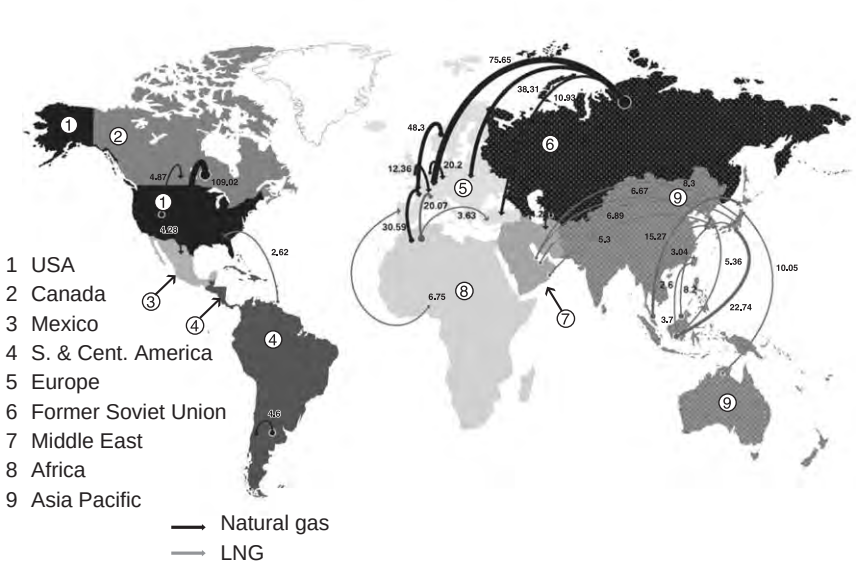

FIGURE 2 Major trade movements of natural gas (billion cubic meters). From the British Petroleum Company (2002), with permission.

shifted westward, because the economic advantages of that region's extensive near-surface deposits and lower sulfur content have increasingly outweighed the greater distances from electric power plants and other markets. European coal mining in the United Kingdom, Germany, Poland, and Russia, in contrast, has felt the greater brunt of acid rain and global warming restrictions, along with declining economics.

The coal reserve base is even more geographically concentrated than that of natural gas, with the United States, Russia, China, India, Australia, and Germany accounting for 77% of the world total in 2002 (Table I). Currently, only the United States, India, and Australia seem intent on using most of this resource base. Although Russian coal production has fallen by about half since the collapse of the former Soviet Union in 1991, the status of China is more uncertain. China led the world in coal production at 1545 million short tons in 1996, which fell to 1314 million short tons in 2000 as part of national policy to control air pollution and improve production efficiency (Germany implemented similar policy), but grew again in 2001 by more than 9%. Regarding global climate change, given the conflicting and unsettled policies of the United States, China, India, and Australia, the disposition of the huge coal resource base remains highly uncertain. The United States and China alone account for almost half of the world's coal consumption.

3. NUCLEAR POWER

The development of civil nuclear power was a stepchild of the military program of the United States to end World War II and of U.S. President Dwight D. Eisenhower's Atoms for Peace Speech to the United Nations General Assembly in 1953. The first commercial plants were commissioned in the United Kingdom, United States, and Russia in the late 1950s, and these nations actively developed this industry in the 1960s. Following the OPEC oil embargo in 1973, France and Japan developed major nuclear programs as well as strategies for energy autarky.

Significant political opposition to nuclear power plants and technology began to surface in the middle to late 1970s, first in the United States and later in several western European nations. Public opposition to nuclear power even spread to Taiwan in the 1990s. The opposition focused on the risk of accidents and radiological contamination, a prospect made worse by reactor sitings close to human population centers in New York, Boston, Philadelphia, Chicago, and coastal United Kingdom. In the aftermath of the accident at the Three Mile Island Unit 2 reactor near Harrisburg, Pennsylvania on March 28, 1979, it was clear that evacuation plans and procedures were inadequate in most nations (though they were improved thereafter).

The United States continued its global lead in nuclear power generation, with 104 nuclear reactor

units and 98.5 gigawatts (electrical; GWe) of installed capacity in 2003 (Table II). France leads large countries in reliance on nuclear power, which accounted for three-fourths of its electricity generation in 2002. Although the commitment to nuclear power and the location of the world's 441 nuclear reactors as of September 2003 (with 362 GWe of generating capacity) was widely distributed, most facilities outside of North America were located in Europe. Of the top 12 nuclear power users, 8 are European nations, with Japan and South Korea also making this list (Table II). The commitment to new reactor sitings and development, however, has stalled. Since 1995, opening of new nuclear power plants occurred only in France, the Czech Republic, Brazil, and especially in Asia (though a few others countries, such as the United States, have continued to expand their output as the capacity factor of many nuclear reactors has increased). There has been a *de facto* moratorium on new nuclear power in most of the world since 1980, with phaseout decisions pronounced in Sweden, Germany, Switzerland, Spain, Belgium, and the Netherlands.

In addition to heightened concern about nuclear proliferation and reactor safety in the 21st century, the nuclear power industry has been stifled by the twin Achilles' heels of reactor decommissioning and radioactive waste disposal. Although disposal sites have been in operation for shorter-lived, low- and medium-level wastes in several countries for decades, most attention has been given to the development of long-term, deep-geologic-disposal sites for high-level wastes (spent fuel rods and vitrified reprocessing wastes). Most progress on this front has been made in the United States and Scandinavia. The Finnish Parliament in May 2001 approved a plan in principle for deep-geologic disposal, though the repository would not be built until the 2010s and would not open until 2020. The disposal site is expected to be near the Olkiluoto nuclear plant in the town of Eurajoki on the west coast (a low-level waste site already exists there). In Sweden, repository siting is at an advanced stage and has been narrowed down to the Oskarshamn and Forsmark nuclear plant sites. A low- and medium-level waste site has existed near Forsmark since 1988 in offshore granite bedrock, 60 m below the Baltic Sea. In the United States, the Waste Isolation Pilot Plant in southeastern New Mexico opened on March 26, 1999 after a delay of 25 years; it accepts military transuranic and mixed hazardous wastes in bedded salt caverns 650 m underground. A high-level waste site in volcanic tuffs at Yucca Mountain, Nevada, 100 miles northwest of Las Vegas (also opposed and delayed), was approved by the U.S. Senate on July 9, 2002 and could open by 2010. Even so, scientific problems continue to be raised at the U.S. waste sites.

TABLE II

Top 12 Nuclear Power Producers in 2003[a]

Nation	Nuclear reactors	Capacity (GWe)[b]	Share of electricity (%)
United States	104	98.5	20
France	59	63.3	78
Japan	53	44.1	39
Germany	19	21.1	30
Russia	30	20.8	16
South Korea	18	14.9	39
United Kingdom	27	12.1	22
Canada	16	11.3	13
Ukraine	13	11.2	46
Sweden	11	9.5	46
Spain	9	7.4	26
Belgium	7	5.7	58

[b] GWe, gigawatts (electrical).

4. RENEWABLE ENERGY

The major renewable sources of energy include hydroelectricity, biomass, wind, solar, and geothermal. Renewable energy sources account for over one-fifth of total world energy use. Geothermal energy is categorized by federal statute in the United States as renewable, but strictly speaking, it is not, because it can be depleted at specific sites. All renewable energy resources can be used to generate electricity. In addition, biomass, solar, and geothermal energies are used for heating and cooking, and biomass is also used for transportation (as ethanol or methanol).

4.1 Hydroelectricity

Hydroelectric power is the largest and cheapest renewable electricity source in the world, although biomass easily surpasses it when other energy applications are considered. This is not to say that hydro power is without adverse environmental impacts, however. Large-scale dams are well known to lead to significant ecological damages, including loss of biodiversity, localized deforestation, soil

erosion, and disruption of free-flowing rivers, as well as displacement of large numbers of humans in many cases. Even so, hydroelectric power releases no direct greenhouse gas emissions and is a significant source of power in many parts of the world.

The United States, China, Canada, and Brazil are the leading producers of hydroelectricity (Table III). Brazil and Canada are the most dependent on hydro power, which accounted for 89 and 61%, of the electricity used in these two countries, respectively, in 2001, although persistent drought and rationing led to power cutbacks in Brazil in that year. Overall, Brazil relies on renewable energy for more than half of its total energy supply. Yet some small nations are even more dependent on renewable sources of electricity. Norway and Iceland, for instance, rely on renewable energy for 99% of their electricity consumption. In recent years, there have been few new large-scale hydroelectric power projects in developed nations because the best dam sites have generally already been tapped. A major exception to this pattern is the 2000-megawatt (MW) Lower Churchill Project on Gull Island in Newfoundland, Canada. In contrast, there have been several highly publicized dam removals and downstream ecological restoration projects in the northern United States. These trends, plus occasional drought, reduced the reliance of the United States on hydro power for electricity to 6% in 2001, down from a peak of 356 million MW-hr in 1997.

Large hydro projects can be found in many developing countries, such as China, India, Malaysia, Vietnam, Brazil, and Azerbaijan. China is building the controversial 18,200-MW Three Gorges Dam Project (the largest in the world) on the Yangtze River; the project is expected to reach full capacity by 2009. More than 1 million people will have to be relocated before the dam's reservoirs can be fully flooded. India, with 150-GWe of hydroelectric potential, has begun to focus on expanding this renewable source of energy, but not without difficulty in obtaining financing and in addressing protests from environmental and human rights groups. Most attention has focused on the Narmada Valley Development Project, which is planned to include up to 30 large dams in addition to numerous smaller ones.

TABLE III

Power Capacity From Hydro, Wind and Geothermal in Selected Countries, 2003[a]

	Gigawatts (electrical)		
Nation	Hydroelectric	Wind	Geothermal
United States	98.9	5.3	2.8
China	70.0	0.4	—[b]
Canada	67.2	0.2	0
Brazil	59.0	—[b]	0
Russia	43.4	—[b]	—[b]
Norway	27.4	—[b]	0
India	24.5	1.7	0
Japan	21.5	0.3	0.5
Italy	13.1	0.7	0.8
Spain	11.5	5.0	0
Mexico	9.6	0.3	0.9
Germany	3.0	12.8	0
Philippines	2.3	—[b]	1.9
Denmark	—[b]	2.8	0

[b] Less than 100 MW.

4.2 Wind and Geothermal

Wind power has been the fastest growing energy source in the world since it became more cost-effective in the 1990s, though it has a long way to go to catch up with hydro power. Leading the way is Germany, supported by its 1990 Electricity Feed Law that requires electric utilities to pay 80–90% of the retail rate for wind power purchases. Germany passed the United States as world leader in wind power development in 1997, and now has almost 13 GWe in capacity (Table III). Other leading wind power producers include Spain, Denmark, and India, though Italy, the United Kingdom, Ireland, and several other European nations are rapidly expanding their wind power programs, including at many offshore sites. Denmark stands out as being most dependent on wind power, which accounts for 20% of that nation's electricity supply.

The two leading developers of geothermal energy are the United States and the Philippines, with most of their facilities being committed to electric power generation and much less to direct use (Table III). In the case of the Philippines, geothermal energy accounted for 21.5% of the nation's electricity supply in 2000. Other leading producers include Mexico, Italy, Indonesia, Japan, and New Zealand. Among these nations, the United States, Mexico,

Indonesia, and the Philippines have the largest expansion plans for geothermal energy facilities.

4.3 Biomass and Solar

Biomass energy in its various forms and uses (firewood, charcoal, crop residues, alcohol fuels, municipal and animal wastes, electricity) accounts for one-seventh of the world's primary energy supplies and over 90% in some developing nations. The United States is the leading electric power producer, with 10.1 GWe of capacity from biomass fuels (wood and wastes). Over half of this is cogenerated, mostly from the paper industry. This makes biomass the next largest source of renewable electricity in the United States after hydro power. The United States also has a significant (though subsidized) ethanol industry, which produced over 2 billion gallons in 2002, mostly from corn, with a refining capacity of over 3 billion gallons. Brazil has an even larger ethanol fuel program from sugarcane; production, which was subsidized, was between 3 and 3.5 billion gallons in recent years. Wood is a common source of biomass energy in Scandinavia, China, Pakistan, India, and sub-Saharan Africa. Unfortunately, much of the biomass energy data are incomplete or unreliable, rendering international comparison difficult. Consequently, most geographers working on this subject conduct case studies, especially of wood fuel use and sustainable development.

Solar energy has many applications. Most attention has been given to low-cost solar cookers, water and space heaters, and photovoltaic cells, though California also 384 MW of solar power plant capacity. The price of photovoltaic modules declined a hundred old from 1972 to 1992. The module price had fallen further to $3.40/W and $2.46/W by 2001 for low- and high-volume purchases, which makes them cost-effective in limited applications. Japan and Germany lead the market for photovoltaics, with over 400 and 250 MW, respectively. Japan is also the world's leading user of household solar thermal collectors. Israel is even more dependent on solar energy. Over 80% of Israeli households have solar water heaters (more than 1.3 million installations), and solar energy accounted for 3% of its total energy use in 2001.

5. INTERNATIONAL COMPARISONS OF ENERGY CONSUMPTION

International comparisons of energy consumption (per capita, per unit of GDP, etc.) are often used as indicators of energy efficiency and gluttony. On this basis, the United States, Canada, Russia, Japan, Australia, Saudi Arabia, and much of western Europe are the "haves," whereas China, India, Pakistan, Bangladesh, Indonesia, the Philippines, Vietnam, Brazil, and most of Africa are the "have nots" (Fig. 3). In some cases these differences in energy use per capita are more than 5:1. Such comparisons, although interesting, are flawed. Aggregate indicators of energy use per capita mask the real determinants of energy use. Decomposition of these patterns has

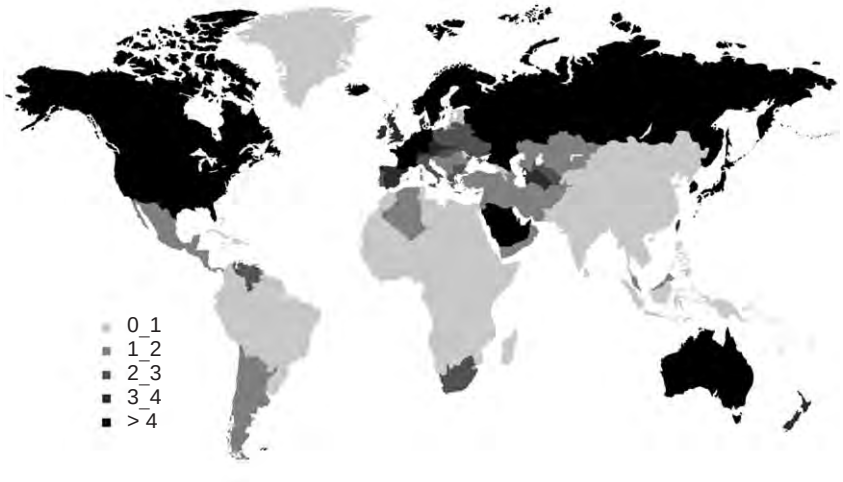

FIGURE 3 Energy consumption per capita by nation (tonnes of oil equivalent). From the British Petroleum Company (2002), with permission.

revealed the varying roles played by technological efficiency, structural economic change, and economic growth in determining energy consumption. Nonetheless, whatever the future energy trends and geographic patterns are in the world, such large inequities in energy use will not be ignored.

Glossary

capital There are two meanings in economics. One is the monetary value of assets owned by an individual firm, etc. or the amount that is available to invest. The second meaning, used herein, refers to a human-made input into the production process, including things such as buildings and machinery, and infrastructure (telecommunications systems and the like). Capital in these forms is also described as reproducible capital, manufactured capital, or human-made capital. Some writers use the term "capital" more widely, to include human capital and/or environmental or natural capital. Human capital refers to expertise or know-how embodied in people through processes of education and training. The term "natural capital" has been used to refer to the stock of environmental resources.

demand elasticity The percentage response in the quantity of a good demanded for a 1% increase in its price.

diminishing returns If use of an input to production is increased, holding the amounts of the other inputs constant, the law of diminishing returns states that eventually the marginal product of an input will decline, though not necessarily becoming negative.

ecological economics A transdisciplinary field including ideas from economics, natural sciences, and other social sciences, in which scholars and practitioners are interested in the broad question of the use of resources by society and in understanding the nature, behavior, and dynamics of the economy–environment system. Many, but not all, ecological economists are highly critical of the mainstream (neoclassical) school of economics.

econometrics The specialized branch of mathematical statistics applied to the analysis of economic data.

economic growth An increase in economy-wide economic production, usually measured by an increase in gross domestic product (GDP); also, the process of the economy growing over time.

elasticity of substitution A measure of the responsiveness of the ratio of the quantities of two productive inputs to a change in the relative prices of the quantities. For example, if the price of energy increases 1% relative to the price of capital and the amount of energy used per dollar of capital decreases by 1%, then the elasticity of substitution is 1. If the decrease in energy use is less, then the elasticity of substitution is less than 1, and vice versa.

embodied energy Used directly in the production of goods and services, energy is also used indirectly through its involvement in producing the other inputs to production. The sum of the two uses is called the embodied energy of the good or service.

externality A negative externality, or external effect, occurs when a production or consumption activity has unintended damaging effects, such as pollution, on other firms or individuals, and no compensation is paid by the producer or consumer to the affected parties. A positive externality occurs when activities have beneficial effects for others who do not pay the generator of the effect, such as freely available research results.

institutions Commonly accepted rules, practices, etc. that govern human social and economic behavior, such as laws, customs, markets, etc.

marginal product If use of an input to production is increased, holding the amounts of the other inputs constant, the increase in output produced is called the marginal product of that input.

neoclassical economics The mainstream school or paradigm of economics characterized by mathematical models based on optimization by individual consumers and producers. A paradigm that arose in the late 19th century and emerged to its dominant position after the World War II; other paradigms include Keynesian, Marxist, Institutional, and neo-Ricardian, and post-Keynesian models.

nonrenewable resource A natural resource such as petroleum, which has zero natural growth over ordinary human timescales; though it may be replenished over geological time. Renewable resources such as forests

 © 2004 Elsevier Inc. All rights reserved.

grow or regenerate at rates that are relatively fast on human timescales.

production function A mathematical representation of the quantitative relationship between productive inputs and the level of output of some good or service, expressing the maximum quantity of output that can be obtained from any particular amounts of inputs.

productivity An index of economic output relative to input. Increases in productivity are often seen as being due to improvements in technology but may also be due to other factors. The most general productivity index is known as total factor productivity. Labor productivity is just output per worker hour and is the measure usually discussed in the financial media.

public goods The consumption of a public good by one person, which does not reduce the amount available for others and once provided to some people, other people cannot be excluded from consuming them.

substitution Shifting the mix of inputs used to produce a given quantity of output. Substitution occurs among already known production methods and does not imply that innovations are introduced.

sustainability As used herein, nondeclining individual consumption or utility over time; many other definitions exist.

technological change The invention and introduction of new methods of production as well as new products; the main focus in economics and herein is on the former.

utility The level of satisfaction (or happiness) of an individual. In a more aggregate context, we refer to the social welfare of a group of people, which is an indicator related to the utilities of the individuals in society.

Resource and ecological economists have criticized the theory that energy plays a minor role in economic growth on a number of grounds, especially the implications of thermodynamics for economic production and the long-term prospects of the economy. Although a fully worked out alternative model of the growth process does not seem to exist, extensive empirical work has examined the role of energy in the growth process. The principal finding is that energy used per unit of economic output has declined, but that this is to a large extent due to a shift in energy use from direct use of fossil fuels such as coal to the use of higher quality fuels, and especially electricity. When this shift in the composition of final energy use is accounted for, energy use and the level of economic activity are found to be tightly coupled. When these and other trends are taken into account, the prospects for further large reductions in the energy intensity of economic activity seem limited. These findings have important implications for environmental quality and economic and environmental policy.

1. INTRODUCTION

This article surveys the relation between energy and economic growth, and more generally the role of energy in economic production. Business and financial economists pay significant attention to the impact of oil and other energy prices on economic activity, but the mainstream theory of economic growth pays little or no attention to the role of energy or other natural resources in promoting or enabling economic growth. The extensive discussions concerning the "productivity slowdown" following the 1970s oil crises were an exception.

This article is structured to cover these key points in a systematic fashion. In the first section there is a review of the background theory of production and growth from different points of view—those based in economics and those based in the natural sciences. The starting premise is that gaining an understanding of the role of energy in economic growth cannot be achieved without first understanding the role of energy in production. The scientific basis of the role of energy in production, and hence also in the increasing scale of production involved in economic growth, is considered first. However, institutional phenomena also affect how this role plays out and therefore the economic view of growth and production and of the potential role of energy is necessarily more complex than just this scientific understanding. The mainstream theory of economic growth is, therefore, reviewed next. The limitations of its consideration of energy and other resource issues have been the subject of strong criticism grounded in the biophysical theory of the role of energy. A review of these alternative viewpoints completes this first section of the article.

The mainstream economics concept of the production function is next used to examine the key factors that could reduce or strengthen the linkage between energy use and economic activity over time. This production theory is very general and is less subject to criticism than are the specific models of economic growth. These key factors are (1) substitution between energy and other inputs within an existing technology, (2) technological change, (3) shifts in the composition of the energy input, and (4) shifts in the composition of economic output. Each of these themes will be discussed in detail.

Numerous ideas and views exist about the potential linkages between energy and economic growth. Choice between these theories has to be on the basis of both inherent plausibility and consistency and, perhaps more crucially, empirical

evidence. Therefore, studies that investigate the strength of the linkage between energy and growth are reviewed. To be useful, such studies must not be grounded in a single theory, potential mechanism, or school of thought. Therefore, the studies reviewed here do not specify structural linkages between energy and output. Because correlation and regression analysis does not imply causality from one variable to another, most of these studies employ the econometric notions of Granger causality and cointegration to test the presence of and direction of causality between the variables.

Finally, the implications of the theory for environmental quality are examined and the recent empirical literature on that topic is discussed.

2. *THEORY OF PRODUCTION AND GROWTH*

2.1 Energy in Production: Physical Theory and Economic Models

Reproducibility is a key concept in the economics of production. Some inputs to production are nonreproducible, whereas others can be manufactured at a cost within the economic production system. Primary factors of production are inputs that exist at the beginning of the period under consideration and are not directly used up in production (though they can be degraded and can be added to), whereas intermediate inputs are created during the production period under consideration and are used up entirely in production. Mainstream economists usually think of capital, labor, and land as the primary factors of production, and goods such fuels and materials as the intermediate inputs. The prices paid for all the different inputs are seen as eventually being payments to the owners of the primary inputs for the services provided directly or embodied in the produced intermediate inputs. In the theory of growth, this approach has led to a focus on the primary inputs, in particular on capital and land, and a much lesser and somewhat indirect treatment of the role of energy in the growth process. The primary energy inputs are stock resources such as oil deposits. But these are not given an explicit role in the standard growth theories, which focus on labor and capital. However, capital, labor, and, in the longer term, even natural resources are reproducible factors of production, whereas energy is a nonreproducible factor of production, although, of course, energy vectors (fuels) are reproducible factors. Therefore, natural scientists and some ecological economists have placed a very heavy emphasis on the role of energy and its availability in the economic production and growth processes.

The first law of thermodynamics (the conservation law) implies the mass-balance principle. In order to obtain a given material output, greater or equal quantities of matter must enter the production process as inputs, with the residual as a pollutant or waste product. Therefore, there are minimum material input requirements for any production process producing material outputs. The second law of thermodynamics (the efficiency law) implies that a minimum quantity of energy is required to carry out the transformation of matter. All production involves the transformation or movement of matter in some way, and all such transformations require energy. Therefore, there must be limits to the substitution of other factors of production for energy. Energy is also an essential factor of production. Though all economic processes require energy, some service activities may not require the direct processing of materials. However, this is only true at the micro level. At the macro level (economy-wide level), all economic processes require the indirect use of materials, either in the maintenance of labor or in the production of capital goods.

Some aspects of organized matter—that is, information—might also be considered to be nonreproducible inputs. Several analysts argue that information is a fundamentally nonreproducible factor of production in the same way as energy. Energy is necessary to extract information from the environment, but energy cannot be made active use of without information and possibly accumulated knowledge. Unlike energy, information and knowledge cannot be easily quantified. But these latter factors of production must be incorporated into machines, workers, and materials in order to be made useful. This provides a biophysical justification for treating capital, labor, etc. as factors of production. Though capital and labor are easier to measure than information and knowledge, their measurement is, still, very imperfect compared to that of energy.

In the mainstream neoclassical economics approach (discussed later), the quantity of energy available to the economy in any period is endogenous, though restricted by biophysical constraints (such as the pressure in oil reservoirs) and economic constraints (such as the amount of installed extraction, refining, and generating capacity), and the possible speeds and efficiencies with which these processes can proceed. Nevertheless, this analytical approach leads

to a downplaying of the role of energy as a driver of economic growth and production. Some alternative, biophysical models of the economy propose that energy is the only primary factor of production. This could be understood as there being a given stock of energy that is degraded (but, due to the law of the conservation of energy, not used up) in the process of providing services to the economy. But this means that the available energy in each period needs to be exogenously determined. In some biophysical models, geological constraints fix the rate of energy extraction. Capital and labor are treated as flows of capital consumption and labor services rather than as stocks. These flows are computed in terms of the embodied energy use associated with them and the entire value added in the economy is regarded as the rent accruing to the energy used in the economy. The actual distribution of the surplus depends on the relative bargaining power of the different social classes and foreign suppliers of fuel. Therefore, the owners of labor, capital, and land appropriate the energy surplus. The production process in the economy as a whole can be represented as an input–output model as originally developed by Nobel Laureate Wassily Leontief and adapted in the energy context by Bruce Hannon and others. The input–output model specifies the required quantities of each input needed to produce each output, with each output potentially an input to another process. It is also possible to trace all final production back to its use of a single primary factor of production, in this case energy.

These ecological economists argue that the energy used to produce intermediate resource inputs such as fuels increases as the quality of resources (such as oil reservoirs) declines. This is like negative productivity growth or technological change. Thus, changing resource quality is represented by changes in the embodied energy of the resources rather than by changes in the input–output coefficients. If resource stocks were explicitly represented, energy would no longer be the only primary factor of production. The neo-Ricardian models developed by Charles Perrings and Martin O'Connor, like all other neo-Ricardian models, have a fixed-proportions technology in terms of capital stocks instead of the flows in the Leontief model. They do not distinguish between primary and intermediate factors of production. Yet that approach can still take biophysical constraints such as mass balance and energy conservation into account.

If the economy can be represented as an input–output model where there is no substitution between factors of production, the embodied knowledge in factors of production can be ignored. An accurate accounting for all energy used to support final production is important. But in the real world the contribution of knowledge to production cannot be assumed to be proportional to its embodied energy. Though thermodynamics places constraints on substitution, the actual degree of substitutability among capital stocks embodying knowledge and energy is an empirical question. Neither the Leontief nor the neo-Ricardian model allows substitution between inputs. The neoclassical production models that are considered next, however, do.

2.2 The Mainstream Theory of Growth

As already explained, there is an inbuilt bias in mainstream production and growth theory to downplay the role of resources in the economy, though there is nothing inherent in economics that restricts the potential role of resources in the economy. The basic model of economic growth is the Nobel prize-winning work by Robert Solow that does not include resources at all. This model subsequently was extended with nonrenewable resources, renewable resources, and some waste assimilation services. These extended models, however, have only been applied in the context of debates about environmental sustainability, not in standard macroeconomic applications.

2.2.1 The Basic Growth Model

Economic growth models examine the evolution of a hypothetical economy over time as the quantities and/or the qualities of various inputs into the production process and the methods of using those inputs change. Here, the simplest model based on the work of Solow is described. In this model, a constant-sized labor force using manufactured capital produces output in terms of gross domestic product (GDP). The model assumes that output increases at a decreasing rate as the amount of capital employed rises. The uppermost curve in Fig. 1 shows this relationship between output (Y) and capital (K). This is termed diminishing returns to capital. It is assumed that a constant proportion, s, of the output is saved and invested in the capital stock. A constant proportion of the existing capital stock depreciates (becomes productively useless) in each period of time. The capital stock is in equilibrium (and so unchanging in size) when saving equals depreciation. This is also shown in Fig. 1. The dynamics implied by Fig. 1 are very simple. To the left of K^*, where capital per worker is scarce, capital investment generates a relatively large increase in future income, and so will

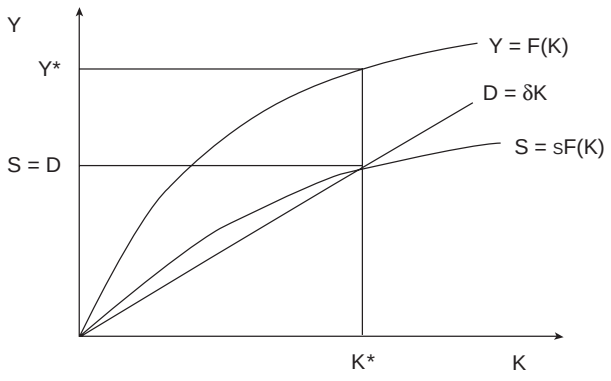

FIGURE 1 The neoclassical growth model.

offer a high rate of return. Moreover, it is clear from the relative positions of the *S* and *D* curves to the left of K^* that the addition to the capital stock (*S*) is greater than depreciation (*D*) and so capital rises. When the capital stock has reached K^*, it will be at a stationary, or equilibrium, state. Additions to capital due to saving are exactly offset by reductions in capital from depreciation.

This simple economy must sooner or later reach a stationary state in which there is no net (additional) investment and economic growth must eventually halt. In a transition process, while a country is moving toward this stationary state, growth can and will occur. An underdeveloped economy, with a small capital stock per worker, can achieve fast growth while it is building up its capital stock. But all economies will eventually settle into a zero growth equilibrium if the savings rate remains constant. No country can grow in perpetuity merely by accumulating capital, due to the diminishing returns to capital accumulation. If the savings rate is increased, growth will occur for a while until a new equilibrium is reached. Of course, the higher the savings the rate, the lower the current standard of living of the population.

If the labor force grows at a fixed rate over time, the total capital stock and the total quantity of output will rise, but capital per worker and output per worker will remain constant once an economy has developed to its equilibrium. The only necessary adjustment to Fig. 1 is that all units are now measured in per capita terms.

According to neoclassical growth theory, the only cause of continuing economic growth is technological progress. As the level of technological knowledge rises, the functional relationship between productive inputs and output changes. Greater quantities or better qualities of output can be produced from the same quantity of inputs. In the simple model being examined, technological progress continually shifts the output function upward, and so raises the equilibrium per capita capital stock and output levels. Intuitively, increases in the state of technological knowledge raise the rate of return to capital, thereby offsetting the diminishing returns to capital that would otherwise apply a brake to growth.

2.2.2 Endogenous Technological Change

The simple model just described does not explain how improvements in technology come about. They are just assumed to happen exogenously, so that this model is said to have exogenous technological change. More recent models attempt to endogenize technological change, explaining technological progress within the growth model as the outcome of decisions taken by firms and individuals. In endogenous growth models, the relationship between capital and output can be written in the form $Y = AK$. Capital, *K*, is defined more broadly than in the neoclassical model. It is a composite of manufactured and knowledge-based capital. Endogenous growth theorists have been able to show that, under reasonable assumptions, the *A* term in the preceding expression is a constant, and so growth can continue indefinitely as capital is accumulated.

The key point is that technological knowledge can be thought of as a form of capital. It is accumulated through research and development (R&D) and other knowledge-creating processes. Technological knowledge has two special properties. First, it is a public good: the stock of this form of capital is not depleted with use. This is important because it implies that the knowledge stock can be stored over time, even when it is being used. Second, it generates positive externalities in production: although the firm doing R&D obtains benefits from the knowledge acquired, others benefit too—the benefits that the firm accrues when it learns and innovates are only partly appropriated by itself. There are beneficial spillovers to the economy from the R&D process so that the social benefits of innovation exceed the private benefits to the original innovator. These externalities create momentum in the growth process. As firms install new capital, this tends to be associated with process and product innovations. The incentive to devote resources to innovation comes from the prospect of temporary monopoly profits for successful innovations. The growth of *K* thus means the growth of a composite stock of capital and disembodied technological knowledge. Therefore, output is able to rise as a constant proportion (*A*) of the

composite capital stock, and is not subject to the diminishing returns shown in Fig. 1.

So, in an endogenous growth model, the economy can sustain a constant growth rate in which the diminishing returns to manufactured capital are exactly offset by the technological growth external effect just described. The growth rate is permanently influenced by the savings rate; a higher savings rate increases the economy's growth rate, not merely its equilibrium level of income.

2.2.3 Growth Models with Natural Resources

The growth models examined so far do not include any natural resources. All natural resources exist in finite stocks or flows, though some, such as sunlight or deuterium, are available in very large quantities. Some environmental resources are nonrenewable, and many renewable resources are potentially exhaustible. Finiteness and exhaustibility of resources make the notion of indefinite economic growth problematic. Even maintaining the current level of output indefinitely—so-called sustainable development—may be difficult.

When there is more than one input (both capital and natural resources), there are many alternative paths that economic growth can take. The path taken is determined by the institutional arrangements that are assumed to exist. Analysts have looked at both optimal growth models that attempt to either maximize the sum of discounted social welfare over some relevant time horizon (often an infinite horizon) or achieve sustainability (nondeclining social welfare) and models intended to represent real economies with perfectly competitive markets or other arrangements.

The neoclassical literature on growth and resources centers on what conditions permit continuing growth, or at least nondeclining consumption or utility. Technical and institutional conditions determine whether such sustainability is possible. Technical conditions refer to things such as the mix of renewable and nonrenewable resources, the initial endowments of capital and natural resources, and the ease of substitution among inputs. The institutional setting includes things such as market structure (competition versus central planning), the system of property rights (private versus common property), and the system of values regarding the welfare of future generations.

In a 1974 paper published in a special issue of *Review of Economic Studies*, Solow showed that sustainability was achievable in a model with a finite and nonrenewable natural resource with no extraction costs and nondepreciating capital, which was produced using capital and the natural resource. However, the same model economy under competition results in exhaustion of the resource and consumption and social welfare eventually falling to zero. In another paper in the same special journal issue, Dasgupta and Heal showed that with any constant discount rate the so-called optimal growth path also leads to eventual depletion of the natural resource and the collapse of the economy. A common interpretation of this theory is that substitution and technical change can effectively decouple economic growth from resources and environmental services. Depleted resources or degraded environmental services can be replaced by more abundant substitutes, or by "equivalent" forms of human-made capital (people, machines, factories, etc.). But this is a misinterpretation. Neoclassical economists are primarily interested in what institutional arrangements, and not what technical arrangements, will lead to sustainability, so that they typically assume a *priori* that sustainability is technically feasible, and then investigate what institutional arrangements might lead to sustainability if it is technically feasible. However, there is a tendency among mainstream economists to assume that sustainability is technically feasible unless proved otherwise.

The elasticity of substitution (σ) between capital (factories, machines, etc.) and inputs from the environment (natural resources, waste assimilation, ecosystem services) is a critical technical term that indicates by how much one of the inputs must be increased to maintain the same level of production, when the use of the other input is reduced. A large value of σ implies that this substitution is easy, and vice versa. Figure 2 shows the different combinations of two inputs that can produce a given level of output for different values of σ. Different levels of output were chosen for the three values of σ to make the figure clearer.

The marginal product is the additional contribution to production of using one more unit of an input, holding the levels of the other inputs constant. A unitary elasticity of substitution ($\sigma = 1$), referred to as "perfect substitutability," means that as the ratio of the two inputs is changed by a given percentage, holding output constant; the ratio of their marginal products changes by the same percentage (in the opposite direction). This relation is shown by the curve (known as an isoquant) in Fig. 2, which is asymptotic to both axes. As resource use decreases toward zero, production can be maintained by increasing capital use toward infinity. Additionally,

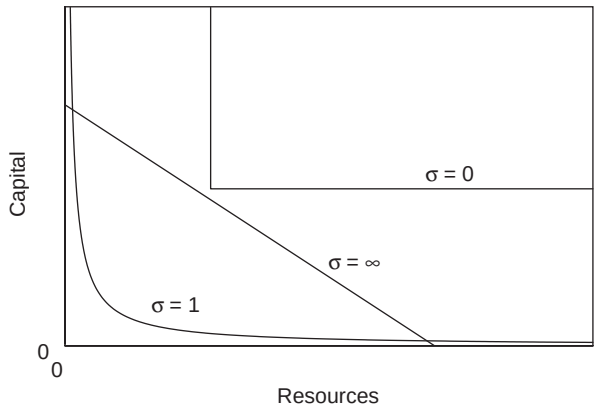

FIGURE 2 The elasticity of substitution.

the total cost of production is constant along the isoquant. Perfect substitutability does not mean that resources and capital are equivalently useful—that case is termed "infinite substitutability" ($\sigma = \infty$). In the latter case, producers see no difference between the two inputs and use the cheapest one. Whenever the elasticity of substitution is greater than 1, the isoquants cross the axes and inputs are nonessential for production. The figure also illustrates the case where no substitution is possible ($\sigma = 0$). In this case, the two inputs must be used in a fixed ratio. As is discussed later, perfect substitutability is an unrealistic assumption from a biophysical perspective, at least if it is assumed to apply at all possible ratios of capital and resources. Demand elasticities for energy, which in theory are related to the elasticity of substitution, also indicate that the elasticities of substitution between energy and other inputs and among different fuels may be between 0 and 1.

Economists such as Solow explicitly dispose of cases where σ for nonrenewable resources and capital is greater or less than unity. In the former case, substitution possibilities are large and therefore the possibility of nonsustainability is not an issue. In the latter case, sustainability is not feasible if an economy uses only nonrenewable resources. Of course, where there are renewable resources, sustainability is technically feasible, at least in the absence of population growth. Neoclassical economists argue that the class of growth models that includes resources can account for mass balance and thermodynamic constraints with the "essentiality condition." If σ is greater than 1, then resources are "nonessential." If σ is less than or equal to 1, than resources are "essential." Essential in this case means that, given positive nonresource inputs, output is only zero when the resource input is zero, and strictly positive otherwise. The Cobb–Douglas production function, a form frequently used in growth models, has the essentiality condition. Economists argue that this at least accounts for the fact that some amount of energy and materials is required to produce goods and services. But when the elasticity of substitution is unity, this "essential" amount can be infinitesimal if sufficient manufactured capital is applied. Economists also note that resources and capital are interdependent in the neoclassical models in that some positive quantity of resources is required to produce capital assets. Thus, the capital stock cannot be increased without depleting the resource stock.

Substitution that is technically possible will not occur unless society invests in sufficient capital over time to replace the depleted natural resources and ecosystem services. How much investment does take place depends on the institutional setting of the economy. For example, in an economy in which sustainability is just technically feasible ($\sigma = 1$) and there are only nonrenewable resources, sustainability will not occur in either a competitive or centrally planned economy where the decision rule is the maximization of the discounted flow of utility of future generations using a constant and positive discount rate. Consumption per capita will eventually decline to zero after an initial period of economic growth because resources and ecosystem services are depleted faster than capital can be accumulated to replace them. However, if the utility of individuals is given equal weight without regard to when they happen to live, and the aim is to maximize the sum of utilities over time, then growth in consumption can occur indefinitely. This is equivalent to maximizing net present value with a zero discount rate. The Hartwick rule is an investment rule that can, in theory, achieve sustainability if sustainability is technically feasible. A constant level of consumption can be achieved by reinvesting resource rents in other forms of capital, which, in turn, can substitute for resources.

The other key factor permitting growth in the face of a limited resource base is technological change. A technological improvement is defined as a gain in total factor productivity, which implies that output increases while a weighted sum of the inputs to production is held constant. Therefore, growth would be possible in the face of finite resources. Studies that examine the roles of resources in growth models with endogenous technological change have so far been less general in their assumptions, compared to research using the exogenous technological change

assumption, and do not yet provide necessary or sufficient conditions for the achievement of sustainability. For example, Sjak Smulders and Michiel de Nooij assume in their model that energy use per capita continues to grow over time and that conservation policies consist of either a reduction in the growth rate or a one-time cut in the level of energy use. This set of assumptions is very different from those in the models just discussed. The results depend on whether the growth rate of energy use is reduced or the level of energy use is cut and on the value of the elasticity of substitution. In these models, energy scarcity or conservation policies can induce technological change. Though this can mitigate the effects of scarcity, non-energy-related research and development may be crowded out. This means that attempts to conserve energy can depress the long-run economic growth rate, even when they would not in a model with exogenous technological change. Integrating these ideas into research on sustainability policy will clearly be a future area of active research.

2.3 Critique and Alternative Views

Many ecological economists have a "preanalytic vision" of the economic process that is fundamentally different from that presented in neoclassical economics. Mainstream growth theory focuses on institutional limits to growth. Ecological economists tend instead to focus on the material basis of the economy. The criticism of growth theory focuses on the limits to substitution and the limits to technological progress as ways of mitigating the scarcity of resources. Substitution of manufactured capital for resources and technological change could potentially get more production out of a limited resource input and circumvent the limited capacity of natural environments to absorb the impacts of energy and resource use by reducing those impacts. But if these two processes are limited, then limited resources or excessive environmental impacts may restrict growth (empirical evidence on these questions is reviewed in Sections 4 and 5).

2.3.1 Limits to Substitution

There is more than one type of substitution between inputs and, therefore, there is more than one reason why substitution may be limited. There can be substitution within a category of similar production inputs (for example, between different fuels) and between different categories of inputs (for example, between energy and machines). There is also a distinction to be made between substitution at the micro level (for example, in a single engineering process or in a single firm) and at the macro level (in the economy as a whole). Additionally, some types of substitution that are possible in a single country are not possible globally.

The first type of substitution (within category), and, in particular, the substitution of renewable for nonrenewable resources, is undoubtedly important. The long-run pattern of energy use in industrial economies has been dominated by substitutions: from wood to coal, to oil, to natural gas, and to primary electricity. It is possible that the elasticity of substitution for within-category types of substitution exceeds unity. This would imply that some particular inputs are nonessential.

Ecological economists emphasize the importance of limits to the other type of substitution, and, in particular, the substitution of manufactured capital for natural capital. Natural capital is needed both for energy capture and for absorbing the impacts of energy and resource use—the sink function. Even if smaller amounts of energy were needed for production, all productive activity, being a work process transforming the materials using energy, will disrupt the natural environment. Often one form of environmental disruption (for example, pollution) is replaced by another form of environmental disruption (for example, hydroelectric dams). Potential reasons for limited substitutability are discussed in the following section.

2.3.1.1 Thermodynamic Limits to Substitution

Thermodynamic limits to substitution are easily identified for individual processes by an energy–materials analysis that defines both the fundamental limitations of transforming materials into different thermodynamic states and the use of energy to achieve that transformation. These types of analyses have shown where technological improvements exhibit strong diminishing returns due to thermodynamic limits, and where there is substantial room for improvements in the efficiency of energy and material use. For example, the thermal efficiency of power plants has been relatively constant for many years, reflecting the fact that power plant design is approaching the thermodynamic limit.

2.3.1.2 Complementarity Limits Substitution

Production is a work process that uses energy to transform materials into goods and services. Nicholas Georgescu-Roegen's fund-flow model describes production as a transformation process in which a flow of materials, energy, and information is transformed

by two agents of transformation: human labor and manufactured capital. The flow of energy, materials, and services from natural capital is what is being transformed, while manufactured capital effects the transformation. Thus, some ecological economists argue that, for example, adding to the stock of pulp mills does not produce an increase in pulp unless there also is the wood fiber to feed them. The latter is essential an argument about material balance.

Mainstream economists think about this question differently. First, they argue that though additional capital cannot conjure wood fibers out of a vacuum, more capital can be used with each amount of wood fibers to produce more sophisticated and valuable products from them and that this is the relevant substitution between capital and resources. In the energy industries, more capital can extract more oil from a petroleum reservoir and extract more useful work downstream in cleaner ways, only subject to thermodynamic limits. Even thermodynamic limits apply only to production of physical product. There is no limit in this view to the potential value of product created through sophisticated manipulation using larger amounts of capital.

2.3.1.3 Physical Interdependence and Macroeconomic Limits to Substitution The construction, operation, and maintenance of tools, machines, and factories require a flow of materials, i.e., energy from natural capital. Similarly, the humans that direct manufactured capital consume energy and materials (i.e., food and water). Thus, producing more of the "substitute," i.e., manufactured capital, requires more of the thing for which it is supposed to substitute. Ecological economists argue that production functions used in growth models do not account for this interdependence, and thus assume a degree of substitutability that does not exist. But both environmental and ecological economics have erred by not distinguishing among the micro- and macro-applications of production functions. Substitution is fundamentally more constrained at the macro level of analysis than at the micro level. For example, home insulation directly substitutes for heating fuel within the household sector. But interdependence means that insulation requires fuel to manufacture, so, for the economy as a whole, the net substitution of insulation for fuel is less than that indicated by an analysis of the household sector, in isolation from the rest of the economy.

In Fig. 3, the curve $E = f(M)$ is a neoclassical isoquant for a constant level of output, where E is energy and M is materials. The indirect energy costs of materials are represented by $g(M)$. For simplicity, the diagram unrealistically assumes that no materials are required in the extraction or capture of energy. Addition of direct and indirect energy costs results in the "net" isoquant $E = h(M)$. Generalizing for material costs to energy extraction appears to indicate that there are eventually decreasing returns to all factors at the macro level, and therefore the socially efficient region of the aggregate production function does not include areas with extreme factor ratios.

At a global level, a country such as Kuwait or Nauru can deplete its natural resources and invest in manufactured capital offshore through the financial markets. But this route to substituting manufactured capital for natural capital is clearly not possible for the world as a whole.

2.3.1.4 Critical Natural Capital Limits Substitution Ecological economists have also argued that at the macro level some forms of "natural capital" are not replaceable by produced capital, at least beyond certain minimum stock sizes. These stocks may provide life-support services to the economy or represent pools of irreplaceable genetic information or "biodiversity." The limited substitutability argument has also been extended to incorporate nonlinear dynamics and irreversible changes. The fear is that excessive substitution of human-made capitals for natural capital will cause the system to approach a threshold beyond which natural systems will lose resilience and suffer catastrophic collapse. Though we cannot demonstrate these forms of nonsubstitutability from basic physical laws, they may be just as important as thermodynamics in constraining actual production functions. In the energy context, this argument is most relevant regarding the sink func-

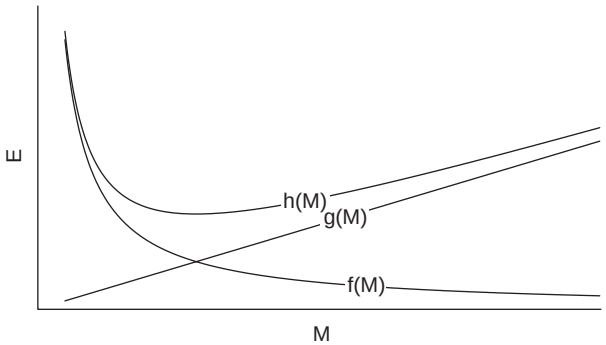

FIGURE 3 Macro-level limits to substitution.

tion of the environment. Using more and more of the environment as a sink for pollution means less and less of it is available for other life-support uses. Compared to current fossil fuel technologies, alternative energy sources may require larger areas of the environment for energy capture and may also generate wastes, etc. in the production of the energy capture and transmission capitals.

2.3.2 Limits to Technological Change

Even if substitution possibilities are limited, sustainability is possible if technological change is natural capital augmenting and unlimited in scope. The arguments for technological change as a solution would be more convincing if technological change were really something different from substitution. The neoclassical approach assumes that an infinite number of efficient techniques coexist at any one point in time. Substitution occurs among these techniques. Changes in technology occur when new, more efficient techniques are developed. However, in a sense, these new techniques represent the substitution of knowledge for the other factors of production. The knowledge is embodied in improved capital goods and more skilled workers and managers, all of which require energy, materials, and ecosystem services to produce and maintain. Thus, however sophisticated the workers and machinery become, there are still thermodynamic restrictions on the extent to which energy and material flows can be reduced.

Another question is whether technology will follow the "right" direction. If natural resources are not priced correctly due to market failure—a common and pervasive phenomenon that is the main topic of study of mainstream environmental economics—then there will be insufficient incentives to develop technologies that reduce resource and energy use. Instead, technological change would result in more resource use, not less.

3. FACTORS AFFECTING LINKAGE BETWEEN ENERGY AND GROWTH

There has been extensive debate concerning the trend in energy efficiency in the developed economies, especially since the two oil price shocks of the 1970s. Taking the example of the U.S. economy, energy consumption hardly changed in the period 1973 to 1991 (Fig. 4). This was despite a significant increase in GDP. These facts are indisputable. The reasons for the break in the trend have been the subject of argument. It is commonly asserted that there has been a decoupling of economic output and resources, which implies that the limits to growth are no longer as restricting as in the past.

The discussion here starts from the neoclassical perspective of the production function to examine the factors that could reduce or strengthen the linkage between energy use and economic activity over time. A general production function can be represented as follows:

$$(Q_1, \ldots, Q_m)' = f(A, X_1, \ldots, X_n, E_1, \ldots, E_p), \quad (1)$$

where the Q_i are various outputs (such as manufactured goods and services), the X_j are various inputs (such as capital, labor, etc.), the E_k are different energy inputs (such as coal, oil, etc.), and A is the state of technology as defined by the total factor productivity indicator. The relationship between energy and an aggregate of output such as gross domestic product can then be affected by substitution between energy and other inputs, technological change (a change in A), shifts in the composition of the energy input, and shifts in the composition of output. Also, shifts in the mix of the other inputs—for example, to a more capital-intensive economy from a more labor-intensive economy—can affect the relationship between energy and output, but this issue has not been extensively discussed in the literature and so will not be pursued further here. It is also possible for the input variables to affect total factor productivity, though in models that invoke exogenous technological change, this is assumed not to occur.

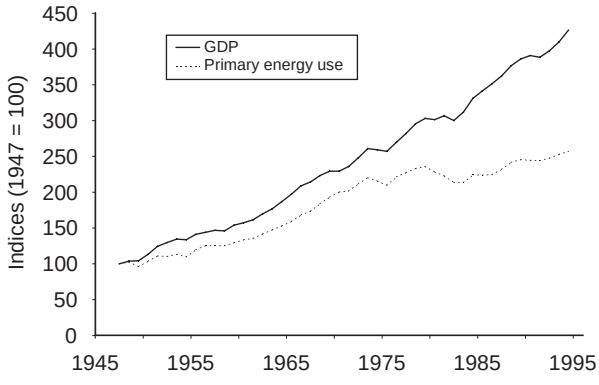

FIGURE 4 United States gross domestic product (GDP) and total primary energy use. GDP is in constant dollars, i.e., adjusted for inflation. Both variables are indexed to 100 in 1947.

3.1 Energy and Capital: Substitution and Complementarity

Econometric studies employing the translog and other functional forms have come to varying conclusions regarding whether capital and energy are complements or substitutes. These studies all estimate elasticities at the industry level. It seems that capital and energy are at best weak substitutes and possibly are complements. The degree of complementarity likely varies across industries, the level of aggregation considered, and the time frame considered.

There are few studies that look at macroeconomic substitution possibilities. In a 1991 paper, Robert Kaufmann and Irisita Azary-Lee demonstrated the importance of accounting for the physical interdependency between manufactured and natural capital. They used a standard production function to account for the indirect energy used elsewhere in the economy to produce the capital substituted for fuel in the U.S. forest products sector. They found that from 1958 to 1984, the indirect energy costs of capital offset a significant fraction of the direct fuel savings. In some years, the indirect energy costs of capital are greater than the direct fuel savings. The results of Kaufmann and Azary-Lee's analysis are consistent with the arguments made previously that scale is critical in assessing substitution possibilities. In this case, the assessment of substitution at one scale (the individual sector) overestimates the energy savings at a larger scale (the entire economy).

3.2 Innovation and Energy Efficiency

Substitution between different techniques of production using different ratios of inputs occurs due to changes in the relative prices of the inputs. Changes in the energy/GDP ratio that are not related to changes in the relative price of energy are called changes in the autonomous energy efficiency index. These could be due to any of the determinants of the relationship between energy and output listed at the beginning of this section, not just technological change. Actually, when there is endogenous technological change, changes in prices induce technological changes. In reality, technological change is at least in part endogenous. As a result, an increase in energy prices does tend to accelerate the development of energy-saving technologies. Periods of decreasing energy prices may result in technological development tending toward more intense use of energy.

Estimates of the trend in autonomous energy efficiency or the related energy augmentation index are mixed. This is likely because the direction of change has not been constant and varies across different sectors of the economy. Jorgenson and Wilcoxen estimated that autonomous energy efficiency in the United States is declining. Jorgenson also found that technological change tended to result in an increase in the share of production costs allocated to energy use—so-called biased technological change. Berndt *et al.* used a model in which the energy augmentation index is assumed to change at a constant rate. They estimate that in the U.S. manufacturing industry between 1965 and 1987, the energy augmentation index was increasing between 1.75 and 13.09% per annum, depending on the assumptions made. Judson *et al.* estimate separate environmental Kuznets curve relations for energy consumption in each of a number of energy-consuming sectors for a large panel of data using spline regression. The sectors are industry and construction, transportation, households and others, energy sector, nonenergy uses, and total apparent consumption, as well as households and agriculture, which are subsets of households and others. Judson *et al.* estimate time effects that show rising energy consumption over time in the household and other sectors but flat to declining time effects in industry and construction. Technical innovations tend to introduce more energy-using appliances to households and energy-saving techniques to industry.

Figure 5 presents the author's estimate of the autonomous energy efficiency index using the Kalman filter, an advanced time series technique that can extract unobserved stochastic series from time series data given a theoretical model that defines the trend of interest. This approach is more sophisticated than that of the studies cited previously, which assume that the index follows a simple linear or quadratic time path. Relative to an overall upward trend, the index shows large fluctuations. Until the mid-1960s, autonomous energy efficiency is increasing and then it starts a sharp decline. However, the results show that the first oil shock in 1973 does not disrupt the overall downward trend in energy efficiency. Only after the second oil shock does the trend reverse and energy efficiency increase.

The Khazzoom–Brookes postulate argues that energy-saving innovations can end up causing even more energy to be used, because the money saved is spent on other goods and services that require energy in their production. Energy services are demanded by the producer or consumer and are produced using

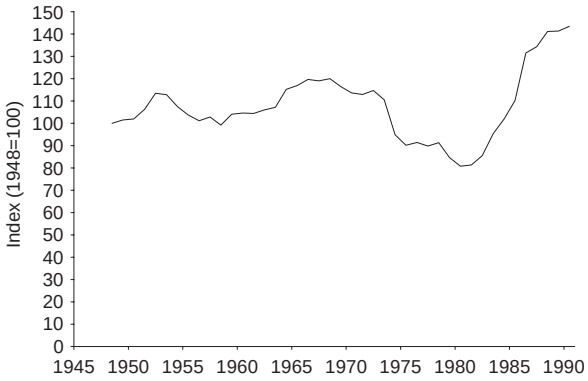

FIGURE 5 United States autonomous energy efficiency index.

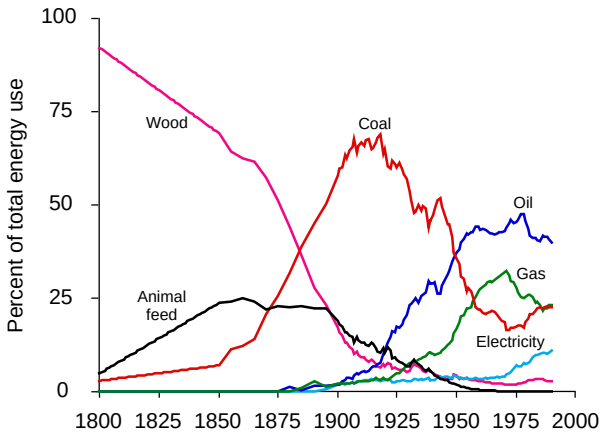

FIGURE 6 Composition of U.S. energy input.

energy. An innovation that reduces the amount of energy required to produce a unit of energy services lowers the effective price of energy services. This results in an increase in demand for energy services and therefore for energy. The lower price of energy also results in an income effect that increases demand for all goods in the economy and therefore for the energy required to produce them. There may also be adjustments in capital stocks that result in an even further increased long-run demand response for energy. This adjustment in capital stocks is termed a "macroeconomic feedback." In a 1997 paper, Richard Howarth argued persuasively that the rebound effect is less than the initial innovation-induced reduction in energy use, so improvements in energy efficiency do, in fact, reduce total energy demand.

3.3 Energy Quality and Shifts in Composition of Energy Input

Energy quality is the relative economic usefulness per heat equivalent unit of different fuels and electricity. One way of measuring energy quality is the marginal product of the fuel, which is the marginal increase in the quantity of a good or service produced by the use of one additional heat unit of fuel. These services also include services received directly from energy by consumers. Some fuels can be used for a larger number of activities and/or for more valuable activities. For example, coal cannot be used directly to power a computer whereas electricity can. The marginal product of a fuel is determined in part by a complex set of attributes unique to each fuel: physical scarcity, capacity to do useful work, energy density, cleanliness, amenability to storage, safety, flexibility of use, cost of conversion, and so on. But also the marginal product is not uniquely fixed by these attributes. Rather the energy vector's marginal product varies according to what activities it is used in, how much and what form of capital, labor, and materials it is used in conjunction with, and how much energy is used in each application. Therefore, energy qualities are not fixed over time. However, it is generally believed that electricity is the highest quality type of energy, followed by natural gas, oil, coal, and wood and other biofuels in descending order of quality. This is supported by the typical prices of these fuels per unit of energy. According to economic theory, the price paid for a fuel should be proportional to its marginal product.

Samuel Schurr was among the first to recognize the economic importance of energy quality. Noting that the composition of energy use has changed significantly over time (Fig. 6), Schurr argued that the general shift to higher quality fuels reduces the amount of energy required to produce a dollar's worth of GDP. If this is ignored, apparent total factor productivity (TFP) growth is greater than is really the case. Researchers such as Cutler Cleveland, Robert Kaufmann, and the Office of Technology Assessment, have presented analyses that explain much of the decline in U.S. energy intensity in terms of structural shifts in the economy and shifts from lower quality fuels to higher quality fuels. In a recent paper, Kaufmann estimated a vector autoregressive model of the energy/GDP ratio, household energy expenditures, fuel mix variables, and energy price variables for the United States. He found that shifting away from coal use and in particular shifting toward the use of oil reduced energy intensity. This shift away from coal contributed to declining energy intensity over the entire 1929–1999 time period.

Figure 7 illustrates the increase in the second half of the 20th century in U.S. GDP and a quality-adjusted index of energy use computed by the author. The index accounts for differences in the productivity of different fuels by weighting them by their prices. There is clearly less evidence of decoupling of energy use and GDP in these data than in those in Fig. 4. If decoupling is mainly due to the shift to higher quality fuels, then there appear to be limits to that substitution. In particular, exhaustion of low-cost oil supplies could mean that economies have to revert to lower quality fuels such as coal.

3.4 Shifts in the Composition of Output

Typically, over the course of economic development, the output mix changes. In the earlier phases of development there is a shift away from agriculture towards heavy industry, and in the later stages of development there is a shift from the more resource-intensive extractive and heavy industrial sectors toward services and lighter manufacturing. Different industries have different energy intensities. It is often argued that this will result in an increase in energy used per unit of output in the early stages of economic development and a reduction in energy used per unit output in the later stages of economic development. Pollution and environmental disruption would be expected to follow a similar path.

Service industries still need large energy and resource inputs. The product being sold may be immaterial but the office towers, shopping malls, warehouses, rental apartment complexes, etc. where the activity is conducted are very material intensive and energy is used in their functioning as well as in their construction and maintenance. Other service industries such as transport clearly heavily draw on resources and energy. Furthermore, consumers use large amounts of energy and resources in commuting to work, to shop, etc. Therefore, a complete decoupling of energy and growth as a result of shifting to the service sector seems unlikely. When the indirect energy use embodied in manufactured products and services is taken into account, the U.S. service and household sectors are not much less energy intensive than are the other sectors of the economy, and there is little evidence that the shift in output mix that has occurred in the past few decades has significantly lowered the energy/GDP ratio. Rather, changes in the mix of energy used are primarily responsible. Furthermore, on a global scale, there may be limits to the extent to which developing countries can replicate the structural shift that has occurred in the developed economies and, additionally, it is not clear that the developed world can continue to shift in that direction indefinitely.

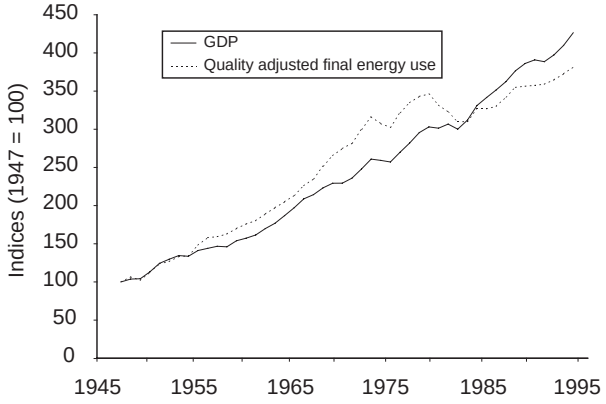

FIGURE 7 United States gross domestic product (GDP) and quality-adjusted final energy use GDP is in constant dollars, i.e., adjusted for inflation. Energy use is a Divisia index (the accumulation of weighted sums of growth rates) of the principal final energy use categories (oil, natural gas, coal, electricity, biofuels, etc.). The different fuels are weighted according to their average prices.

4. EMPIRICAL TESTING

Here the focus is on the empirical evidence for the tightness of coupling between energy use and economic output. Ordinary linear regression or correlation methods cannot be used to establish a casual relation among variables. In particular, it is well known that when two or more totally unrelated variables are trending over time they will appear to be correlated simply because of the shared directionality. Even after removing any trends by appropriate means, the correlations among variables could be due to causality between them or due to their relations with other variables not included in the analysis. Two methods for testing for causality among time series variables are Granger causality tests and cointegration analysis.

Granger causality tests whether one variable in a linear relation can be meaningfully described as a dependent variable and the other variable as an independent variable, whether the relation is bidirectional, or whether no functional relation exists at all. This is usually done by testing whether lagged values of one of the variables significantly add to the explanatory power of a model that already includes

lagged values of the dependent variable, and perhaps also lagged values of other variables.

Whereas Granger causality can be applied to both stationary and integrated time series (time series that follow a random walk), cointegration applies only to linear models of integrated time series. The irregular trend in integrated series is known as a stochastic trend, as opposed to a simple linear deterministic time trend. Time series of GDP and energy use are integrated. Cointegration analysis aims to uncover causal relations among variables by determining if the stochastic trends in a group of variables are shared by the series. If these trends are shared, either one variable causes the other or they are both driven by a third variable. It can also be used to test if there are residual stochastic trends that are not shared by any other variables. This may be an indication that important variables have been omitted from the regression model or that the variable with the residual trend does not have long-run interactions with the other variables. The presence of cointegration can also be interpreted as the presence of a long-run equilibrium relationship between the variables in question.

Both cointegration and Granger causality tests are usually carried out within the context of vector autoregression models. These models consist of group of regression equations in which each dependent variable is regressed on lagged values of itself and of all the other variables in the system.

Many analysts have used Granger causality tests or the related test developed by Christopher Sims to test whether energy use causes economic growth or whether energy use is determined by the level of output in the context of a bivariate vector autoregression. The results have been generally inconclusive. When nominally significant results were obtained, the majority indicated that causality runs from output to energy use. In a 1993 study, the author tested for Granger causality in a multivariate setting using a vector autoregression (VAR) model of GDP, energy use, capital, and labor inputs in the United States over a the post-World War II period. He also used a quality-adjusted index of energy input in place of gross energy use. The multivariate methodology is important because changes in energy use are frequently countered by the substitution of other factors of production, resulting in an insignificant overall impact on output. When both of these innovations are employed, energy is found to "Granger-cause" GDP. These results are supported by other studies that found that changes in oil prices Granger-cause changes in GDP and unemployment in VAR models, whereas oil prices are exogenous to the system.

Yu and Jin were the first to test whether energy and output cointegrate. They found that no such relationship exists between energy use and either employment or an index of industrial production in the United States. However, the lack of a long-run equilibrium relationship between gross energy use and output alone does not necessarily imply that there is no relation between the variables. Few analysts believe that capital, labor, and technical change play no significant role in determining output. If these variables are integrated, then there will be no cointegration between energy and output, no matter whether there is a relationship between the latter two variables. Also, decreasing energy intensity (due to increased energy efficiency), shifts in the composition of the energy input, and structural change in the economy mean that energy and output will drift apart. Similar comments apply to the bivariate energy-employment relationship. Further, using total energy use in the economy as a whole but measuring output as industrial output alone may compound the insensitivity of the test.

It would seem that if a multivariate approach helps in uncovering the Granger causality relations between energy and GDP, a multivariate approach should be used to investigate the cointegration relations among the variables. The author investigated the time series properties of GDP, quality weighted energy, labor, and capital series, estimating a dynamic cointegration model using the Johansen methodology. The cointegration analysis showed that energy is significant in explaining GDP. It also showed that there is cointegration in a relationship including GDP, capital, labor, and energy. Other analysts have found that energy, GDP, and energy prices cointegrate and that when all three variables are included there is mutual causation between energy and GDP. The inconclusive results of the earlier tests of Granger causality are probably due to the omission of necessary variables—either the quantities of other inputs (and quality adjustment of the energy input) or energy prices.

5. ENVIRONMENTAL IMPLICATIONS

5.1 Theory

The argument has been made here that there is a very strong link between energy use and both the levels of

economic activity and economic growth. What are the implications of this linkage for the quality of the environment? The focus here is now on immediate environmental impacts (issues of sustainability were discussed in Section 2).

Energy use has a variety of impacts. Energy extraction and processing always involve some forms of environmental disruption, including both geomorphological and ecological disruption as well as pollution. Energy use involves both pollution and other impacts, such as noise from transport, and land-use impacts, such as the construction of roads, etc. As all human activities require energy use; in fact, all human impacts on the environment can be seen as the consequences of energy use. Energy use is sometimes seen as a proxy for the environmental impact of human activity in general. Creating order in the economic system always implies creating disorder in nature, though this disorder could be in the sun or space rather than on Earth. The factors that reduce the total amount of energy needed to produce a dollar's worth of GDP, discussed in Section 3, therefore, also act to reduce the environmental impact of economic growth in exactly the same way as they reduce energy consumption. However, not all impacts of energy use are equally harmful to the environment and human health.

A shift from lower to higher quality energy sources not only reduces the total energy required to produce a unit of GDP, but also may reduce the environmental impact of the remaining energy use. An obvious example would be a shift from coal use to natural gas use. Natural gas is cleaner burning and produces less carbon dioxide per unit of energy derived. However, we need to be careful here. Nuclear-generated electricity is a higher quality fuel compared to coal, at least as measured by current prices, but its long-term environmental impacts are not necessarily lower. Incorporating the cost of currently unpriced environmental externalities into the prices of fuels would, though, raise the apparent quality of those fuels. This is not a contradiction, because a higher market price would mean that those fuels would only be used in more productive activities.

The environmental impact of energy use may also change over time due to technological innovation that reduces the emissions of various pollutants or other environmental impacts associated with each energy source. This is in addition to general energy-conserving technological changes that reduce the energy requirements of production, already discussed. Therefore, despite the strong connections between energy use and economic growth, there are several pathways through which the environmental impact of growth can be reduced. Again, however, if there are limits to substitution and technological change, then the potential reduction in the environmental intensity of economic production is eventually limited. Innovations that reduce one type of emission (for example, flue gas desulfurization) often produce a different type of waste that must be disposed of (in this case, gypsum that is possibly contaminated with heavy metals) as well as other disruptions required to implement the technology (in this example, limestone mining).

5.2 Empirical Evidence: The Environmental Kuznets Curve

In the 1970s, the debate on the relation between growth and the environment focused on the report, *The Limits to Growth*, by the Club of Rome. The common wisdom was that economic growth meant greater environmental impacts and the main way to environmental gains was reduced population and consumption. Economists and others argued that substitution and innovation could reduce environmental impacts (as was described in Section 2). But these were minority views. The mainstream view was that environment and economy were conflicting goals. By the late 1980s, however, with the emergence of the idea of sustainable development, the conventional wisdom shifted to one of "too poor to be green." Less developed countries lacked the resources for environmental protection and growth, and development was needed to provide for environmental protection. This idea was embodied in the empirical models that became known as environmental Kuznets curves (EKCs). The hypothesis states that there is an inverted U-shape relation between various indicators of environmental degradation and income per capita, with pollution or other forms of degradation rising in the early stages of economic development and falling in the later stages. The EKC is named for the economist Kuznets, who hypothesized that the relationship between a measure of inequality in the distribution of income and the level of income takes the form of an inverted U-shape curve. However, Kuznets had no part in developing the EKC concept.

The idea has become one of the "stylized facts" of environmental and resource economics. This is despite considerable criticism on both theoretical and empirical grounds. The EKC has been inter-

preted by many as indicating that no effort should be made to adopt environmental policies in developing countries, i.e., when those countries become rich, the current environmental problems will be addressed by policy changes adopted at that later time. As a corollary, it is implied that little in the way of environmental clean-up activity is being conducted in developing countries. These views are challenged by recent evidence that, in fact, pollution problems are being addressed and remedied in developing economies. In addition to the data and case studies provided by Susmita Dasgupta *et al.*, the author shows that for sulfur (widely believed to show the inverted U-shape relation between emission and income per capita), emissions in fact rise with increasing income at all levels of income, but that there are strong time effects reducing emissions in all countries across all income levels. In the author's opinion, this new evidence supersedes the debate about whether some pollutants show an inverted U-shaped curve and others—for example, carbon dioxide and "new toxics"—show a monotonic relationship. All pollutants show a monotonic relation with income, but over time pollution has been reduced at all income levels, *ceteris paribus*. Similarly, the debate about whether the downward sloping portion of the EKC is an illusion resulting from the movement of polluting industries to offshore locations is also now moot. This phenomenon might lower the income elasticity of pollution in developed economies relative to developing economies, but it does not seem sufficient to make it negative. The true form of the emissions–income relationship is a mix of two of the scenarios proposed by Dasgupta *et al.*, illustrated in Fig. 8. The overall shape is that of their "new toxics" EKC—a monotonic increase of emissions in income. But over time this curve shifts down. This is analogous to their "revised EKC" scenario, which is intended to indicate that over time the conventional EKC curve shifts down.

Although the environmental Kuznets curve is clearly not a "stylized fact" and is unlikely to be a useful model, this does not mean that it is not possible to reduce emissions of sulfur and other pollutants. The time effects from an EKC estimated in first differences and from an econometric emissions decomposition model both show that considerable time-related reductions in sulfur emissions have been achieved in countries at many different levels of income. Dasgupta *et al.* provide data and case studies that illustrate the progress already made in developing countries to reduce pollution. In addition, the income elasticity of emissions is likely to be less than 1—but not negative in wealthy countries, as suggested by the EKC hypothesis. In slower growing economies, emissions-reducing technological change can overcome the scale effect of rising income per capita on emissions. As a result, substantial reductions in sulfur emissions per capita have been observed in many Organization for Economic Cooperation and Development (OECD) countries in the past few decades. In faster growing middle income economies, the effects of rising income overwhelm the contribution of technological in reducing emissions.

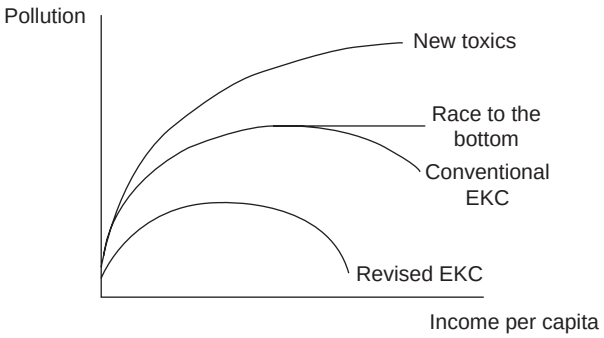

FIGURE 8 Environmental Kuznets curve (EKC): different scenarios. From Dasgupta *et al.* (2002).

This picture relates very closely to the theoretical model described in the previous Section 5.1. Overall, there is a strong link between rising energy use, economic growth, and pollution. However, the linkages between these three can be mitigated by a number of factors, including shifting to higher quality fuels and technological change aimed both at general increases in economic productivity and, specifically, at reducing pollution. However, given the skepticism regarding the potential for unlimited substitution or technological progress, there may be limits to the extent that these linkages can continue to be loosened in the future.

Glossary

comparative advantage A country has a comparative advantage in a particular good if the ratio of costs to produce the good, relative to the cost to produce another good, is lower than the same cost ratio in other countries. Comparative advantage is the basis for trade: Countries gain if they export the good they produce relatively most efficient.

economic growth Steady increases in gross domestic product.

energy intensity Energy supply divided by gross domestic product.

externality A situation in which market transactions affect persons who are not involved in the transaction directly (i.e., not through market prices).

gross domestic product (GDP) The sum of all output produced by economic activity within a country. Gross national product includes net income from abroad (e.g., rent and profits).

general equilibrium A situation in which all markets in the economy are in equilibrium.

market equilibrium A situation characterized by a certain volume of trade and a price of a certain good such that no market party wants to change behavior: No seller of the good wants to increase or decrease supply, and no consumer wants to reduce or increase demand.

Organization for Economic Cooperation and Development (OECD) The North American and Western European countries, Greece, Turkey, and Mexico.

real price Relative price of a commodity in terms of another basket of commodities. GDP is often measured in real prices (also labeled "at constant prices") to eliminate the effects of inflation (where inflation is the upward trend common in all prices, leading to a downward trend in the purchasing power of money).

total factor productivity (also multifactor productivity) Outputs per unit of input. Changes in total factor productivity measure technological change by accounting for how much of the increase in production is due to other factors besides changes in inputs.

Economic growth is the steady increase in output produced by economic activity within a country (gross domestic product). A central question is whether economic growth is compatible with a nondeteriorating environment and whether the environmental consequences of economic growth have a major impact on welfare levels derived from growing output of marketed goods. International trade has grown even faster than national income. It has been questioned whether increased trade has been bad for the environment and whether it has caused rich countries to relocate their polluting industries to developing countries. The following is another important question: How large are the costs associated with environmental regulation in terms of competitiveness, productivity, and employment? This article deals with these questions by reviewing empirical evidence and economic theory on resource use and economic growth.

1. INTERACTIONS BETWEEN THE ECONOMY AND THE ENVIRONMENT

1.1 Economic Growth and Resource Use

Statistics on national production levels and indicators of environmental pressure have been collected during

 © 2004 Elsevier Inc. All rights reserved.

the past few decades (and reconstructed for the more distant past) to document the link between economic growth and the environment. The theory of economic growth and economic theories of natural resources provide explanations and interpretations of the trends as well as methods to assess future developments. The basic approach in most statistical and theoretical analyses is the decomposition of aggregate production of a nation into, on the one hand, the current state of technology and, on the other hand, the inputs into the national production process. The main inputs are labor (hours worked), capital (produced means of production that can be used over a certain time period), and natural resources.

Natural resources comprise energy inputs and material inputs. An important distinction is between renewable and nonrenewable resources. Renewable resources are biotic populations, flora, and fauna, which have the potential to grow by means of natural reproduction. For example, the theory of renewable resources studies fishery and forestry. Nonrenewable resources are minerals of which physical supplies do not grow on a relevant timescale for humans. Examples are metals (e.g., aluminum, copper, and gold) and fossil fuels (e.g., oil, coal, and natural gas).

The basic characteristic of natural resources is that they cannot be produced, but they serve as an essential input in production. A higher rate of resource usage implies faster depletion of the available stock of the resource. In this sense, resource inputs differ in a fundamental way from other inputs used in production, such as labor and capital: Labor is not used up and man-made capital can be accumulated. Another important difference is that the available resource stock may directly affect welfare as an amenity (nonuse value). Resource economics studies the trade-off between extraction of the resource for current consumption and conservation for later dates. Environmental quality can also be considered as an input in the aggregate production process. Pollution is an inevitable by-product of production. Pollution can be seen as a degradation of environmental resources, such as clean air and soil.

1.2 Externalities, Markets, and Incentives

Economic growth is the result of growth in inputs and increases in the productivity of the inputs—that is, changes in technology. Economics further explains why inputs and technology change over time. Inputs such as materials, labor, and capital are traded in factor markets. Prices match demand and supply and provide consumers and suppliers with information and incentives. Population growth, for example, increases the potential working force and the supply of labor inputs in the economy increases. This fuels growth if wages adjust so that the growing working force is employed in production. With more labor in production, capital can be operated at a higher productivity level. This increase in the return to capital fuels investment in new capital so that growth in capital inputs also fuels output growth. Similarly, the demand for materials and energy increases. If these are available in limited supply, their prices increase, which provides incentives to develop technologies that save on their use. Thus, although growing scarcity of inputs may impose a drag on growth, it may also induce technological change that fuels economic growth.

Markets provide a powerful coordination mechanism. In sectors of the economy in which the demand for resources such as materials or labor is high, prices increase and this attracts resources to these sectors, away from other sectors. Thus, resources tend to be allocated to those sectors in which they are in highest demand. The high demand reflects a high willingness to pay for the resources and implies that their value is considered to be high. This explains why the market mechanism in principle can enhance efficiency and welfare in the economy.

The market can only coordinate social preferences (demand for certain goods or services) and (technical) possibilities and resource endowments in a welfare-maximizing way if prices reflect these preferences and possibilities. This requires (i) that the owners of production factors (the inputs such as labor, capital, and materials) can charge a price that reflects their production cost and (ii) that consumers can express their willingness to pay. For many environmental goods, these preconditions are not met. In the absence of environmental regulation, there are no markets for clean air or climate. Pollution entails a cost to society but not a cost to the polluting producers. Waste can be disposed freely but imposes a cost on society. When economic activity (i.e., market transactions) imposes costs or benefits on persons who are not involved in the transaction directly, externalities are said to be present. Externalities cause markets to function imperfectly and welfare to be impaired. This is why environmental policies may improve welfare. These policies have to correct environmental externalities, for example, by making firms pay for the pollution costs they impose on society.

We can now more precisely define the cost of pollution for society. From an economic perspective,

pollution (and, similarly, environmental degradation or resource depletion) is costly to the degree that it causes externalities. Because the value of environmental quality is not reflected in the prices in the economy, the economic decisions that are based on these prices give rise to more pollution than society finds optimal.

The ideal (optimal) environmental regulation imposes measures to eliminate all external costs of pollution; that is, it makes all parties in society internalize all social costs of pollution. In such a situation, welfare is maximal, but pollution is not necessarily (and very unlikely) at the technical minimum. Although depletion of natural resources and polluting consequences of production are by definition bad for the environment, they are not necessarily bad for welfare. They provide the inputs for production of valuable things. As long as the benefits from increases in production outweigh the costs of environmental degradation, economic growth enhances welfare.

The following sections examine how economic growth, international trade, and environmental regulation affect the environment and welfare. To examine the impact on aggregate welfare, changes in the physical state of the environment have to be made comparable to changes in economic production, which requires a valuation method to place values on environmental improvements. Since this is a difficult and subjective task, I also discuss the physical effects, by which I mean the impact on pollution, pollution concentration, and resource stocks measured in physical terms. This is the conservationist perspective, to be contrasted with the economic approach that deals with welfare effects.

2. TRENDS IN ECONOMIC GROWTH AND RESOURCE USE

2.1 Trends in Economic Growth

From 1820 to 1995, total world production [gross domestic product (GDP)] grew on average at an annual rate of 2.2%, which amounts to a more than 40-fold increase over a mere 175 years. This rate of change is unprecedented: In the 1800 years before this period, world GDP increased less than 7-fold. Per capita economic growth has also been enormous during the past century. With the current world population of approximately 5.5 billion, five times as large as in 1820, per capita GDP is now almost eight times higher than it was 175 years ago.

Differences among countries are major. In 1988, output per worker in the United States was more than 30 times higher than that in sub-Sahara Africa. Developing countries often have per capita income levels that are less than 10% of U.S. levels (e.g., in 1988, India, 9%; China, 6%). Per capita income in Western Europe is on average 30% lower than that in North America, but income gaps are smaller than they were four decades ago. Typically, among the richer countries, there is convergence in income levels, whereas the gap between the poorest and richest countries grows.

2.2 Trends in Energy and Materials

Economic growth directly translates into growing demand for energy resources and materials since they are necessary inputs in production. However, in the process of growth, some energy resources or materials may be substituted for others so that not all of them are used at an increasing rate. Technological change has allowed many sectors of the economy or even entire economies to produce at a lower overall energy intensity.

Primary energy supply in the Organization for Economic Cooperation and Development (OECD) countries was approximately 50% higher in 1999 than in 1971, but GDP increased faster. Indeed, from 1960 to 2000, energy use was decoupled from economic growth, at least in the European Union, Japan, and the United States (at annual rates of 0.4, 0.2, and 1.4%, respectively). The oil shortages in the 1970s induced energy conservation programs. Also, the growing relative importance of services relative to manufacturing caused energy efficiency to increase. In recent years, growth in energy use has accelerated due to increased transport and electricity use in service sectors. Trends in materials use vary considerably for different materials. Iron and steel have grown slower than GDP, paper use has grown in line with GDP, but plastics and aluminum have grown faster than GDP.

The concern is that growing energy and materials use results in scarcity of resources and imposes a threat to future growth. Stocks of virgin ores decline. The stock of materials embedded in products grows, leaving less available for recycling. If growth fuels demand for resources and supply becomes smaller, prices can be expected to rise. However, most price indicators do not reflect growing scarcity. The prices of most commodities have declined since 1960. Here, prices are measured in real terms (i.e., relative to the prices of a representative basket of produced goods). Most economists have concluded that resource scarcity will not limit growth, at least not during

the coming decades and not if we consider scarcity of those resources that are traded in well-developed global markets, such as most minerals and energy resources.

Declining prices may reflect technological progress, which allows mining at lower cost or exploration of new resource deposits. According to most economic theories, this is likely to be a temporary phenomenon, and in the long term prices of nonrenewable resources are expected to increase. This does not necessarily imply that future growth will no longer be fuelled by lower costs of energy and materials, since technological change, as well as exploration and development of new economically useful resources, may overcome scarcity limits.

The growing use of certain energy resources and materials has severe impacts on the natural environment. In general, economists agree that free market forces do not serve very well society's demand for environmental amenities or conservation of natural resources for which markets are illegal, incomplete, or do not exist (e.g., water and air quality, rare species, biodiversity, and ecosystem services). Emissions of CO_2 from fossil fuel combustion pose major threats to air pollution and climate. Despite the decoupling of energy use from economic growth in the developed economies and despite the decline in the carbon content per unit of energy used, total CO_2 emissions have risen in almost all countries in the past few decades. In large developing countries such as India, China, and Brazil, absolute CO_2 emissions have increased very rapidly. In contrast to the OECD experience, their CO_2 emissions per unit of GDP have risen at fast rates (up to 2.6% percent per year in India from 1971 to 1998).

Other major threats to the environment come from the use of hazardous industrial waste, emissions, and toxic chemicals that are used in the production process and discarded as some form of industrial waste. As a result of environmental regulation, emissions from production activities (industry) have actually declined. However, waste and emissions from consumption activities are growing. Municipal waste and hazardous waste have increased in recent decades in developed countries at a rate faster than those of the population and GDP.

2.3 Cross-Country Differences in Resource Intensities

Differences in energy used per unit of GDP are large. In North America, per capita energy use is more than twice that in Japan, France, or the United Kingdom and approximately 1.5 times that in Germany and Australia, mainly due to differences in per capita income and in energy used per unit of output. Differences in the structure of production (in terms of the relative importance of industrial production sectors) are hardly responsible for the differences in per capita energy use.

3. EXPLANING THE LINK BETWEEN GROWTH AND RESOURCE USE

3.1 The Environment–Income Relationship

Economists have tried to identify underlying mechanisms in resource use and growth trends. A central question is how environmental pressure changes with economic growth. One hypothesis is the so-called environmental Kuznets curve (EKC) hypothesis, according to which environmental pressure or resource use first increases with GDP but, after a certain threshold income level, declines with per capita GDP. The hypothesis has been tested for several resources, energy sources, and emissions. The evidence is mixed: The EKC shows up, but only for some pollutants and not in all countries.

In the typical approach, pollution in the major cities (or other measurement stations) of a set of countries is compared and related to the level of income in these cities. If pollution rises with the level of income but also declines with the square of the level of income, the EKC holds.

The EKC is found for water pollutants and for air pollutants, such as SO_2, suspended particulate matter (dark matter as well as heavy particles), NO_x, and CO. These pollutants cause health problems close to the place where they are emitted (i.e., these are local pollutants), whereas their impact occurs simultaneous with emissions (i.e., these are short-lived or flow pollutants). The EKC is generally rejected for municipal waste, CO_2, and aggregate energy consumption: These variables monotonically increase with the level of income in a cross section of countries. Since it is the accumulation of municipal waste in landfills, rather than the annual flow, that imposes environmental pressure, it is a stock pollutant. CO_2 is partly a local flow pollutant, but its main impact is through concentration of CO_2 in the atmosphere on the global climate (i.e., it is a global pollutant as well as a stock pollutant). Other evidence on the main global stock pollutants and environmental indicators is only

indirect. For example, wilderness land is monotonically declining with the level of income, which is a crude measure of the negative relation between income and biodiversity.

3.2 The Role of Environmental Regulation

The common pattern is that local pollutants and flow pollutants are more likely to first rise and then fall with income than global pollutants or stock pollutants. The main driving force behind the lower pollution levels in richer countries is policies to reduce pollution. In richer countries, citizens are willing to pay more for improvements in environmental quality and succeed in convincing their local and national governments to impose the necessary regulation to reduce urgent pollution problems. Since reducing local flow pollutants has the most visible effects for the constituencies of the local authorities, regulation is mainly directed at these rather than global or stock pollutants. The latter affect other regions or future generations, respectively, but not so much the authorities' electorate. In this interpretation, environmental improvement only occurs when environmental regulation becomes more stringent in richer economies. That is, environmental problems are not solved automatically by economic growth. Growth will be accompanied by reductions in pollution only if a number of conditions are fulfilled.

First, when becoming richer, people must care more about environmental quality. There is no strong evidence in favor of this claim. For example, in developing countries, environmental quality and availability of natural resources are often much more crucial for households than in developed countries. However, within developed countries, willingness to pay for improvements in health increases with income. As a result, richer citizens may be more in favor of costly measures to reduce pollutants with direct health impacts.

Second, only if the costs of reducing pollution do not increase too much with national income will citizens vote for pollution reduction. Technological change is important in this respect. On the one hand, cleaner production processes have been developed, mitigating the cost of pollution reduction. On the other hand, some new production processes and the production of new goods require more energy and resource use. For example, the rapid spread of computers and the growing demand for transport make the economies heavily dependent on electricity and fossil fuels so that reductions in energy use have a major cost in terms of loss of production. This may explain why electricity and fossil fuel use do not decline with income, despite concern about the environment.

Third, actual environmental policies need to reflect societies' preferences for environmental quality. Indeed, in countries with a relatively high degree of political and civil freedom, environmental problems decline more rapidly with income. In countries with high indicators of corruption, natural resource depletion is faster.

Pollutants differ in terms of their (health) impact, the degree to which they are local and short-lived, and the cost of reduction. As a result, when comparing emissions of different pollutants in a particular country, some may increase and others may decrease with income. That is, the Kuznets curves, if they exist at all for the pollutants at hand, overlap. It implies that although environmental quality improves due to the reduction in one pollutant, aggregate measures of environmental quality may deteriorate because this pollutant is replaced by other pollutants. This may be a problem particularly since stock pollutants replace short-lived pollutants, which amounts to a shift of the environmental burden to future generations. Similarly, Kuznets curves of different countries overlap. While rich countries reduce emissions of a certain pollutant, poor countries may simultaneously increase emissions in their growth process. Thus, pollution is shifted from rich to poor countries. As a result, the existence of an EKC for a certain pollutant does not guarantee that worldwide environmental quality improves over time. This phenomenon is particularly important because the poor countries, which tend to increase emissions with production, account for a much larger share of the world economy than rich ones and some of them are growing at above-average rates (notably China).

4. INTERNATIONAL TRADE AND THE ENVIRONMENT

4.1 The Pollution Haven Hypothesis

The evidence on the EKC indicates that national environmental policies differ between high-income and low-income countries, and that as a result of income growth pollution in the Northern hemisphere may be reduced over time at the cost of increasing pollution in the Southern hemisphere. There have

been concerns that this process is reinforced by international trade of goods and by foreign direct investment between North and South. More stringent environmental policies in the North force pollution-intensive industries located in the North to raise their prices relative to the prices charged by firms in the South. Consumers in the North may then profitably import more goods from the South and firms in the North may profitable relocate their plants to the South. This claim on the effects of differences in stringency of environmental regulation is called the pollution haven hypothesis.

Empirical evidence for the pollution haven hypothesis is not very strong. The hypothesis has been tested in various (mainly indirect) ways. Typically, in a first step polluting industries are identified based on their emissions per unit (dollar) of output or pollution control costs as a fraction of value added. At the top of these rankings are industries such as iron and steel, nonferrous metals, mining, pulp and paper, industrial chemicals, petroleum refineries, rubber, and leather products. In a second step, the performance of these sectors in different countries is related to the country's environmental stringency, controlling as much as possible for other country differences. Stringency is either measured as an index based on law and regulation or a measure of pollution control expenditures.

Within the United States, polluting industries tend to export smaller volumes and build fewer new plants, and there is less investment in states with more stringent environmental regulation than in states with more lenient environmental regulation. Among different countries, the effects of differences in environmental regulations are more difficult to trace. Overall, industrial countries have reduced their share in world trade of goods from polluting industries relative to developing countries during the past few decades. However, there is no evidence that this trend is mainly due to differences in environmental regulation or due to international trade. The pattern of growth in these countries may be caused by a shift to pollution-intensive industries (as a movement along the upward sloping part of the EKC). Moreover, industrial countries remain the largest exporters in the most polluting industries. Hence, we must reject the claim that internationally most pollution is created in countries with lax environmental standards. The main explanation for this finding is that other factors besides environmental regulation are much more decisive in determining production cost or location advantages. The share of compliance costs for environmental regulation is small relative to the cost savings that can be gained from the availability of skilled workers able to operate advanced technologies, access to large consumer markets, and political stability. Polluting industries sometimes have high transport costs, so proximity to consumer markets is important. Polluting industries are also typically capital-intensive and operated by skilled workers. These factors make developed countries a more attractive location for polluting industries. Hence, differences between North and South in availability (i.e., endowments) of capital and skilled workers offset the differences in environmental regulation.

4.2 Is Trade Beneficial?

For given differences in endowments of capital and labor, relatively lax environmental regulation in some countries, particularly poorer ones, is likely to shift some of the dirty industries to the South. The question is whether this is always undesirable. According to a standard economic argument, there may be mutual benefits from relocation of pollution-intensive industries between different countries. For example, countries with low income but enough space to keep pollution away from their populations may be willing to accept pollution if this can greatly boost income. High-income countries with high population density care less about increases in income if they are obtained at the cost of pollution problems. In this case, both types of countries benefit if pollution is relocated from high-income to low-income countries.

Although lax environmental policies in the South seem to burden citizens in the South with pollution havens, workers in the North may be concerned about the stringent environmental policies in their countries. The North loses jobs in pollution-intensive industries and export performance in these sectors declines when these industries move to the South. However, at the same time, trade with the South allows the North to improve performance in clean industries so that again trade creates mutual benefits for North and South (although these benefits may be obtained only after some time-consuming, and therefore costly, adjustments in the economy). Indeed, also if the North did not engage in trade with the South, environmental regulation would result in job losses in polluting industries and shifts to clean industries, but it would forego the benefits from importing and consuming goods that can be produced at lower costs in other countries and the opportunity to export goods that can be produced at a comparative advantage in the North.

In general, differences in environmental regulation may reflect differences in social costs to deal with pollution and form a true basis for mutually beneficial trade. However, if national environmental regulation ignores the average citizen's preference for pollution and fails to reflect the social costs of pollution, trade is not always mutually beneficial. This is why large multinational corporations have been criticized when they negotiate concessions with elite governments and exploit their monopoly power. However, evidence on unbalanced benefits and costs from the activities of such firms is not available.

Other situations in which trade does not necessarily lead to mutual gains occur when pollution is transboundary—that is, when pollution from one country harms citizens of other countries. Since national governments are not likely to take into account these pollution spillover effects, they tend to set pollution regulation too lax. For all countries to gain from trade, environmental regulation in each country should reflect the cost of pollution not just to its own citizens but also to the world community as a whole. Thus, if SO_2 emissions in the United Kingdom hardly affect British citizens but cause forests in Scandinavia to die, the United Kingdom may be tempted to impose lax regulation of SO_2 emissions, thus creating a comparative advantage in SO_2-intensive goods and boosting export of these goods. This trade would harm Scandinavia.

A final situation of harmful international trade may arise when countries have strategic reasons to set overly lax or overly stringent environmental policies. Some environmentalists fear that governments set environmental policies overly lax. Governments may have an incentive to accept environmental standards that are lower than is socially desirable in order to attract foreign direct investment or give domestic industry a cost advantage over foreign firms, thus enabling them to make higher profits (which has been called ecological dumping). However, if many governments try to protect their polluting industries in this way, they may all fail in a "race to the bottom": The lax standard in one country is offset by the response in the other country to also lower environmental regulation. Only if firms' location choices and cost levels are sufficiently responsive to differences in environmental standards can national governments use environmental policies as a strategic instrument against other countries. In the past, the lack of strong evidence for pollution havens has been interpreted as evidence against significant firm responses to environmental stringency and the fear of strategic use of environmental policy seemed ungrounded. Recently, however, evidence of firm responses has become stronger so that strategic environmental policy may still be reason for concern.

4.3 Is Trade Good for the Environment?

Although there is no hard evidence on the magnitude of the net benefits (or costs) of trade in polluting goods, and there is no strong evidence regarding major effects of environmental regulation on trade and foreign direct investment, there are detailed analyses of the effects that an increase in world trade has on pollution in different countries. Trade has significant effects on pollution, but often more trade implies a cleaner environment.

World trade has increased enormously during the past few decades. Between 1973 and 1998, world merchandise exports and global foreign direct investment increased at annual rates of 9 and 14%, respectively. This expansion of trade is not responsible for increases in world pollution. The share of dirty products in world trade has declined. Comparing open economies (countries with high shares of exports and imports in GDP) to closed economies (countries with little foreign trade), statistical analysis shows that open economies have less pollution per unit of GDP (other things being equal). Open economies tend to adopt clean technologies more rapidly.

Trade often has a beneficial impact on the environment because of the interaction between comparative advantages and adjustment of environmental regulation. High-income countries tend to have higher environmental standards. However, high-income countries can also produce pollution-intensive (which are often skilled-labor or capital-intensive) products at a relatively low cost due to access to advanced technology and large endowments of skilled labor and capital. This implies that high-income countries have a comparative advantage in producing pollution-intensive goods. When they liberalize trade, they tend to export more of these goods. Thus, world trade becomes greener since trade shifts production of polluting goods to countries in which environmental standards are higher. Moreover, international trade increases income, which leads to a policy response since richer countries tend to impose more stringent environmental regulation. Thus, countries with lower incomes tighten their environmental regulation. Multinational firms adopt environmental practices overseas that are (partly) determined by environmental regulations in their home countries under pressure of consumer actions and for fear of loss of reputation.

Although evidence on an aggregate level suggests that international trade is benign to the environment, in certain areas trade has a serious adverse impact on the environment. Certain types of pollution or natural resource use remain unregulated, and it is in these areas that there are concerns. One example is transport. The growth in world trade has been accompanied by increases in transport movements, which are heavily energy intensive. The pollution costs (externalities) associated with transport are not fully reflected in regulation so that welfare losses and excessive pollution may stem from the increase in transport. Since the costs of transport cross borders, appropriate policies require international coordination, which is often difficult to establish. Second, transport involves the problem of invasive species: The accidental or intentional introduction of harmful nonindigenous species of plants and animals can damage environmental resources. The cost of screening and quarantines is often prohibitive. Third, the concentration of agriculture in certain locations without appropriate regulation puts stress on biological diversity with potential loss of soil quality in larger regions in the long term. It destroys the habitat of species and may lead to extinction of species and loss of biodiversity.

5. ENVIRONMENTAL REGULATION AND PRODUCTIVITY

5.1 The Cost of Environmental Regulation

Environmental regulation aims at improving environmental quality but may come at the cost of jobs, productivity, or other undesirable economic effects. To justify environmental regulation on economic grounds, it should be shown in a cost–benefit analysis whether the benefits are large enough to incur the costs. In some cases, the costs are found to be small or even negative; that is, there are benefits to be reaped not only in terms of environmental improvement but also in other fields. Estimates of the total costs of environmental regulation vary enormously between studies.

The traditional argument is that environmental regulation imposes costs on firms as well as governments and consumers. Governments incur costs of administration of the regulation. Firms are burdened with costs because they have to install and operate pollution control equipment and intensify monitoring, and they face higher administrative burdens. Second, under certain types of regulation, they may face pollution charges, expenditures on buying pollution permits or quotas, or fines insofar as they emit more than the quotas that are allocated to them. Third, depending on the degree that they pass on costs through higher prices, demand for their output will decline and they will suffer from lower profits.

The total burden on polluting firms depends heavily on firm characteristics and the employed technology. Estimates of direct costs of complying with environmental regulation vary from less than 1% of GDP in 1972 to more than 2.5% at the end of the 1990s in the United States and slightly lower in Western Europe. Petroleum and coal industries faced pollution control capital expenditures up to one-fourth of total capital expenditures, whereas for rubber and plastics production industries the number was only 2%.

More crucial from an economic perspective is that the burden of regulation depends on the design of the regulation, particularly the flexibility firms are given to choose their own way to comply with the regulation. At the one extreme, the regulator prescribes the technology the firms have to use or the pollution control actions they have to take, leaving little flexibility for the firms. At the other extreme, the regulator allows firms a specified emissions allowance and leaves it to the firms' discretion to determine by what means to reduce emissions as well as whether to trade pollution allowances with other firms (system of marketable pollution permits). Compared to the former type of regulation (the command-and-control approach), the latter type (the market-based approach) minimizes the costs of regulation. First, it allows firms to choose the cheapest way to reduce emissions. Profit-maximizing firms will have an incentive to do so. Second, it gives incentives to firms that can reduce emissions at lowest cost to do most of the reduction and sell their pollution allowances to other firms. Thus, total pollution control costs are minimized. Alternative market-based instruments are charges (taxes) proportional to emissions.

Market-based instruments have been applied less frequently than command-and-control instruments, but their importance has increased. Marketable permits have been successful with respect to reductions of lead content in fuel, air pollutants, and SO_2 emissions in particular. Estimates of the cost savings potential of changing from command-and-control to market-based instruments range from 50 to 90%.

Sometimes, regulated firms have zero cost options to comply with more stringent environmental

regulation, or even make profits. Case studies have documented situations in which the reductions of materials or toxic chemical use for environmental reasons saved enough of the firm's expenditures on inputs to easily repay the investment cost of adjusting the production process. Even without environmental regulation, the investment would have been justified since it allowed for a real efficiency improvement.

It is unlikely that these situations arise systematically since managers of firms are supposed to search for opportunities to improve efficiency and exploit them even without intervention by environmental regulators. Thus, when firms maximize profits and regulation constrains their choice of technologies, the smaller choice menu must lead to fewer opportunities to operate at certain profit levels and regulation is costly. This conclusion is unlikely to change if we acknowledge the limits to profit maximization because of informational and managerial problems. No doubt, inefficiencies in firms' production processes and organization remain pervasive since managers' span of control is insufficient to assess and eliminate all of them. Because of the small share of environment-related costs, managers may systematically ignore environment-related inefficiencies. Then, environmental regulation may make managers more focused on cost savings potentials related to pollutants and materials use. However, it may come at a cost by turning their attention from other inefficiencies so that on balance it is unlikely that environmental regulation can systematically (i.e., economywide) improve overall efficiency.

Opportunities for cost savings have been explored by engineering or "bottom-up" studies. These studies start from an emissions reduction target for the economy as a whole and then identify all the technological measures by which this target can be achieved. For each of them, the researcher estimates the cost incurred by firms and adds these up to an economywide total. Often, the numbers are surprisingly low, suggesting that technological opportunities abound to improve the environment at low cost. The problem with these studies is that many hidden costs are ignored. Adoption of new technologies will not only change firms' emissions but also change product characteristics and quality, employment structure, and input demand. It requires adjustments beyond the simple installation of pollution control equipment. The entire production and marketing process may be affected.

The alternative method for assessing pollution control costs, the "top-down" approach, involves a statistical (and econometric) analysis of the relationship between production costs and environmental regulation and between emissions and regulation across industries. The statistical results are used to make a projection of how costs are affected by a hypothetical change in emissions, which corresponds to the policy target. This requires building a stylized model of the entire economy, which involves the incorporation of many assumptions and additional statistical results regarding how markets work and react to policy changes. Top-down studies suggest much higher costs of environmental policy than do bottom-up studies. Hence, adjustment costs are substantial. Drawbacks of this method are that it necessarily relies on historical data on firms' reactions to regulation and it cannot incorporate the details of available new technologies to meet the environmental target. The results are also quite sensitive to the modeling structure and assumptions made.

Econometric techniques have also been used to estimate the effects of environmental regulation on employment. One would expect to find a negative correlation between stringency of environmental regulation and employment changes in pollution-intensive industries. Most studies find minor effects when relating environmental regulation across U.S. states to employment. Often, the correlation between employment in dirty industries and environmental regulation is positive. The main explanation is that we should not expect a causal relation from environmental stringency to employment but rather view both employment and regulation as being determined simultaneously by economic and political factors. States with a strong economy, industries with high productivity, and high income can afford—and may actually prefer—more stringent regulations than poorer states; at the same time, the former may experience strong employment growth as a result of the favorable economic conditions.

5.2 General Equilibrium Effects

To assess the overall costs of environmental regulation, one must measure not only how it directly imposes costs on a regulator and regulated firms but also how it affects other areas of the government's budget and how it affects customers and suppliers of regulated firms. Almost all activities in the economy are linked to each other: A consumer buys goods from firms and receives his or her income from (other) firms and pays taxes to governments, which subsidize firms and provide infrastructural goods for firms. Hence, regulating certain firms may affect the entire economy through these linkages. Such indirect

effects are labeled general equilibrium effects because they reflect the effects after all markets in the economy have reacted and adjusted such that a new equilibrium in the economy as a whole results.

The linkages between economic activities may sometimes mitigate the costs of environmental regulation and sometimes reinforce them. When regulated firms reduce their polluting activities, they buy less from their suppliers, which also experience a loss in sales. However, other firms may benefit. Regulated firms may need to buy specialized equipment to control pollution, so firms selling this equipment benefit. When regulated firms pass on their higher costs through higher prices, their customers switch to other producers. Hence, firms likely to benefit from regulation are those that supply goods that customers view as a suitable substitute for the regulated firms' goods.

The overall cost of environmental regulation is the sum of all gains and losses. The indirect gains are not likely to fully offset the direct costs for one obvious reason: Regulation aims at reducing pollution, and this requires reductions in polluting inputs. If the economy as a whole has to cut back on inputs, total output is likely to decline, too. This effect may be reinforced over time through effects on investment. Investment in new capital goods fuels growth in the economy. The return to investment is likely to be smaller if new capital goods have to be run with less energy or polluting inputs so that the incentive to invest is crowded out through more stringent environmental regulation. Thus, growth may be impaired by environmental regulation.

The economywide impact of environmental regulations can only be estimated, rather than directly measured, since we cannot observe how the economy would have evolved in the absence of the regulation. Estimates therefore heavily depend on the model that is used for the estimation. Based on standard macroeconomic or growth-theoretic models, estimates of the total cost are on the same order of magnitude as the direct pollution control costs, approximately 2% of GDP. Some researchers have noted that the surge in regulatory costs coincides with the growth slowdown in the 1970s. However, all calculations show that only a very small portion of the slowdown can be attributed to environmental regulation.

5.3 In Search of "Double Dividends"

Despite the fact that environmental regulation amounts to restricting inputs in the economy and is therefore likely to reduce output, counterarguments have been advanced that environmental regulation may bring about large gains. The key argument is that environmental policy shifts economic activity away from polluting sectors to other sectors in which the contribution of economic activity to welfare is larger. Hence, although regulation forces the economy to reduce polluting inputs, it may increase total output by improving the average efficiency at which inputs are employed.

5.3.1 Elimination of Inefficient Subsidy and Tax Programs

Efficiency gains can arise from environmental regulation if efficiency differs between sectors, particularly if efficiency in polluting sectors is lower than in clean sectors. Normally, differences in efficiency are eliminated by market forces, but (nonenvironmental) regulation may distort these market forces and create sectors in which resources are inefficiently used. Important examples are agriculture and energy. In the OECD, agricultural output is heavily subsidized so that high-cost/low-productivity agricultural activities in these countries remain viable. This support creates inefficiencies, and the tax revenue could be better spent from an efficiency standpoint. The widespread use of energy subsidies to firms also creates support for low-productivity, energy-intensive production. If these subsidies are abolished and replaced by environmental regulation that reflects, for example, the adverse impacts of pesticide on soil and water quality or those of energy use on world climate, efficiency gains can be large by shifting economic activity away from inefficient farming and energy-intensive industries.

5.3.2 Environmental Tax Reform

Gains from environmental regulations have also been claimed to be feasible when they can be combined with reductions in certain taxes. On the one hand, governments have relied on taxes on labor and capital to fund their budgets. These taxes may reduce the incentive to participate in the labor market or to invest in capital so that the taxes distort markets and create inefficiently low levels of employment and investment. On the other hand, environmental taxes (charges on emissions and auctioning off of pollution permits) not only give incentive to address environmental problems but also raise revenue.

Indeed, the first important insight from the theory of public finance theory is that it is better to "recycle" the revenues from environmental taxes through reductions in distortionary taxes than to use them

to fund the general government budget. However, the second insight is that replacing distortionary taxes on labor and capital by revenue-raising environmental taxes will reduce the efficiency of the tax system and increase the burden of taxation. That is, the improvement in the environment (a first dividend) is not likely to be offset by a cheaper way for the government to raise taxes (which would give a second, nonenvironmental, dividend). The reason is that a change from taxing labor and capital to taxing pollution narrows the base on which the taxes can be levied. Capital and labor income each constitute a much larger fraction of total income than the share of pollution in total cost. As noted previously, environmental taxation reduces inputs in production and forces firms to spend more on pollution control. This reduces output and income in the economy, the tax base becomes smaller, and the government raises less tax revenue from nonenvironmental taxes. The revenues from environmental taxes are insufficient to make up for the loss of revenues from nonenvironmental taxes.

In practice, the replacement of nonenvironmental taxes by revenue-raising environmental taxes may yield a double dividend if the existing tax system is highly inefficient in other, nonenvironmental dimensions (e.g., if capital is excessively taxed relative to labor). In this case, the tax system can be improved even without the introduction of environmental taxes, but vested interests or distributional concerns may prevent these tax reforms. Results from economic simulation models suggest that gains from the combination of environmental taxation and tax reform may yield substantial benefits in practice but not for all groups in society. The major challenge is to find ways to compensate losers from tax reform without providing the wrong incentives. For example, workers and capital owners in polluting industry are likely to be negatively affected by environmental tax reform, but compensating them for losses should not reduce their incentive to invest funds and to find alternative employment outside the polluting industry.

5.3.3 Environmental Quality as a Source of Productivity

Environmental regulation has short-term costs but long-term gains. These gains are primarily in terms of a cleaner environment; they take time to materialize since the recovery of environmental quality is time-consuming. However, as a feedback effect, a cleaner environment may improve productivity in the economy, which may offset the economic costs. The most obvious example is the effect on productivity in sectors that heavily rely on environmental resources. Policies to improve water and air quality of certain regions may boost the attractiveness of these regions for tourism or residential development. Hence, profits and productivity of tourism and construction may increase. Policies aimed at marine resources may also boost fish populations, thus improving productivity of the fishery. Forest management may give rise to both environmental benefits and improved yields for forestry.

In general, productivity of sectors or the economy as a whole is measured by multifactor productivity, which is a measure of the amount of outputs per unit of inputs. The factor productivity of conventional inputs, such as labor and capital, may increase if environmental quality improves. Capital equipment and residential buildings may depreciate more slowly if there is less air pollution. The productivity of labor may benefit from health improvements that are induced by better environmental quality. Less working days are lost if health improves, which increases output per unit of input. Health care costs decrease, alleviating private and government budgets. Substantial costs can be avoided if climate change, such as an increase in sea level (which directly affects agriculture, urban areas in coastal regions, and dike maintenance costs) and the loss of harvest in agriculture due to draughts or changes in precipitation, is mitigated.

5.4 Confronting Costs and Benefits

Most empirical research suggests that improvements in environmental quality require costly regulation, despite the various general equilibrium effects on efficiency and productivity that may mitigate the direct costs of regulation. The focus on costs of environmental regulation may distract attention from its benefits: These costs are incurred to achieve environmental benefits. It is worthwhile to incur the costs if the benefits outweigh the costs in a social cost–benefit analysis.

The social benefits from environmental improvements are often major, but they are less visible than the costs of environmental regulation. Measuring the benefits requires putting a value on improvements in environmental quality, health, and environmental amenities. When questioned in surveys, individuals indicate that they are willing to give up large amounts of money and income to pay for these improvements. We can also infer individuals' valuation of environmental amenities from the amount of money individuals spend on traveling to locations with

environmental amenities or the premium people are willing to pay on houses located near them. The data from these studies can be used to construct an aggregate indicator of the value of environmental improvements, which can then be compared to the cost estimates to undertake a social cost–benefit analysis.

The problem that the value of environmental amenities is unobservable (that there are no market prices) can thus be solved. However, perceptions may still be biased. Since neither market transactions nor market prices are associated with environmental goods, the current system of national accounts does not include the value of environmental goods; it only measures the value of marketed goods. As a result, the environmental benefits that environmental policies create are not part of national income, and environmental improvements do not count as economic progress. Attempts have been made to adjust national income data so as to include imputed values of environmental improvements and degradation. These "green GDP" data would more appropriately measure well-being and progress than do current GDP data. As long as these adjustments are not standard, there seems to be a trade-off between environment and growth. Once we take into account the value of environment for well-being, however, there is a close positive correlation between environment and economic progress.

2. **Modeling Energy Demand: An Analytical Framework**
3. **Modeling Energy Demand: Empirical Analysis**

Glossary

asymmetry In the present context, this refers to the asymmetric effect of changes in income or price on energy demand. Specifically, changes in energy demand caused by a Δ increase in income or price will not necessarily be of equal magnitude to changes caused by a Δ decrease in income or price (see also imperfect price-reversibility).

dematerialization The reduction of raw material (energy and material) intensity of economic activities, measured as the ratio of material (or energy) consumption in physical terms to gross domestic product in deflated constant terms.

economic structure The structure of production and consumption in an economy. Specifically, the share of goods and services produced and consumed by various economic sectors.

energy security The concept of maintaining a stable supply of energy at a "reasonable" price to avoid the macroeconomic costs associated with interruption of energy supply or increases in energy price.

imperfect price-reversibility In the present context, this refers to the asymmetric effect of changes in price on energy demand. Specifically, changes in energy demand caused by a Δ increase in price, though opposite in impact, will not necessarily be of equal magnitude to changes caused by a Δ decrease in price.

income elasticity of energy demand The percentage change in energy demand caused by a 1% change in income, holding all other factors constant.

price elasticity of energy demand The percentage change in energy demand caused by a 1% change in price, holding all other factors constant.

primary energy requirements The quantity of energy consumed by the end user (total final consumption) plus the losses incurred during the conversion, transmission, and distribution.

rental price of capital The opportunity cost of purchasing/owning capital.

total final consumption The total quantity of energy consumed at end use.

user cost of capital The rental price plus the cost of operating and maintaining capital.

The demand for energy is a *derived* demand. Energy's value is assessed not by its intrinsic appeal, but rather by its ability to provide a set of desired services. When combined with energy-using capital equipment, energy provides the work necessary to produce goods and services in both industry and in the household. As such, energy consumption, whether in the firm or household, is the result of a set of simultaneous decisions. Energy consumers must determine the quantity and type of capital equipment to purchase, where type is differentiated by technological characteristics such as efficiency and fuel input, and they must also determine a rate of capital utilization. Thus, the quantity of energy consumed is a function of capital utilization, as well as the engineering characteristics of capital equipment.

1. THE DEMAND FOR ENERGY: AN INTRODUCTION

To the extent that technologies make it possible, consumers of energy can choose between different sources of energy, and, in fact, energy use by source varies greatly across countries. In industrialized countries, the majority of energy consumed is referred to as commercial energy, which is differentiated from traditional forms of energy. The distinction between commercial and traditional energy can be made as an economic one. Specifically, commercial energy (for example, oil, natural gas, coal, and electricity) is traded in broader, larger-scale markets, whereas, traditional energy (for example,

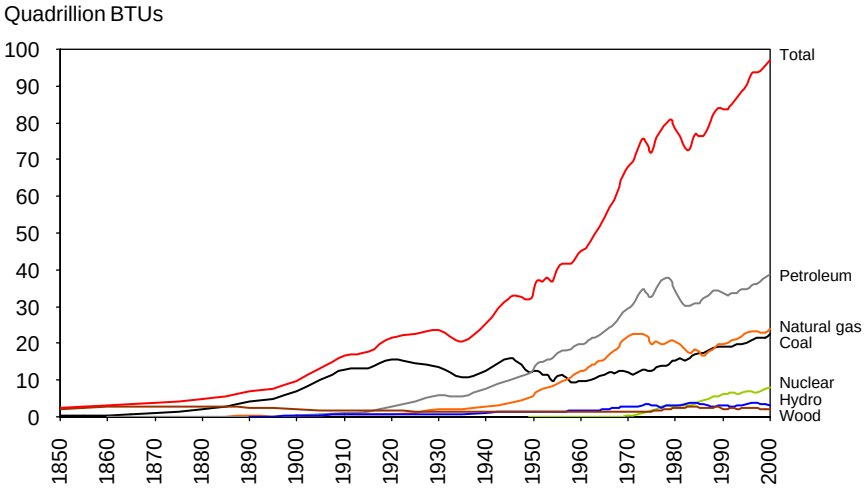
 © 2004 Elsevier Inc. All rights reserved.

waste and other biomass) is usually only traded, if at all, in smaller local markets. Typically, only in less developed countries will there be large shares of total energy consumed in traditional forms, since the proliferation of stocks of energy-using capital equipment, an occurrence associated with rising incomes, begets a substitution to commercial energy.

On a global scale, the 20th century was dominated by the use of fossil fuels. According to the U.S. Department of Energy, in the year 2000 global commercial energy consumption consisted largely of petroleum (39%), followed by coal (24%), and natural gas (23%), with hydro (6%) and nuclear (7%) splitting the majority of the remainder. However, this breakdown has not been constant over time either globally or within nations. In the United States, for example, wood was the primary source of energy consumption prior to industrialization (see Fig. 1). At the onset of industrialization, however, fossil fuels became the dominant energy source, and a number of factors, such as relative prices and environmental considerations, have dictated the composition of energy use since.

1.1 Energy Demand: A Context for Discussion

Energy is crucial to the economic progress and social development of nations. The development of new technologies and emergence of new production processes during the 19th and 20th centuries enabled an increase in productivity through the substitution of mechanical power for human and animal power. This, in turn, led to unprecedented economic growth and improved living standards, as well as, of course, large increases in energy consumption. For example, the consumption of coal and crude oil products for the locomotive, and later the automobile, significantly reduced the cost of transportation of people and goods, thereby creating growth opportunities for businesses and entrepreneurs. In addition, electrification has played a pivotal role in social development and welfare by making possible greater access to information via radio and television, providing a cleaner, more efficient means of storing and preparing food, and controlling enclosed environments to provide warmth and cooling. In the industrialized



Shares of Total Energy by Select Year

1850	1900	1950	2000
Coal: 9.3%	Coal: 71.4%	Coal: 35.6%	Coal: 23.0%
Petroleum: 0.0%	Petroleum: 2.4%	Petroleum: 38.5%	Petroleum: 39.1%
Natural gas: 0.0%	Natural gas: 2.6%	Natural gas: 17.2%	Natural gas: 24.5%
Wood: 90.71%	Wood: 21.0%	Wood: 4.5%	Wood: 2.3%
Hydro: 0.0%	Hydro: 2.6%	Hydro: 4.2%	Hydro: 3.1%
Nuclear: 0.0%	Nuclear: 0.0%	Nuclear: 0.0%	Nuclear: 8.0%

FIGURE 1 Energy demand in the United States increased fairly consistently from 1850–2000, but the source of that energy continually changed. Initially, wood was the primary form of energy use, but, driven by structural and technological change, coal, and later petroleum and natural gas, took the majority share of energy demand as the U.S. economy expanded. From the U.S. Energy Information Administration.

society of the 21st century, energy is necessary lest modern economic activity would cease and modern standards of living would diminish. Moreover, in developing nations, a lack of availability of energy supplies will prohibit further economic and social development.

Due to the importance of energy to economic and social progress, it is difficult to separate a discussion of energy demand from energy policy. In fact, a reoccurring theme in energy economics in general has been that of energy security. According to Bohi, Toman, and Walls, "Energy security refers to loss of economic welfare that may occur as a result of a change in the price or availability of energy" (p. 1), thus suggesting a link between energy and economy. The energy-economy link is supported by an abundance of empirical research demonstrating a strong correlation between increases in oil prices and decreases in macroeconomic performance, for both the United States and many other oil-importing industrialized countries. In fact, almost every recession in the post–World War II era in the United States, as well as many other energy-importing nations, has been preceded by a spike to the price of energy (see, for example, Hamilton; Ferderer; and Mork, Mysen, and Olsen). Because of this, governments, especially in those countries that are dependent on imported energy resources, have been concerned with maintaining security of supply at a reasonable price.

Projections of energy demand are necessary to develop national energy policies aimed at minimizing exposure to international price fluctuations and maximizing energy availability. On a less global scale, projections of energy demand are also important to the development of corporate business plans and the establishment of operational parameters for public utilities that must develop strategies to fulfill public service obligations. Therefore, the modeling and projection of energy demand is very important in the formation of policy in general, at both the national and local levels as well as in the private sector. Sound energy policy requires an adequate understanding of the economics of energy.

The economics of energy are generally concerned with the manner in which both nonrenewable and renewable energy resources are allocated over time and across space. A resource is considered nonrenewable when the sum, over time, of the services it provides is finite, or at least not replaceable in a reasonable time frame. Energy economists have been heretofore concerned primarily with the allocation of nonrenewable resources, largely because global energy consumption has consisted primarily of the consumption of fossil fuels. Dating back to Hotelling's classic paper, there have been numerous theoretical studies of optimal depletion rates and associated pricing rules given different sets of assumptions, as well as empirical studies designed to test theory. The well-known r-percent rule, as well as an apparent disregard for the impact of still underappreciated factors such as technological change in the extractive industries, the development of lower cost alternatives, and expansion of the resource base through exploration activities, influenced predictions by many scholars and industry analysts in the late 1970s and early 1980s that oil prices would top $100 per barrel by 2000. This projection never occurred.

Also of considerable influence to these erroneous projections was an apparent extrapolation of demand trends without properly considering the impact of allowing for, among other things, structural change in economies as they develop and the effect of increased energy prices on the composition and characteristics of capital stocks. In general, as economies develop they move from agricultural to industrial to service economies. This structural transformation has important implications for the manner in which energy demand grows relative to income. Specifically, as less energy intensive activities make up a larger proportion of total economic activity the income elasticity of demand will decline. In short, the income elasticity of nations is not constant.

The characteristics of energy-using capital stocks are also an important determinant of energy demand that cannot be ignored when forecasting. When considering an entire economy, the type of capital employed by firms and in households is largely dependent on economic structure, but certain characteristics of capital, such as embodied technology, are sensitive to price. Therefore, price-induced technological change will alter the energy requirements for a given level of output, allowing for an expansion of economic activity without an appreciable increase in energy demand. To illustrate, consider the United States transportation sector. According to the Energy Information Administration, the average fuel rate of a passenger automobile increased from about 14.3 miles per gallon in 1978 to about 20.2 miles per gallon in 1990, an average annual increase of 2.9%. During the same time period, transportation fuel consumption increased at only 0.7% per year, despite increases in both motor vehicle stocks and motor vehicle utilization (miles driven per vehicle). Clearly, efficiency gains offset increased utilization and growing vehicle stocks thus

limiting the increase in fuel consumption. Apart from allowing output to increase for a given level of fuel consumption, an increase in the energy efficiency of capital stocks also leads to asymmetry in the response of energy demand to changes in price, as noted in Gately and Huntington. Specifically, if certain capital investments aimed at increasing energy efficiency are made in response to a price increase, they will not be undone when price falls. Thus, energy demand tends to respond differently to price increases than to price decreases.

1.2 Elasticity of Energy Demand

The experiences of the 1970s and 1980s led to an explosion in the number of energy demand studies, a trend that has been somewhat revitalized by the emergence of concerns about the emissions of greenhouse gases from the combustion of fossil fuels. A large majority of these studies have resulted in the estimation of, or made use of previously estimated, income and price elasticities of energy demand. Income and price elasticities of energy demand are of the utmost importance to forecasting energy demand. Moreover, the manner in which these relationships may or may not evolve in response to future economic growth, changes in economic structure, and various policy initiatives is also important. Income and price elasticities are, in general, the rules of thumb by which broader energy policy is directed. There is, however, no real consensus as to an appropriate value of income or price elasticity. Much of the disagreement in empirical research is certainly due to different model specifications, but it is also due to some confounding issues that are difficult to isolate, such as the effects of changes in technology, changes in capital stock utilization, capital stock turnover, shifts in economic structure, and changes in energy policy.

The income elasticity of energy demand is defined as the percentage change in energy demand given a 1% change in income holding all else constant, or

$$\varepsilon_y = \frac{\%\Delta e}{\%\Delta y} = \frac{de}{dy} \cdot \frac{y}{e},$$

where e denotes energy demand and y denotes income. This measure provides an indication of how demand will change as income changes. The income elasticity of energy demand had long been reported as being greater than or near to 1. Research, however, has indicated that this may be greatly overstated for industrialized countries, as there is increasing evidence that energy intensity is inversely related to economic development, being greatly influenced by changes in economic structure and the state of technology.

The price elasticity of energy demand is defined as the percentage change in energy demand given a 1% change in price holding all else constant, or

$$\varepsilon_p = \frac{\%\Delta e}{\%\Delta p} = \frac{de}{dp} \cdot \frac{p}{e},$$

where p denotes the price of energy. This measure gauges the influence of energy price on energy demand and is often used as a barometer to assess the impact of various conservationist policies, such as emissions abatement programs or energy tax/subsidy schemes. For example, one can approximate the reductions in emissions achieved by taxing energy if the impact of that tax on the quantity and composition of energy consumption is known. The price elasticity can also be used to determine the impact of energy price disruptions on energy demand and, hence, any subsequent loss in macroeconomic output. However, the long- and short-run effects of energy prices can be difficult to disentangle. Energy demand is predicated on ownership of an energy-using capital good, the owner's decision as to the energy efficiency of the capital good, which is made when the capital is purchased, and utilization of the capital good. Once a capital good has been purchased, the capital utilization decision will dictate the responsiveness of energy demand to price in the short run, assuming the short run implies that capital and technology are fixed so that the consumer cannot "trade up" to higher energy efficiency. In the long run, however, the consumer is free to turn over capital equipment in favor of higher energy efficiency. Thus, the long-run response to price involves a decision on both capital utilization rates and energy efficiency.

There is an important consideration that bears mention here with regard to calculating income and price elasticity of energy demand. When estimating an income elasticity of energy demand, for example, it is not sufficient to simply divide the percentage change in energy demand by the percentage change in income. Nor it is not sufficient to simply use linear regression analysis to estimate an income elasticity of energy demand if income is the only explanatory variable. Both of these approaches completely ignore the influence that other variables may have on energy demand, which can lead to erroneous, statistically biased results. Nonetheless these are common mistakes often made by well-meaning energy analysts.

To illustrate, recall that income elasticity of energy demand is the percentage change in energy demand given a 1% change in income, *holding all else constant*. If we take energy demand to be a function of income, price, and possibly some other set of variables, then, in general, the total derivative of energy demand is given as

$$de = \frac{\partial e}{\partial y} dy + \frac{\partial e}{\partial p} dp + \cdots .$$

If we hold all factors but income constant, the preceding equation reduces to

$$de = \frac{\partial e}{\partial y} dy.$$

We can then multiply both sides by

$$\frac{1}{dy} \cdot \frac{y}{e}$$

to yield

$$\frac{de}{dy} \cdot \frac{y}{e} = \frac{\partial e}{\partial y} \cdot \frac{y}{e}.$$

The left-hand side of this equation is the income elasticity of energy demand, as defined earlier, but we only arrive at this result when all variables except income are held constant. It is a simple matter to show that not holding all other variables constant will result in a remainder term on the right-hand side of the preceding equation (i.e., the term in brackets):

$$\frac{de}{dy} \cdot \frac{y}{e} = \frac{\partial e}{\partial y} \cdot \frac{y}{e} + \left\{ \frac{\partial e}{\partial p} \cdot dp \cdot \frac{1}{dy} \frac{y}{e} + \cdots \right\}.$$

If, therefore, we seek an estimate of income elasticity, we cannot ignore the other relevant variables as it introduces a bias similar to the term in brackets. For example, if energy consumption has been increasing at 2% per year for 10 years, and income has been increasing at 3% per year for the same time period, a naïve approximation of income elasticity of energy demand would be 0.67 (= 2%/3%). However, if we consider that price may have been changing during the past 10 years, then our naïve estimate is incorrect. Specifically, if price had been falling, then, given a downward sloping demand curve, an income elasticity of 0.67 is an overestimate and can lead to serious problems when forecasting future demand. Therefore, when modeling energy demand, it is important to recognize that many variables influence energy use, and those variables must be carefully accounted for. This is precisely why a sound theoretical foundation is necessary when analyzing energy demand.

1.3 A Note on Energy Accounting

Before discussing the aspects of energy demand modeling about which the researcher must be conscious, it is important to highlight exactly what is referred to when discussing energy demand. When modeling energy demand, the researcher is usually interested in the quantity of energy required to perform a specified activity. For example, operating a drill-press requires electricity, driving an automobile requires gasoline or diesel fuel, and heating a household requires natural gas, heating oil, or electricity. Simply accounting for the energy consumed at end use, however, does not fully account for all the energy consumed to make the activities listed above possible. Specifically, raw energy supplies (such as coal, crude oil, and wet natural gas), while they can be directly consumed, are generally converted into products (such as gasoline, heating oil, propane, ethane, dry natural gas, and electricity) that are then consumed in various end uses. The energy conversion industries, such as refining, processing, and electricity production, use primary energy inputs to produce usable products. Energy balance tables are a means of accounting for the process of energy conversion and eventual consumption. Figure 2 illustrates the general flow that energy balance tables capture. Total primary energy requirements (TPER) are the energy needed to produce the energy necessary for total final consumption (TFC). TPER is greater than TFC due to the energy expended in the conversion, transmission, and distribution activities.

2. *MODELING ENERGY DEMAND: AN ANALYTICAL FRAMEWORK*

As stated earlier, the demand for energy is derived from the demand for goods and services provided by energy-using capital equipment. In residences and commercial establishments, energy is consumed, in conjunction with some energy-using durable good, to provide services such as space heating and cooling, lighting, cooking, and cleaning. Similarly, in industry, energy is used to produce steam and power automated processes, and in transportation, energy is required to make use of the services provided by automobiles, airplanes, trains, and so on. Therefore,

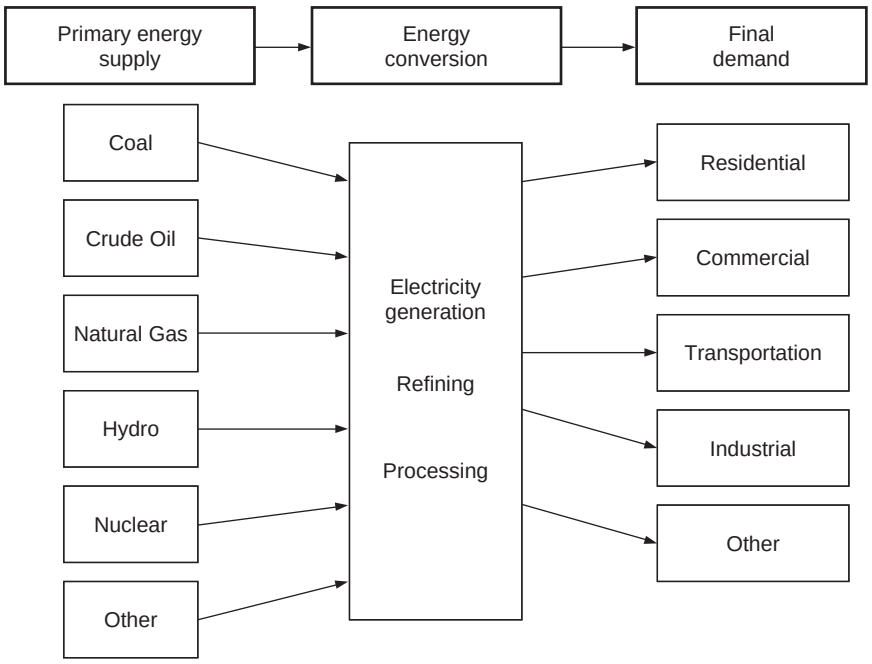


FIGURE 2 Primary energy supply is the energy required to meet final demand. Some energy is expended in the energy conversion industries in order to make usable energy products, so primary energy supply is greater than final demand.

implicit in the decision to consume energy is an underlying set of decisions that each energy consumer faces. Consumers of energy must decide to purchase the capital equipment that provides the desired service (heating, cooling, transportation, and manufacturing), they must choose the characteristics of the capital equipment (energy efficiency and type of energy input), and they must choose the rate at which the capital will be utilized. These decisions are conditional on, among other things, the energy cost of capital utilization. It is this particular aspect of demand modeling that is sometimes difficult to capture. In the short run, capital stocks are assumed fixed, so energy price fluctuations will influence the utilization rate of capital. In the long run, the energy consumer can replace capital equipment thereby improving energy efficiency. In empirical studies, this can pose difficulties due to limited time series data (both in length and breadth), thereby confounding the differentiation between the long- and short-run impacts of energy price movements. It is therefore important to develop a theoretical framework that is capable of addressing these concerns in order to lend guidance to assessing and conducting empirical analysis.

The quantity of energy consumed in the production of goods and services is dependent on the technical nature of energy-using capital equipment. The relationship between energy consumption and capital equipment can be given as

$$\text{energy} \equiv \left(\frac{\text{capital utilization rate}}{\text{capital equipment efficiency}}\right) \times \text{capital stock}, \quad (1)$$

where efficiency is an equipment-specific technological parameter, defined to be service output per unit energy. It is important to note that this relationship is, in general, equipment specific, and there is one such relationship for each type of capital equipment. This is important because it is an oversimplification to aggregate capital stocks and energy if one wishes to analyze the relationship between capital and energy. In the case of motor vehicles, efficiency is miles per gallon, and in the case of central air conditioners, efficiency is British thermal units (BTUs) per watt-hour. As efficiency increases, the energy required per unit of service declines. The capital utilization rate denotes the service rendered by capital equipment, such as miles driven per vehicle, thus energy use is positively related to capital utilization. Equation (1) is an identity because its units simplify to energy≡energy.

Notice that the right-hand-side of Eq. (1) contains the three choice variables involved in any decision to consume energy. Because capital stocks and technology are key determinants of energy use, static models of energy demand are limited in their ability to

capture the full response of energy use to changes in economic variables, such as income and price. Nevertheless, the static model built on sound microeconomic principles provides a reasonable starting point. As such, and because static models are widely used, we will begin with a brief description of them before moving to a dynamic framework.

2.1 Static Models

Following the energy balance structure indicated in Fig. 2, the demand for energy originates in different end-use sectors: industrial, residential, commercial, transport, and other. More generally, energy consumption can be modeled as either providing utility to households or as an input in the production process for firms. For treatment of the former problem, it is generally assumed that a consumer maximizes his or her welfare by consuming some bundle of goods and services subject to a budget constraint. Energy is assumed to be proportional to the service it provides, and therefore consumer welfare is influenced by energy consumption. (As demonstrated later, if one wishes to allow for substitution possibilities across types of energy commodities, it is a simple matter to incorporate various types of energy along with their specific costs.) The resulting demand for energy by the representative individual in this problem will be influenced by a number of factors, including but not limited to energy price, the price of other goods, and income (other variables, such as weather and durable goods stocks, can also have an influence, depending on the model specifications).

Expressing the preceding argument mathematically, we have that a representative consumer maximizes utility, $U(z, e)$, which is function of energy consumption, e, and all other consumption, z, subject to the constraint that expenditures cannot exceed income, y. As usual, we assume utility is a concave twice-differentiable function of its arguments. If the modeler wishes to examine the substitution possibilities across energy products, the energy variable can be a vector of n energy products, $e = [e_1, e_2, \ldots, e_n]$. Allowing the price of good j to be represented as p_j, the consumer is assumed to

$$\max_{z,\, e_1, \ldots, e_n} U(z, e_1, \ldots, e_n)$$

subject to $y \geq p_z z + p_{e_1} e_1 + \cdots + p_{e_n} e_n$.

The first-order necessary conditions for a maximum for this problem can be solved to yield demand equations for each of the energy products and for all other consumption. The resulting function for energy demand is given as

$$e_j^* = e_j(y, p_z, p_{e_1}, \ldots, p_{e_n}), \tag{2}$$

where the star denotes an optimal choice. Thus, the demand for energy commodity j is a function of income, own price, the price of all other energy commodities, and the price of all other consumption goods.

A firm also demands energy to produce goods and services. The typical firm is interested in maximizing profits, or minimizing the cost of producing a given level of output, and it must purchase energy as well as all other inputs to production. As it turns out, the firm's problem is not unlike the household's problem. The firm's demand for energy in this problem can be shown to be a function of its output, the price of energy, and the price of all other inputs.

Formalization of this problem is as follows. Consider a representative firm that minimizes costs, c, for a given level of output, $\bar{q}$. Output is a function of capital (k), materials (m), labor (l), and energy, $q = f(k, l, e_1, \ldots, e_n, m)$, and costs are the sum of payments to the factors of production, $c = rk + wl + p_{e_1} e_1 + \cdots + p_{e_n} e_n + p_m m$, where r are rent payments to capital, w are wages paid to labor, and p_j is the price of factor j. The firm's problem is then stated as

$$\min_{k, l, e_1, \ldots, e_n, m} c$$

subject to

$$\bar{q} = f(k, l, e_1, \ldots, e_n, m)$$

$$c = rk + wl + p_{e_1} e_1 + \cdots + p_{e_n} e_n + p_m m.$$

The reader can verify that the solution to this problem is not very different than the solution to the utility maximization problem, other than a change of terminology. (In fact, the dual to the household's [firm's] problem is one of cost minimization [profit maximization].) The firm will choose inputs such that their marginal values in production will be equal. Solution of the first-order conditions for a maximum for this problem yields a general function for the demand for energy

$$e_j^* = e(\bar{q}, r, w, p_{e_1}, \ldots, p_{e_n}, p_m).$$

Thus, by Eq. (3), the firm weighs the price of all possible factor inputs when choosing its energy consumption for a given level of output.

These problems are static representations of energy demand. As such, they are most appropriate in deriving short-run demand functions, when capital and technology are fixed. Comparative statics can be a useful tool in this setting for analyzing the impact of a rise in capital stocks, say, but they disregard the

intertemporal choices an energy consumer faces with regard to type of capital, utilization of capital, and efficiency of capital. A more general approach would allow for a dynamic specification of demand. A dynamic model accounts for intertemporal choice of capital stock characteristics and utilization, as well as the effects of each on energy demand. As such, a dynamic framework is capable of addressing the asymmetries that exist in the energy-income and energy-price relationships. In the static setting such explorations are left to pontification and conjecture.

2.2 Dynamic Models

Dynamic models of capital ownership and energy use allow for a more complete analysis of energy demand because, for one, they are capable of capturing factors that generate the asymmetries mentioned previously. In addition, dynamic models incorporate the intertemporal choices that a consumer (firm) must make when maximizing welfare (profits) over some time horizon. Medlock and Soligo (2002) developed a dynamic model of motor vehicle ownership and fuel use that generalizes to many other types of energy-using capital equipment. They showed that the demand for energy is determined by the consumer's wealth, the price of energy, the price of other goods, the user cost (or cost of owning and maintaining) capital, and the energy efficiency of the energy-using capital stock. Because the model they developed is dynamic, it captures the notion that the decision to consume energy is made jointly with the decision to purchase and maintain a stock of energy-using capital equipment, the latter of which incorporates the elimination of potential intertemporal arbitrage opportunities.

It is useful to consider the framework developed by Medlock and Soligo (2002). To begin, consider a modification of the household's problem. For ease of exposition, energy consumption has been denoted as a single commodity. Relaxation of this constraint allows for multiple types of capital and hence multiple types of energy consumption. Denoting time using the subscript t the consumer will maximize the discounted sum of lifetime utility,

$$\sum_{t=0}^{T} \beta^t U(z_t, e_t),$$

subject to the constraint that capital goods purchases (i_t), purchases of other goods (z_t), purchases of energy (e_t), and savings (s_t) in each period cannot exceed this period's income (y_t) plus the return on last period's savings ($(1+r)s_{t-1}$). It is assumed that capital goods depreciate at a rate δ, savings earn a rate return r, the discount rate is such that $0<\beta<1$, and all initial conditions are given. (Note we can complicate the problem somewhat be allowing access to credit markets, but this adds little to the present context.)

The problem is thusly formulated. Consumers will

$$\max_{z,e,s} \ \sum_{t=0}^{T} \beta^t U(z_t, e_t)$$

subject to

$$\begin{aligned} & p_{z,t}z_t + p_{e,t}e_t + p_{k,t}i_t + s_t \le y_t + (1+r)s_{t-1} \\ & e_t \equiv \frac{u_t}{\varepsilon_t} k_t \\ & i_t = k_t - (1-\delta)k_{t-1} \\ & z_t, u_t, k_t \ge 0 \quad t = 1, \ldots, T \end{aligned}$$

where $p_{j,t}$ is the price of good j and all initial values are given. Note the second constraint is a restatement of Eq. (1). It is through this constraint that the relationship between energy and capital is made explicit.

The marginal conditions for this consumer's problem lend considerable insight into the manner in which consumers will respond to changes in income and energy prices. Specifically, the marginal conditions yield

$$U_k \frac{u_t^*}{\varepsilon_t} = U_z \left(p_{e,t} \frac{u_t^*}{\varepsilon_t} + p_{k,t} - p_{k,t+1} \left(\frac{1-\delta}{1+r} \right) \right), \quad (4)$$

where the star denotes the optimality. Equation (4) indicates that the consumer will allocate income such that the marginal value of the energy services attained from the capital stock is equal to the marginal value of consumption of all other goods. The term in brackets in Eq. (4),

$$p_{e,t} \frac{u_t^*}{\varepsilon_t} + p_{k,t} - p_{k,t+1} \frac{(1-\delta)}{(1+r)},$$

is defined as the "user cost," μ_k, of capital stock, and it is this term that bears significant mention. The first term, $p_{e,t}\frac{u_t^*}{\varepsilon_t}$, indicates that the consumer chooses user cost to the extent that capital utilization is a choice variables. If the optimal choice of utilization were such that $u_t^* = 0$ user cost reduces to

$$p_{a,t} - p_{a,t+1} \frac{(1-\delta)}{(1+r)},$$

which, following Diewert, is the rental price $(p_{R,t})$ of owning capital equipment.

Simultaneous solution of the first-order conditions will yield a set of demand equations, one for each of the arguments in the utility function at each of the

$t+1$ time periods. By Eq. (1), once a solution is obtained for k_t^* and u_t^*, we can solve for the optimal consumption of energy. Thus, the optimal choice of energy demand is determined by the optimal choice of capital stocks and capital utilization, with efficiency given. The demand for energy is found to be a function of income, the user cost of capital, and the price of all other goods. Since user cost is a function of energy price, energy efficiency, and the rental price of capital, we can generically state the demand for energy as

$$e_t^* = e\left(y_t, p_{z,t}, p_{e,t}, p_{R,t}, \varepsilon_t\right). \tag{5}$$

Note that Eq. (5) is altered if efficiency is taken to be choice variable, although a distinction must be made between the long and short run. This is not done here for ease of exposition, as it would require the differentiation of types of possible capital purchases by the use of additional constraints. (One such example is Tishler.) The added insight gained from allowing a choice across multiple energy efficiencies is that consumers may choose to increase efficiency if energy prices rise in order to prevent the user cost of capital from rising. This type of response allows for the previously mentioned asymmetries.

We could also increase the complexity of the problem by allowing for multiple types of capital equipment (a household typically has refrigerators, air conditioners, ovens, etc.) and multiple fuel sources, which would result in, for example, natural gas prices appearing in, say, an electricity demand function. Again, however, this is not done here for ease of exposition. Such analysis is left to the reader for further exploration.

3. MODELING ENERGY DEMAND: EMPIRICAL ANALYSIS

Empirical studies often use the general form of Eq. (2) or Eq. (5) to specify a function to be estimated as an approximation of the "true" demand function. This can lead to substantial variation in published results since parameter estimates are sensitive to the model specification. This is not an unimportant fact since policy recommendations are often made on the basis of empirical research. Moreover, it highlights the importance of sound theoretical justification for model specification.

A simple and popular demand specification is the log-linear demand equation given as

$$\ln e_t^* = a + \alpha \ln y_t + \eta \ln p_{e,t}, \tag{6}$$

where e^* is the "optimal" quantity of energy demanded, y is income, p_e is energy price, and a is a constant. The subscript t denotes the time period. (Such a demand specification implies a demand function of the form $e_t^* = A y_t^{\alpha} p_{e,t}^{\eta}$). Equation (6) is easily estimated to directly yield an income elasticity, α and a price elasticity, η. Because energy demand is not necessarily a function of only income and price, additional parameters are also sometimes included in the specified demand equation. For example, when estimating energy demand across countries, a *per capita* income measure is generally preferred because it normalizes income with respect to population. Population may also be added explicitly as an independent variable, as well as other parameters of importance such as capital stocks, weather/climate, and the prices of alternative fuels, the latter two of which are particularly important when modeling the demand for individual fuel types whose consumption varies seasonally.

An alternative specification to Eq. (6) allows energy demand to be a function of past realizations of income and price. It can be shown that this is equivalent to assuming the existence of a lag adjustment mechanism of the form

$$\left(\ln e_t - \ln e_{t-1}\right) = \gamma\left(\ln e_t^* - \ln e_{t-1}\right),$$

where $\gamma \in [0, 1]$ is the speed of adjustment. Eliminating the term $\ln e^*$ in Eq. (6) by direct substitution results in the equation

$$\ln e_t = \gamma a + \gamma\alpha \ln y_t + \gamma\eta \ln p_{e,t} + (1-\gamma)\ln e_{t-1}, \tag{7}$$

where α is the long-run elasticity of demand with respect to income, η is the long-run elasticity of demand with respect to price, and $\gamma\alpha$ and $\gamma\eta$ are the respective short-run elasticities.

While econometric specifications such as Eqs. (6) and (7) are attractive because they are easily estimated and yield elasticity terms directly, they implicitly assume that elasticity is constant across all ranges of income and price, a point that has been challenged in the literature. Moreover, it does not adequately capture the influence of changes in the composition of capital stocks over time, a phenomenon that could alter energy required per unit output and result in asymmetric demand responses to changes in income and price. One means of controlling for these factors directly is to estimate the components of Eq. (1) in order to derive an estimate of energy demand for a specific end use. Olof and Schipper take such an approach with regard to forecasting long-term motor fuel demand in several

countries. The advantage of such an approach is that it is robust to the simultaneous set of decisions the consumer makes when determining energy consumption.

Other adjustments can and have been made to Eqs. (6) and (7). For example, one can employ dummy variables on the price and income coefficients, thereby separating price and income effects into increases and decreases, in order to capture any asymmetric response of energy demand. One can also specify a demand function that is nonlinear in all or some of the included variables. Such a specification could allow, for example, a declining income elasticity of energy demand. Still other approaches involve an entirely different approach to deriving an equation for energy demand. This class of models involves estimating the first-order conditions that would arise from a theoretical model similar to that presented earlier. Thus, rather than using general solutions such as those given in Eqs. (2) or (5), consumer utility functions or production functions are to be specified, and analytical solutions are obtained. While potentially cumbersome mathematically, this type of approach has the advantage of including all relevant variables, and the interactions therein, from theoretical framework in a simultaneous equations setting.

In sum, there are numerous specifications that can be potentially explored when analyzing energy demand. But it must be noted that the different types of alternative specifications are tailored to identify specific characteristics of the data being analyzed and are usually specific to the question posed by the researcher. While no one specification is necessarily more correct than another, some are certainly more adequate than others in capturing certain aspects of energy demand, and thus they highlight what should, and sometimes should not, be considered in empirical modeling.

Regardless of the specification chosen, a strong understanding of the economic forces at work in individual markets is crucial to empirical analysis. For instance, when modeling the near-term demand for natural gas, it is important to account for both weather and alternative fuel prices (heating oil for example), as well as income and own price. This is due to the fact that natural gas demand increases considerably in the winter months as heating demand increases. Therefore, for reasons discussed earlier, not accounting for weather and alternative fuel prices will lead to biased estimates of income and price elasticity.

3.1 Empirical Considerations: The Energy-Income Relationship

3.1.1 Economic Development and Dematerialization

The assumption of constant income elasticity of energy demand is inconsistent with empirical evidence that energy intensity increases then decreases during the course of economic development. In general, econometric analysis of countries across time and space yield the result that the income elasticity of energy demand is higher in lower income countries. The energy intensity of an economy resembles an inverted U-shape across increasing levels of per capita income, as discussed in 2001 by Medlock and Soligo. This arises because various sectors grow at different rates and at different times during the course of economic development. Industrialization results in large increases in commercial energy use. This is followed by smaller increases in energy demand during the post-industrial phase of development, in which the service sector grows relative to all other sectors. Figure 3 illustrates the general pattern of energy intensity that arises during the course of economic development, as well as the general relationship between energy intensity and income elasticity of energy demand. The reader can readily verify that if the income elasticity of energy demand exceeds unity, then, holding all else constant, energy intensity is rising. Similarly, if the

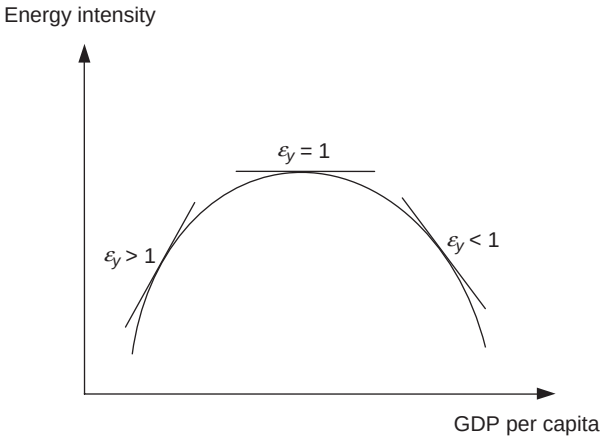

FIGURE 3 Generally, due to structural transformation and technological change, energy intensity follows an inverted U-shape during the course of economic development. This has implications for income elasticity. When income elasticity of energy demand exceeds unity, then, holding all else constant, energy intensity is rising. Similarly, if the income elasticity of energy demand is less than unity, then, holding all else constant, energy intensity is falling.

income elasticity of energy demand is less than unity, then, holding all else constant, energy intensity is falling. Note that declining energy intensity does not imply that energy demand declines, only that energy demand grows more slowly than output.

A rising then declining energy intensity is generally consistent with the theory of dematerialization, which was defined by Bernardini and Galli in 1993 as "the reduction of raw material (energy and material) intensity of economic activities, measured as the ratio of material (or energy) consumption in physical terms to gross domestic product in deflated constant terms." There are two basic ideas that constitute the theory of dematerialization. One, intensity-of-use of energy and materials initially increases then decreases with increasing GDP in all countries. Two, the later in time a country develops the lower its maximum intensity-of-use in energy and materials will be. These concepts, as they pertain to energy, are illustrated in Fig. 4.

The idea that the intensity-of-use of energy first increases then decreases is related to the impact of changing economic structure on energy use. In general, the process of industrialization results in large increases in commercial energy consumption, which causes energy intensity to initially increase. As consumer wealth rises, however, the structure of consumption changes increasing the demand for light manufactures and services. As these new demands are met, the structure of a nation's capital stock will change to reflect its output. Growth in the service sector relative to other sectors serves to reduce energy intensity as the energy required per unit of output from capital employed in the service sector is generally lower than that in the industrial sector.

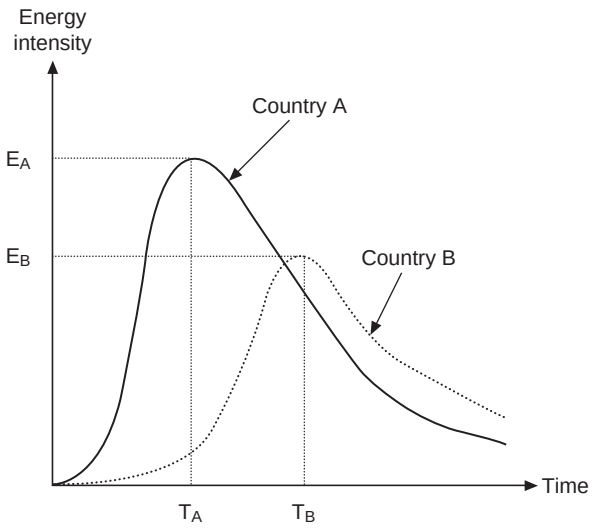

FIGURE 4 Consider two countries, country A and country B. Assume that gross domestic product per capita is positively correlated with time, and allow country A to develop more rapidly than country B. *Ceteris paribus*, the energy intensity of country A, reaches its peak (T_A, E_A) before country B (T_B, E_B). Moreover, country B benefits from the production processes and technologies developed by country A. Therefore, the peak energy intensity in country B is lower than the peak energy intensity in country B. Or, otherwise stated, $E_A > E_B$ because $T_A < T_B$.

The decline in intensity-of-use of energy and materials can also be hastened by the introduction of newer energy resources and materials with price and/or quality advantages, and also by the introduction of technologies that increase the energy efficiency of capital equipment. Industrialization in the West saw massive increases in the use of coal, as it was the primary fuel of choice for meeting energy requirements. However, increasing wealth generated new demands, and better, more suitable alternatives, namely oil and natural gas, eventually took the place of coal. For example, growth in private and small-scale transportation could be more easily facilitated with petroleum products than with coal, since the latter is more cumbersome and less efficient to meet that end. As environmental pressures mount and the associated costs are internalized, it is probable that ever cleaner alternative energy sources will become economically competitive, and therefore it is likely the intensity-of-use of other fuel sources will continue to rise over time as the intensity-of-use of fossil fuels continues to decline.

The second of the ideas central to the theory of dematerialization, which comes to bear because the diffusion of newer technologies and the economic/environmental lessons learned in the industrialized world could contribute to lowering the maximum energy intensity of developing nations, is difficult to test in a casual manner. While one can examine cross-country data to make comparisons, it is necessary to control for factors specific to individual countries that could influence energy intensity. Such research has not to date been completed. Nonetheless, the implication of the time dependency of maximum energy intensity is substantial. If developing countries, in general, will never reach the maximum intensity of energy use that was reached in industrialized countries in the 20th century, then expectations should be gauged accordingly. Long-term forecasting, therefore, should anticipate the possibility of these developments, particularly when assessing the impact of future economic development on the demand for energy.

3.1.2 Asymmetry in the Energy-Income Relationship

When considering the energy-income relationship, we must be mindful of the fact that the manner in which income influences energy demand is not symmetric. In other words, an increase in macroeconomic output will increase energy demand, but a decline in output will not necessarily have an equal and opposite effect. The reason for this is related to the arguments underpinning dematerialization, and possible explanations can be tied to Eq. (1). Specifically, different sectors grow at different rates and at different times during the course of economic development. As mentioned earlier, it is an oversimplification to assume Eq. (1) holds at the aggregate level. Doing so ignores the fact that capital stock characteristics are tied to specific capital stocks, and the proliferation of types of capital is very much dependent on economic structure. For example, the capital employed in industrial and manufacturing facilities is differentiated from the capital employed in households by the service they provide and the engineering characteristics they possess. Moreover, these items are more or less prevalent given the level of economic and social development, as well as the structure of production and consumption, within a nation.

Asymmetry in the energy-income relationship arises largely because not all expansions (recessions) are created equal. Some sectors of an economy may expand (contract) more rapidly than others during certain periods of time. Since different economic sectors are generally characterized by different types of capital, it is possible that some periods of macroeconomic expansion (contraction) will result in the expansion (contraction) of a sector in which energy intensity is very high relative to other sectors. Therefore, growth (reduction) in energy use could be larger in those time periods.

To illustrate, consider a two-sector economy (denoted as sectors A and B). Total energy consumption is given as the sum of energy use in each of the two sectors, $e = e_A + e_B$. Sector A has an energy intensity measured as

$$\frac{e_A}{y_A},$$

and sector B has energy intensity measured as

$$\frac{e_B}{y_B},$$

where y_j is the output of sector j and total output is given as $y = y_A + y_B$. Assume that sector A is more energy intensive than sector B, or $\frac{e_A}{y_A} > \frac{e_B}{y_B}$. Note that total energy intensity can be written as

$$\frac{e}{y} = \frac{e_A + e_B}{y} = \frac{e_A}{y_A} \cdot \frac{y_A}{y} + \frac{e_B}{y_B} \cdot \frac{y_B}{y}$$
$$= \frac{e_A}{y_A} \cdot \theta_A + \frac{e_B}{y_B} \cdot \theta_B,$$

where θ_j is the sector j share of total output.

It follows for a given rate of total economic growth, if sector A grows faster than sector B, the effect on total energy demand will be larger than if sector B grows faster than sector A. To see this, hold energy intensity within each sector constant. Taking the partial derivative of the preceding equation with respect to the output shares yields

$$\frac{\partial\left(\frac{e}{y}\right)}{\partial\theta_A} = \frac{e_A}{y_A} \text{ and } \frac{\partial\left(\frac{e}{y}\right)}{\partial\theta_B} = \frac{e_B}{y_B}.$$

But we know, by assumption, that

$$\frac{e_A}{y_A} > \frac{e_B}{y_B},$$

so growth in sector A has a larger impact on total energy intensity than growth in sector B.

It should be noted that reality is not as simple as this example. Specifically, technological innovations do cause sector-specific energy intensities to change over time (although, as the example illustrates, they need not do so for total energy intensity to change over time). However, if we assume that the time period is reasonably short, our assumption of constant sector-specific energy intensity is not a gross approximation. Allowing for a dynamic sector-specific energy intensity would, however, indicate just how complicated the long-term energy-income relationship can become.

3.2 Energy Demand and Imperfect Price Reversibility

It is well documented that energy prices have a significant negative impact on both energy demand and macroeconomic performance. However, this relationship is not symmetric. In other words, much as is the case with the energy-income relationship, rising energy prices will reduce growth in macroeconomic output and energy demand, but falling prices will not have an equal and opposite effect. This imperfect price reversibility arises due to the characteristics of the energy-consuming capital stock. When energy prices rise, there is incentive for the holders of energy-using capital stocks to take steps to increase efficiency. This could come in the

form of either retrofitting existing capital or replacing it with newer capital. In either case, these steps require capital investment that will not be reversed when energy prices fall. Likewise, improvements in technologies (most of which are embodied in newer capital) induced by higher energy prices will not be reversed when prices fall.

Imperfect price reversibility follows from examination of Eq. (1). In the short run, when energy prices increase, the user cost of capital also increases (see Eq. (4)) since capital and technology are fixed. Thus, the energy consumer will re-optimize his or her portfolio by reducing energy use where possible. Since capital and technology are fixed in the short run, this can only be done by reducing capital utilization rates (u_t). Not only will the decline in capital utilization result in a decline in energy demand, it will also result in a reduction in economic activity.

In the long run, allowing capital and technology to vary will, in general, still result in a decrease in energy demand, but it can complicate the macroeconomic response to energy price increases. As technologies change and capital stocks are turned over, older stocks are replaced with stocks in which newer, more energy-efficient technologies are embodied. The improved efficiency can generate asymmetry in the response of demand to price by preventing energy use from rising appreciably when energy prices decline. In addition, better efficiency can reduce the impact on energy demand of future price increases because, by Eq. (4), increasing efficiency lowers the user cost of energy-using capital. Thus, a Δ price decrease will not have an equal and opposite effect as a Δ price increase. Similarly, a Δ price increase in the future will not necessarily have the same impact as a Δ price increase in the present. To emphasize the point, we can again consider the U.S. experience in the consumption of motor fuels to illustrate the dynamics at work in the long and short run. As indicated in Fig. 5, average fuel efficiency of passenger vehicles in the United States was virtually unchanged from 1960 to 1978. For the majority of this period, oil prices were relatively stable, and vehicle utilization (measured as miles per vehicle) grew steadily. However, the oil price shocks of the 1970s and early 1980s were followed by an immediate decrease in vehicle utilization. During the same period, average vehicle efficiency was relatively stable. From 1979 to 1992, however, average vehicle efficiency increased at close to 5% per year, prompted by the energy efficiency policies adopted following the oil price shocks of the 1970s. The increases in efficiency in the early 1980s offset increasing prices, as 1981 saw vehicle utilization, fuel efficiency, and the real price of gasoline all increase.

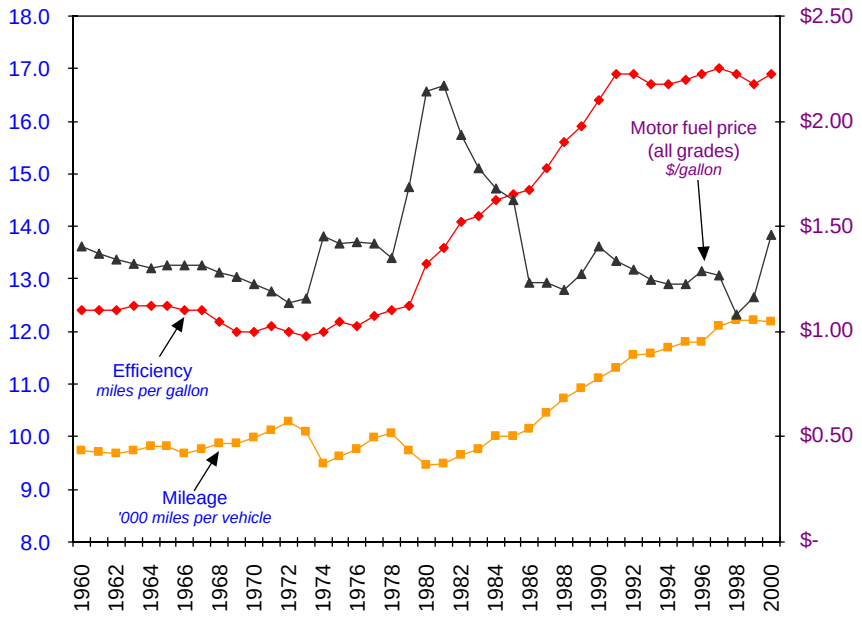

FIGURE 5 Energy prices for transportation increased dramatically from 1974 through 1982. In response, motor vehicle utilization declined initially, but a subsequent, albeit later, increase in efficiency of the motor vehicle fleet served to offset higher fuel prices, thereby reducing user costs.

Glossary

externality An economically significant effect of an activity, the consequences of which are borne (at least in part) by parties other than the party who engages in the activity, and which are not accounted for through trade.

diffusion The gradual adoption of new process or product innovations by firms and individuals.

innovation The initial market introduction or commercialization of new process or product inventions.

invention The development and creation of a prototype new idea, process, or piece of equipment.

market barriers Disincentives to the diffusion and/or use of a good, such as high costs or prices, which may or may not represent market failures.

market failures The failure of private markets to provide certain goods at all or at the most desirable level, typically arising from a situation in which multiple parties benefit from a good without decreasing one another's benefits, and in which those who have paid for the good cannot prevent others from benefiting from it.

technological change The process of invention, innovation, and diffusion whereby greater and/or higher quality outputs can be produced using fewer inputs.

This article reviews economic concepts relevant to decision making about energy efficiency investments and related policy choices. We describe economic perspectives on the process of energy-saving technological change, the distinction between market failures and market barriers in energy-using product markets, and the important role that discounting plays in this area.

1. OVERVIEW

Energy efficiency is defined here to mean energy services provided per unit of energy input (for example, gallons of water heated to a specified temperature per British thermal units of natural gas input). Within this framework, energy efficiency is conceived primarily at the disaggregated, product level, rather than at a more aggregated sectoral level. As with virtually all economic problems, the economics of energy efficiency is at its heart a question of balancing of costs and benefits. For the individual energy user, this involves weighing the higher initial cost of purchasing energy-efficient products against the expected benefits of future cost savings when operating the products, among other considerations. Due to this difference in the timing of energy efficiency costs and benefits, issues related to discounting feature prominently in analyses of energy-efficient technology adoption. For suppliers of energy-using products, decisions regarding energy-efficient innovations likewise depend on the expected profits from such technology development. Profits from innovation depend in turn on the expected

 © 2004 Elsevier Inc. All rights reserved.

demand for energy-efficient technologies and the degree to which firms can appropriate the value created by their innovations.

On both the demand and supply side of this market for energy-efficient technology, potential market imperfections can lead to underinvestment in energy efficiency. This raises the possibility that corrective government policies could provide economic gains if they are practicable and provide net benefits after inclusion of all public and private implementation costs. The degree to which such opportunities exist in practice is the subject of significant debate. Finally, environmental pollution associated with energy production—particularly carbon dioxide emissions from fossil fuels—represents an additional reason why private markets might underprovide energy efficiency if energy users do not face the cost of any resultant environmental harm.

2. *THE PROCESS OF TECHNOLOGICAL CHANGE*

Many readers may be unfamiliar with the way economists typically view the process of technological change, thus it is useful to first establish this common understanding. Furthermore, to understand the potential for public policy to affect energy efficiency, it is also necessary to understand the process through which technology evolves: invention, innovation, diffusion, and product use. Invention involves the development of a new idea, process, or piece of equipment. This activity typically takes place inside the laboratory. The second step is the process of technology innovation, in which new processes or products are brought to market. Another way of describing this stage is commercialization. The third step is diffusion, the gradual adoption of new processes or products by firms and individuals, which then also decide how intensively to use new products or processes.

Tying this all together, it would be possible, for example, to think of a fundamentally new kind of automobile engine being invented. This might be an alternative to the internal combustion engine, such as a system dependent on energy-efficient fuel cells. The innovation step would be the work carried out by automobile manufacturers or others to commercialize this new engine—that is, bring it to market, then offer it for sale. The diffusion process, then, would reflect the purchase by firms and individuals of automobiles with this new engine. Finally, the degree of use of these new automobiles will be of great significance to demand for particular types of energy. The reason it is important to distinguish carefully among these different conceptual steps—invention, innovation, diffusion, and use—is that public policies can be designed to affect various stages and will have specific and differential effects.

2.1 Technology Adoption and Diffusion

Beginning at the end of the technological change process, research has consistently shown that diffusion of new, economically superior technologies is never instantaneous. The S-shaped diffusion path shown in Fig. 1 has typically been used to describe the progress of new technologies making their way into the marketplace. The figure portrays how a new technology is adopted at first gradually and then with increasing rapidity, until at some point its saturation in the economy is reached. The explanation for this typical path of diffusion that has most relevance for energy conservation investments is related to differences in the characteristics of adopters and potential adopters. This includes differences in the type and vintage of their existing equipment, other elements of the cost structure (such as access to and cost of labor, material, and energy), and their access to technical information. Such heterogeneity leads to differences in the expected returns to adoption and, as a result, only potential adopters for whom it is especially profitable will adopt at first. Over time, however, more and more will find it profitable as the cost of the technology decreases, quality improves, information about the technology becomes more widely available, and existing equipment stocks depreciate. The longevity of much energy-using equipment reinforces the importance of taking a longer term view toward energy efficiency improvements—on the order of decades (see Table I).

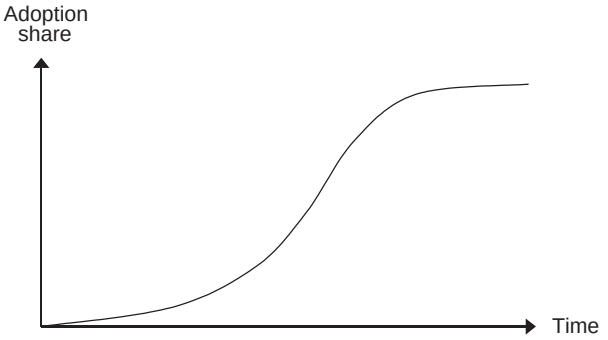

FIGURE 1 The gradual S-shaped path of technology diffusion.

Several studies have explored the effect of energy prices and technology adoption costs on energy efficiency investments. From a policy perspective, the effect of higher energy prices can be interpreted as suggesting what the likely effects of taxes on energy use (or carbon dioxide) would be and the effects of changes in adoption costs can be interpreted as indicating what the effects of technology adoption subsidies would be. As suggested by the economic cost–benefit paradigm, these studies have found that higher energy prices increase and adoption costs decrease the extent of adoption of energy-efficient technology (for example, building insulation, more efficient home appliances, or more efficient industrial motors). An additional interesting finding in this line of research is that the adoption of these technologies is more sensitive to the cost of the equipment than it is to the expected cost of energy. This implies that a policy of subsidizing the purchase of new efficient equipment may be more effective than a policy of taxing resource use, for policies that should in theory create the same magnitude of economic incentive.

There are at least three possible explanations for this divergence. One possibility is a behavioral bias that causes purchasers to focus more on up-front cost than they do on the lifetime operating costs of an investment. An alternative view is that purchasers focus equally on both, but uncertainty about future energy prices or whether they will face these costs (because they could move, for example) makes them give less weight to energy prices than they do to capital cost, which is known. A final interpretation might be that consumers have reasonably accurate expectations about future energy prices, and their decisions reflect those expectations, but the proxies for these expectations that are used by researchers are flawed, causing their measured effect to be smaller than their true effect. For example, studies often use current realized energy prices as a proxy for expected future energy prices. Current prices fluctuate more than expected future prices, however, leading to a downward bias in the coefficient on the energy price proxy relative to the true relationship with expected prices.

Although empirical evidence indicates that subsidies may be more effective than comparable taxes in encouraging technology diffusion, it is important to recognize some disadvantages of such subsidy approaches. First, unlike energy prices, adoption subsidies do not provide incentives to reduce utilization. Second, technology subsidies and tax credits can require large public expenditures per unit of effect, because consumers who would have purchased the product even in the absence of the subsidy still receive it.

TABLE I

Technology Diffusion and the Rate of Capital Stock Turnover[a]

Type of asset	Typical service life (years)
Household appliances	8–12
Automobiles	10–20
Industrial equipment/machinery	10–70
Aircraft	30–40
Electricity generators	50–70
Commercial/industrial buildings	40–80
Residential buildings	60–100

[a] Technology diffusion is closely related to the concept of "capital stock turnover," which describes the rate at which old equipment is replaced and augmented by new. New equipment can be purchased either to replace worn out and obsolete units or as a first-time purchase. A primary driver of replacement purchases for durable energy-using products is the useful lifetime of the product. The rate of economic growth is also important, especially for first-time durable-goods purchases; the rate of home construction is particularly relevant for residential equipment. The typical lifetimes for a range of energy-using assets illustrate that the appropriate time frame for thinking about the diffusion of many energy-intensive goods is on the order of decades.

2.2 Technology Innovation and Invention

Now it is possible to move back in the process of technological change from diffusion to innovation. In the energy efficiency area, it is helpful to think of the innovation process as affecting improvements in the attributes or characteristics of products. In Fig. 2, this process is represented as the shifting inward over time of a curve representing the trade-offs between different product characteristics for the range of products available on the market. On one axis is the cost of the product, and on the other axis is the energy flow (use; that is, the energy intensity) associated with a product. The downward slope of the curves indicates the trade-off between equipment cost of energy efficiency. Innovation means an inward shift of the curve—greater energy efficiency at the same cost, or lower cost for a given energy efficiency.

As with technology diffusion, studies have shown that increases in the price of energy have induced technological innovations in energy efficiency of commercialized products, such as household appliances (e.g., air conditioners, water heaters), automobiles, tractors, and jet aircraft. Moving back even further in the process of technological change to

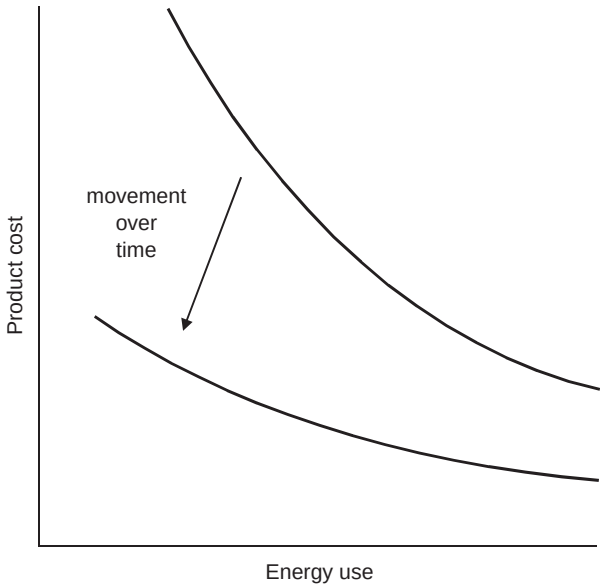

FIGURE 2 Innovation in product characteristics.

examine invention, other studies have analyzed U.S. patent data, finding that the rate of energy-conserving device patent applications (e.g., for waste heat, heat pumps, solar energy, and fuel cells) is significantly and positively associated with the price of energy.

3. UNDERSTANDING THE ENERGY EFFICIENCY GAP

Renewed attention is now being given by policymakers to energy efficiency, primarily due to concerns about global climate change associated with carbon dioxide emissions from fossil fuels. Much attention has been placed on the role that technological improvements in energy efficiency can play in reducing carbon emissions and in lowering the cost of those reductions. In such policy contexts, it is frequently asserted that there exists an "energy efficiency gap" between current energy use, on the one hand, and optimal energy use, on the other hand. From this perspective, the energy efficiency gap discussed earlier can now be thought of as a debate mainly about the gradual diffusion of energy-saving technologies that seem to be cost-effective.

Clearly, an estimate of the magnitude of this gap will be determined mainly by how optimal behavior is defined. Several major conceptual issues surround different approaches to defining an optimal energy-use scenario, with implications for guidance regarding public policy for energy and energy technologies. The standard economic approach defines "good" public policy to be that which maximizes the appropriately weighted sum of the values of goods and services enjoyed by society throughout time (including intangibles such as the environment). From this perspective, energy efficiency is not a goal in itself, but only a means to the end of overall economically efficient (and equitable) resource allocation. To the extent that energy generation and/or use creates environmental problems—one of the primary reasons why energy use is a public policy concern in the first place—such effects can in principle be incorporated in analyses by placing appropriate values on the environmental and nonenvironmental benefits and costs associated with energy generation and use.

The crux of the debate surrounding the energy efficiency gap lies in differing interpretations of what has been called the paradox of gradual diffusion of apparently cost-effective energy-efficient technologies. Why are compact fluorescent light bulbs, improved thermal insulation materials, and energy-efficient appliances not more widely used? Many studies have demonstrated that there exist such technologies (and processes)—ones that simple net-present-value calculations show to be cost-effective at current prices and market interest rates, but which enjoy only limited market success. The phrase market barriers has been used to refer to any factors that may account for this apparent anomaly. Others have used the phrase market barriers even more broadly to include, for example, low energy prices that are a disincentive to the adoption of more energy-efficient technologies. Differing views about the nature of these barriers lead to fundamentally different views about optimal energy use and the role of government policy.

As already noted, the diffusion of economically superior technologies is typically gradual. Awareness of this empirical reality should make the existence of the energy efficiency gap much less perplexing, but it does not answer the question of whether the optimal rate of diffusion is greater than the observed rate. To some degree, responses to the observation that new technologies always diffuse slowly depend on subjective perspectives. Some are inclined to note that if technology diffusion is typically not optimal, then there is no basis for presuming that the market is working efficiently, and hence no reason to eschew government intervention designed to improve it. On the other hand, others are more inclined to maintain that the government cannot possibly worry about trying to optimize the diffusion rate for all technologies, and that the government should hence stay out altogether, even if the no-intervention result is not optimal.

As will be described further here, at a theoretical level there are several reasons why technology diffusion will not, in general, occur at an economically efficient rate. But, if the purpose of assessing the efficiency gap is to identify desirable government policy interventions, then it is necessary to know whether the market barriers that cause slow diffusion can be mitigated by government intervention such that overall resource allocation is improved. In this context, the appropriate definition of the optimal level of energy efficiency is that which is consistent with efficient overall resource use, including efficient use of government resources.

Those market barriers that might justify a public policy intervention to overcome them are referred to in economics parlance as market failures. Normative economics teaches that in the presence of market failures, unfettered markets may not operate to produce outcomes that are socially optimal. When analysts speak of no-cost climate policies based on energy efficiency enhancement, they are often implicitly or explicitly assuming the presence of market failures in energy efficiency. By implication, there are some market barriers—such as "low" energy prices, "high" technology costs, and "high" discount rates—that are not necessarily market failures. In such cases, the existence of an energy efficiency gap does not, in and of itself, call for policy responses. On the other hand, there are also some market failures that do not relate to problems in individual decision-making per se, but that might still provide justification for policy interventions. In other words, even if the energy efficiency paradox is resolved in the sense that people's decisions are found to be consistent with the costs they face, there could be other reasons—particularly environmental pollution from energy use—why the resulting behavior would deviate from the social optimum. These classes of market failures and non-market-failure explanations of the energy efficiency gap are considered next.

4. MARKET FAILURES

In this section, the focus is on several sources of potential market failure that may affect energy-conserving technology adoption rates. Three of these relate to the availability of information. There are also market failure issues that do not help explain nonadoption at current technology costs and energy prices, but which are still relevant to policy debates about the energy efficiency gap. These include environmental externalities, broader innovation and adoption externalities, and issues related to energy supply pricing and national security.

4.1 Inadequate Information

First, information has important public good attributes: once created it can be used by many people at little or no additional cost. It may be difficult or impossible for an individual or firm that invests in information creation to prevent others who do not pay for the information from using it. It is well known that such public goods will tend to be underprovided by ordinary market activity. Second, if the act of adopting a new technology is inherently a source of useful information for others, then the act of adoption creates a positive externality by providing information to others for which the adopter is unlikely to be compensated. It takes time for the many potential users to learn of the new technology, try it, adapt it to their circumstances, and become convinced of its superiority. An important mechanism in this learning process is the observation of the adoption of the new technology by others. If a neighbor or competitor tries something new, and others see that it works, it becomes much safer and easier for the observers to try it. Hence the adopter of a new technology creates a positive externality for others, in the form of the generation of information about the existence, characteristics, and successfulness of the new technology. This phenomenon is often called learning by using. This (positive) externality is another form of market failure.

Incomplete information can also foster principal-agent problems, as when a builder or landlord chooses the level of investment in energy efficiency in a building, but the energy bills are paid by a later purchaser or a tenant. If the purchaser has incomplete information about the magnitude of the resulting energy savings, the builder or landlord may not be able to recover the cost of such investments, and hence might not undertake them. This is another potential form of market failure. A home-builder, acting as agent for the ultimate home-buyer, may have incentives to take actions that are different from what the principal would prefer. The extent to which this market failure is significant in practice is not well established.

4.2 Environmental Externalities

Economic analysis of environmental policy is based on the idea that the potentially harmful consequences of economic activities on the environment constitute

an externality. An externality is an economically significant effect of an activity, the consequences of which are borne (at least in part) by a party or parties other than the party who controls the externality-producing activity. An electricity generator that pollutes the air imposes a cost on society. The firm that owns the generator has an economic incentive to use only as much fuel as it can productively employ, because this input is costly to the firm. In jargon, the cost to society of having some of its fuel used up is internalized by the firm, because it has to pay for that input. But the firm does not (in the absence of appropriate environmental policy intervention) have an economic incentive to minimize the external costs of pollution associated with that fuel.

Although the details and refinements are important, all environmental policies, at their core, are designed to deal with this externality problem, either by internalizing environmental costs so that polluters will make efficient decisions regarding their consumption of environmental inputs, or else by imposing from the outside a level of environmental pollution that policymakers believe to be more efficient than that otherwise chosen by firms. If environmental externalities are not fully addressed by environmental policy—for political or other reasons—the resulting level of energy efficiency will likely be too low. But this may not be true if the government is already intervening to change the energy efficiency of products available in the market place (or is otherwise intervening to control the pollution associated with energy use). For example, Corporate Average Fuel Economy (CAFE) standards result in the production and sale of cars that are more efficient than consumers would otherwise demand. Depending on the actual magnitude of environmental externalities, it is possible that the efficiency of automobiles is greater than would be socially optimal.

4.3 Broader Innovation and Adoption Externalities

In addition to the externality associated with pollution, innovation and diffusion are both characterized by externalities, as well as other market failures. In the case of pollution, the problem is that a polluter imposes costs on others, and hence has an inadequate incentive, from a social perspective, to reduce those costs. With respect to technology, the problem is the reverse. A firm that develops or implements a new technology typically creates benefits for others, and hence has an inadequate incentive to increase those benefits by investing in technology. Pollution is a negative externality, and so the invisible hand allows too much of it. Technology creates positive externalities, and so the invisible hand produces too little of it.

With respect to innovation, the positive externality derives from the public-good nature of new knowledge. Whereas patents and other institutions try to protect firms' investments in innovation, such protection is inherently imperfect. A successful innovator will capture some rewards, but those rewards will always be only a fraction—and sometimes a very small fraction—of the overall benefits to society of the innovation. Hence innovation creates positive externalities in the form of knowledge spillovers for other firms, and spillovers of value for the users of the new technology.

In addition, production costs tend to fall as manufacturers gain production experience in a process commonly called learning by doing. If this learning spills over to benefit other manufacturers, it can represent an additional externality. In any event, the existence of these innovation and adoption externalities suggests a rationale for public support of research and development in general, not for energy-efficient technology in particular. An argument particularly supporting energy-efficient technologies in this regard would require stating that spillovers related to these technologies were somehow greater than for technologies more generally in the economy.

4.4 Market Failures in Energy Supply

4.4.1 Average-Cost Pricing

Actual energy prices, particularly for electricity, may differ from marginal social cost because of subsidies and because of pricing based on average rather than marginal cost. During the 1980s, it was widely perceived that the incremental costs of increasing electricity supplies were significantly greater than the average costs of existing electrical capacity. Because the prices consumers pay are typically based on historical average costs, it was frequently suggested that consumers faced inadequate incentives to conserve electricity. Each kilowatt of capacity that did not need to be built saved society much more than it saved the persons whose conservation decisions reduced the need for such new capacity. If true, this would be one reason why public policy should seek to promote greater energy efficiency than private individuals choose on their own.

Although this argument remains conceptually valid in part, several things have changed since the 1980s that weaken the argument considerably. First, the deregulation of electricity production for about 40% of the U.S. population has meant a movement toward competitive electricity prices; this trend will continue. Second, there is widespread excess capacity in the electricity industry in most of the United States, although there is substantial regional variation. Thus, it is simply no longer true that the incremental cost of capacity is well above the price paid by most consumers. Indeed, given the availability of wholesale bulk power at prices closer to variable cost than to total cost, it could be argued that the social value of reducing electrical utility loads is actually less than the prices paid by most consumers. Furthermore, this situation is likely to prevail for many years, depending on the growth of electricity demand. Thus, regulatory distortions in the utility industry no longer provide an argument for policy interventions to foster energy conservation. One caveat, however, is that at peak demand periods, the marginal cost of supply often exceeds the price. This provides an argument not for energy efficiency in general, but rather for load-shifting to off-peak periods, energy conservation during peak periods, or time-of-day pricing.

With respect to technology incorporated in new buildings, it can be argued that these buildings are likely to last long into the future, at which time new electrical capacity may once again be needed, so that consumers choosing energy-inefficient technology are imposing a social cost above their own energy costs, albeit one that is very uncertain and remote in time. With respect to retrofit investments, however, even this argument is unavailable, because these investments can simply be postponed until such time as they are needed to forestall the need to expand capacity.

4.4.2 Security Externalities

It has also been suggested that there are externalities associated with the economic and military security costs resulting from domestic U.S. dependence on oil imported from politically unstable regions. For this argument to be valid, it would have to be the case that, at the margin, these national security costs are reduced if oil consumption is marginally reduced. This seems unlikely to be the case.

5. NON-MARKET-FAILURE EXPLANATIONS OF THE ENERGY EFFICIENCY GAP

Non-market-failure explanations of the energy efficiency gap consist essentially of explaining why observed behavior is indeed optimal from the point of view of individual energy users. To be useful, such explanations must advance beyond the tautological assertion that if the observed rate of diffusion is less than the calculated optimal rate, there must be some unobserved adoption costs that would modify calculations of what is optimal.

A slightly less tautological approach would be to maintain the assumption—based on general experience—that private agents act in their own interests, unless it can be shown that specific market failures exist. Under this approach, it can quickly be concluded that no paradox exists, unless and until it can be demonstrated that the theoretical market failures already discussed are important in explaining observed behavior. This amounts to a policy prescription that markets should be "considered innocent until proved guilty." There is no scientific basis for such a prescription. On the other hand, it is important to keep in mind that although market failure may be considered a necessary condition for government policy intervention, it is not a sufficient condition. For government policy to be desirable in economic terms, it must be the case that a market failure exists and that there exists a government policy that, in overcoming the market failure, generates benefits in excess of the costs of implementation. Analyses of past government and utility energy conservation programs demonstrate that although some such programs certainly have had positive net benefits, the benefits of others have been lower than predicted.

5.1 Irreversibility and the Option to Wait

One such non-market-failure explanation is that uncertainty about the future benefits of energy-efficient technologies, combined with the irreversible nature of the efficiency investment, makes the effective discount rate for analyzing the net present value of energy savings significantly greater than is typically used in the calculations that suggest the existence of a paradox. Simple net-present-value analysis typically does not account for changes over time in the savings that purchasers might enjoy from an extra investment in energy efficiency, which

depends on trends and uncertainties in the prices of energy and conservation technologies. When making irreversible investments that can be delayed, the presence of this uncertainty can lead to an investment hurdle rate that is larger than the discount rate used by an analyst who ignores this uncertainty.

The magnitude of this option-to-wait effect or option value depends on project-specific factors, such as the degree of energy price volatility, the degree of uncertainty in the cost of the investment, and how fast the prices of energy and conservation technologies are changing over time. The effect is magnified when energy and technology price uncertainty is increased and when energy prices are rising and technology costs are falling more quickly. Under conditions characterizing most energy conservation investments, this effect could raise the hurdle rate by up to about 10 percentage points. On the other hand, if there is no opportunity to wait, this effect can be ignored.

Note that uncertainty, in contrast to imperfect information, is not a source of market failure in and of itself. It is reasonable and appropriate for individuals to take uncertainty into account in making investment decisions, and to apply relatively high hurdle rates to irreversible investments when returns are uncertain. To the extent that consumers' true effective discount rates are high for this reason, this would not represent a market failure or a reason for policy intervention from an economic perspective.

5.2 Unaccounted for Costs and Overestimation of Energy Savings

There are typically costs of adoption that are not included in simple cost-effectiveness calculations. It is by no means costless to learn how a technological improvement fits into a home or firm or to learn about reliable suppliers. Even after basic information about a technology has been disseminated, the purchase price of a new product is only a lower bound on its adoption cost. Another type of hidden cost is the possibility that qualitative attributes of new technologies may make them less desirable than existing, less efficient technologies. An obvious example is the difference in hue between florescent and incandescent lighting and the delay time in achieving illumination with many florescent lights.

Some have argued that not only costly information acquisition but also biased estimates of likely energy savings play a role. There is evidence that analysts have substantially overestimated the energy savings that higher efficiency levels will bring, partly because projections often are based on highly controlled studies that do not necessarily apply to actual realized savings in a particular situation. For example, studies have found that actual savings from utility-sponsored programs typically achieve 50 to 80% of predicted savings. Other studies have drawn similar conclusions based on analysis of residential energy consumption data, finding that the actual internal rate of return to energy conservation investments in insulation was substantially below typical engineering estimates for the returns from such investments. On the other hand, the bias could be offset in the opposite direction, because some studies indicate that consumers systematically overestimate energy savings associated with some types of new technologies.

5.3 Heterogeneity in Energy Users

Another possible non-market-failure explanation for the energy efficiency gap is associated with the fact that even if a given technology is cost-effective on average, it will mostly likely not be for some individuals or firms. If the relevant population is heterogeneous—with respect to variables such as the purchaser's discount rate, the investment lifetime, the price of energy, the purchase price, and other costs—even a technology that looks very good for the average user will be unattractive for a portion of the population. Heterogeneity in these and other factors leads to differences in the expected value that individual purchasers will attach to more energy-efficient products. As a result, only purchasers for whom it is especially valuable may purchase a product. Depending on how the efficiency gap is measured, such underlying heterogeneity can provide yet another non-market-failure explanation. For example, it may not make sense for someone who will only rarely use an air conditioner to spend significantly more purchasing an energy-efficient model—they simply may not have adequate opportunity to recoup their investment through energy savings. Analysis based on single estimates for the important factors previously discussed—unless they are all very conservative—will inevitably lead to an optimal level of energy efficiency that is too high for some portion of purchasers. The size of this group, and the magnitude of the resulting inefficiency should they be constrained to choose products that are not right for them, will of course depend on the extent of heterogeneity in the population and the assumptions made by the analyst.

6. DISCOUNTING AND IMPLICIT DISCOUNT RATES

Much discussion surrounding the energy efficiency gap is couched in terms of arguments about the appropriate discount rate to use in evaluating energy savings. It is useful to distinguish among a number of separate and distinct questions regarding the appropriate discount rate. First, an attempt can be made to estimate the implicit discount rate that consumers appear to be using when they make energy efficiency decisions. Second, there can be speculation about the correct discount rate for consumers to use in making such decisions. Third, the implicit discount rate (explained below) or the correct rate can be compared with other private discount rates in the economy. Fourth and finally, it can be asked whether any of these rates are equal to the social discount rate that ought to be applied in evaluating future energy savings when making public policy decisions.

The observation that consumers have high implicit discount rates when they make energy efficiency decisions is actually neither more nor less than a restatement of the existence of the energy efficiency gap. To estimate implicit discount rates, studies examine decisions actually made and calculate the discount rate that makes those decisions privately optimal, given estimates of the costs and future energy savings of the investments and given the assumption that there are no important market failures impeding the adoption of efficient technologies. There is substantial empirical evidence of implicit discount rates for energy-conservation investment decisions in the range of 20 to over 100% for products such as air conditioners, space heating, and refrigerators. The energy efficiency gap can thus be restated as the observation that these implicit discount rates appear to be much higher than other interest rates in the economy. To observe that implicit discount rates are high, however, says nothing about the reason people make the decisions they make. One possibility is that people are applying normal discount rates in the context of significant market failures; another possibility is that people actually utilize high discount rates in evaluating future energy savings. Note that "actually" does not mean "literally." It is not necessary that people know how to perform net-present-value calculations; rather, they make decisions balancing costs today and costs tomorrow, with those trade-offs incorporating their true discount rate. The truth is likely some combination of the two. Thus, high implicit discount rates, on their own, are neither a market failure nor an explanation of observed behavior.

Further, if only the relevant investment decisions are observed, it is fundamentally impossible to determine whether the observed behavior results from market failures, from truly high discount rates, or perhaps from misestimation of the true costs and savings of adoption. To make that distinction would require either observing something that distinguishes the market-failure explanations from the non-market-failure ones, such as whether people with better information are more likely to purchase more efficient models, or else calculating from some basis other than the investment decisions what an appropriate discount rate for these investments would be. Thus, to investigate the energy efficiency gap by changing the discount rates people use in making investment decisions amounts to assuming the answer. If the outcome with lower discount rates is considered the optimal result, then it is implicitly assumed that all market barriers are indeed market failures. Conversely, postulating that the optimal result is the one in which consumers are assumed to discount at observed high implicit rates, then it is implicitly assumed that there are no market failures.

To make this a bit more concrete, suppose that through calculations it is found that consumers' true discount rates for some set of energy efficiency investments are approximately 20%—higher than mortgage interest rates, but in the range of rates on personal credit cards. What would this suggest for public policy? If mandatory efficiency standards were being considered, for example, then requiring efficiency any greater than what someone with a 20% discount rate would choose would have the effect of making that consumer worse off. Thus, to the extent that high implicit discount rates correspond to truly high discount rates, rather than to market failures, there is nothing particularly wrong with those high rates, and they do not correspond to any efficiency gap that ought to be addressed by public policy. Instead, the question of whether relevant market failures exist is again the issue.

Finally, there is the issue of the social discount rate. Several decades of academic and policy debates have failed to resolve fully the question of what the social rate of discount should be, even as a conceptual matter. However, there is a strong argument that policies to increase energy efficiency can be justified only on the basis of the appropriate true private rate of discount, not some (lower) social rate. If the only reason why investment in energy-efficient technology is suboptimal is the divergence

between the private and social discount rates, then it is certainly true that a theoretical argument could be made to support public policies to increase that investment. The problem is that this same argument would also apply with equal force to all other forms of investment—plant and equipment, research, education, and so on. It may be that the government should be doing more to encourage all of these forms of investment, but that is surely an issue beyond the scope of energy policy.

Further, if the social rate of discount is really very low, then the set of available investment opportunities that should be undertaken probably exceeds the nation's annual gross national product. Obviously, the government can not undertake all of these projects. If the notion that public policy should have as its objective undertaking all investments for which rates of return exceed the social discount rate is taken seriously, then the reasonable prescription is to increase investment, beginning with the investments with the highest rates of return. But increasing investment reduces consumption, and long before investment opportunities were exhausted, consumption would be so significantly reduced that the social discount rate would rise. Increasing investment up to the point where the private and social rates of return coincide can be imagined, but it is impossible to know how much greater investment would be at that point or what the discount rate would be. Given this, a policy prescription to increase investment in energy efficiency should be based on a conclusion that the (social) rate of return to this form of investment is higher than the rate of return available on other forms of investment in the economy. Otherwise, this form of investment could well be increasing at the expense of other forms that are even more beneficial. Of course, saying that the social rate of return on energy efficiency investments exceeds the social rate of return on other investments means precisely that current investment in energy efficiency is inadequate when evaluated at the appropriate private rate of discount.

7. SUMMARY

It is possible to synthesize much of the above discussion by examining graphically the concepts behind the major, alternative notions of the energy efficiency gap. To understand the basic elements of the debate, it is helpful to distinguish first between energy efficiency and economic efficiency, as in Fig. 3. The vertical axis measures increased energy efficiency (decreased energy use per unit of economic activity). The horizontal axis measures increased economic efficiency (decreased overall economic cost per unit of economic activity, taking into account energy and other opportunity costs of economic goods and services). Different points in the diagram represent the possible energy-using technologies available to the economy as indicated by their energy and economic efficiency. As a concrete illustration of this distinction, consider two air conditioners that are identical except that one has higher energy efficiency and, as a result, is more costly to manufacture because high-efficiency units require more cooling coils, a larger evaporator, and a larger condenser, as well as a research and development effort. Whether it makes sense for an individual consumer to invest in more energy efficiency depends on balancing the value of energy that will be saved against the increased purchase price, which depends on the value of the additional materials and labor that were spent to manufacture the high-efficiency unit. The value to society of saving energy should also include the value of reducing any associated environmental externalities; but again this must be weighed against the costs. Starting from the baseline situation, as represented by the lower left corner of Fig. 3, the adoption of more energy-efficient technology is represented as an upward movement. But not all such movements will also enhance economic efficiency. In some cases, it is possible simultaneously to increase energy efficiency and economic efficiency. This will be the case if there are market failures that impede the most efficient allocation of society's

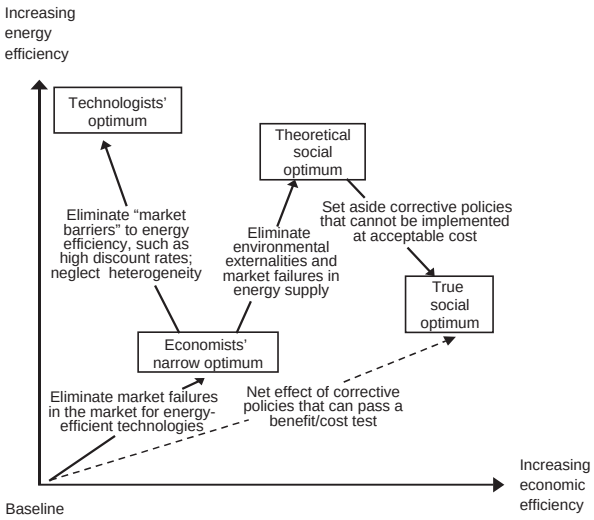

FIGURE 3 Alternative notions of the energy efficiency gap.

energy, capital, and knowledge resources in ways that also reduce energy efficiency. These are examples of what economists and others refer to as win-win or no regrets measures.

At the risk of excessive simplification, technologists can be characterized as believing that there are plentiful opportunities for low-cost or even negative-cost improvements in energy efficiency, and that realizing these opportunities will require active intervention in markets for energy-using equipment to help overcome barriers to the use of more efficient technologies. In terms of Fig. 3, the economist's notion of a narrow optimum is where market failures in the market for energy-efficient technologies have been corrected, the result being greater economic efficiency and energy efficiency. This optimum is narrow in the sense that it focuses solely on energy technology markets and does not consider possible failures in energy supply markets (such as underpriced energy due to subsidies or regulated markets) or, more important, environmental externalities associated with energy use (such as global climate change). Market failures in the choice of energy-efficient technologies could arise from a variety of sources, as discussed previously.

Eliminating broader market failures takes us to what is called the theoretical social optimum in Fig. 3. This represents both increased economic and increased energy efficiencies, compared with the economists' narrow optimum. This ignores the reality that the baseline efficiency already reflects policy measures motivated by environmental concerns. As emphasized previously, it is possible that these measures already achieve as much or more additional efficiency as would be justified by the environmental externalities of energy use. But not all market failures can be eliminated at acceptable costs. In cases in which implementation costs outweigh the gains from corrective government intervention, it will be more efficient not to attempt to overcome particular market failures. This takes us from a theoretical social optimum to what is referred to as the true social optimum in Fig. 3. Market failures have been eliminated, but only those for which elimination can pass a reasonable benefit–cost test. The result is the highest possible level of economic efficiency, but a level of energy efficiency that is intermediate compared with what would be technologically possible.

In contrast to the economist's perspective, if non-market-failure market barriers (such as high discount rates caused by uncertainty about payback) were also removed, the technologists' optimum would be achieved. This alternative notion of an optimum is found by minimizing the total purchase and operating costs of an investment, with energy operating costs being discounted at a rate the analyst (not necessarily the purchaser) feels is appropriate. Clearly, if no distinction is made between barriers to adoption that are market failures and those that are not, and no choice is made to eliminate all barriers, a higher estimate of energy efficiency will be achieved, but not economic efficiency. An important implication of this perspective is that comparisons of an engineering ideal for a particular energy use with the average practice for existing technology are inherently misleading, because the engineering ideal does not incorporate all the real-world factors influencing energy technology decision-making.

How these alternative definitions of optimal energy efficiency and the energy efficiency gap relate to specific empirical estimates depends, of course, on the assumptions that underlie those estimates. Many published studies of the potential for energy efficiency correspond to what is labeled technologists' optimum. That is, they assume that the resolution of the energy paradox must be that the simplest calculations are correct and that a host of market failures explain observed behavior. Certainly, estimates of efficiency potential derived from forcing low discount rates into analyses of consumers' and firms' decisions do not correspond to any policy-relevant notion of optimal. Unfortunately, it is easier to explain what is wrong with existing approaches than it is to specify what is the right approach. It is clear, however, that in order to understand what is wrong with some of the existing approaches to estimating the energy efficiency gap and to begin the process of searching for the right measure, the first requirement is to disentangle market-failure and non-market-failure explanations for observed decisions regarding energy-efficiency investments.

Glossary

depletable resources Those natural resources for which total physical availability is fixed over any meaningful time horizon for economic decision-making; oil and coal are classic examples. The quality and other attributes of different deposits may vary.

economic scarcity The result of not having enough resources to meet all of one's needs. Consequently, choices must be made and something of value must be foregone or given up in order to gain something else of value. In the case of depletable resources, if there is not enough of the resource to meet all needs in each time period, then there is a scarcity value to the resource stock.

Hotelling rule Named for Harold Hotelling, the intertemporal efficiency condition in a simple depletable resource model that the *in situ* value of the resource stock increases at the rate of interest. The rule does not hold in such a simple form in more complex models, such as when there are stock effects.

Hotelling valuation principle The valuation of a resource deposit on the basis of current price, marginal extraction cost, and the amount of the resource in the deposit.

***in situ* value** The incremental increase in present value that would occur with a one-unit increase in the initial resource stock. It also is referred to in the literature as the "user cost" or "scarcity rent" associated with depletion of the resource stock.

marginal cost The added economic cost of increasing an activity such as resource extraction or reserve discovery.

stock effect Usually, the increase in marginal extraction cost that occurs when a resource stock is depleted, either because it is physically more difficult to extract the resource (e.g., well pressure declines) or because lower quality or higher cost deposits are exploited.

The basic logic underlying all neoclassical economic theories of "optimal" energy supply is maximization of the present value of some stream of economic returns. The economic theory of optimal resource depletion has evolved since Hotelling's classic 1931 article. The power of the theory to support improved empirical understanding of actual behavior is considered herein. The empirical literature indicates that this theory has so far provided only limited empirical understanding.

1. INTRODUCTION

The economic principles governing the efficient production of depletable energy resources (oil, natural gas, and coal) have been a subject of interest and controversy for over 70 years. The pathbreaking article on the subject by Hotelling in 1931 was motivated by then-current concerns about scarcity of energy and other natural resources that have a remarkably familiar ring to contemporary ears. More recently, the energy crisis of the 1970s motivated new concerns about the availability of sufficient energy resources

and the capacity of economic markets to allocate those resources effectively over space and time.

In this article, the basic logic underlying all neoclassical economic theories of optimal energy resource provision, maximization of the present value of some stream of economic returns, is first presented and discussed. Then, how the economic theory of optimal resource depletion has evolved since Hotelling's article is assessed. Considered in turn are theories of economically efficient energy resource extraction and new resource development. After presenting the basic theoretical framework, the discussion centers on extensions incorporating investment in fixed production capacity, uncertainty, and various market distortions, as well as extensions incorporating nondepletable "backstop" energy resources.

The utility of an economic theory is to be found not merely in its conceptual elegance, but also in its power to support improved empirical understanding of actual behavior. The empirical literature indicates that this work has so far provided only limited empirical understanding of observed energy supply behavior. Some key examples in which the theory and application of depletable energy supply have been developed in the literature. Some relatively recent surveys provide more detailed references (those by Cairns, Walls, Epple and Londregan, Toman and Walls, and Krautkraemer).

2. BASIC HYPOTHESES IN THE ECONOMICS OF DEPLETABLE ENERGY SUPPLY

The fundamental assumption underlying all of mainstream economic theory is that economic actors are motivated to make choices by the goal of maximizing some measure of economic returns. The textbook model of commodity supply is a simple case in point. In that model, competitive producers (producers lacking any market power, taking prices of inputs and outputs as given) seek to maximize profit, the excess of gross revenue over their opportunity cost of production, including returns to capital and entrepreneurial effort. Profit is maximized when the market price of output, a measure of incremental gain from expanding production, equals the incremental cost of output expansion taking into consideration all possible technological possibilities for cost-effectively combining various inputs.

The same assumption underlies the economics of depletable energy supply. However, in that theory, the measure of returns assumed to motivate behavior is a present value of current and future net revenues that accrue over time from a sequence of production decisions. A present-value metric is used in depletable energy economics because (for reasons explained further later) the act of producing or developing more or less resource today has unavoidable consequences for future potential returns, owing to the interplay of economics, geology, and technology. If these future consequences were ignored by totally myopic producers, their cumulative effects would come as an unanticipated and unwelcome surprise later. Because there is every reason to assume that producers are aware of these intertemporal connections and, being aware, are motivated to account for them, it makes more sense from the standpoint of theoretical logic to suppose that producers systematically account for them in evaluating the present value of a sequence of decisions over time.

The foregoing does not imply that energy producers are omniscient or free of forecast error. That is prima facie not the case. Later in this article there is a discussion of how the theory of depletable energy supply has been extended to incorporate various kinds of uncertainties. Those extensions emphasize the key role that expectations play in influencing supply behavior. What is assumed in the economics of depletable energy supply, however, is that producers are capable of avoiding systematic and persistent errors over time. This assumption can and sometimes is questioned, but no known persuasive economic theory based on alternative assumptions has been formulated.

It is worth noting in this regard that the calculation of a present value involves the choice of discount rate(s) to deflate future returns relative to current returns. In characterizing producer behavior in depletable energy supply theory, the appropriate discount rates would reflect the competitive rate of return capital invested in the energy industry could earn in other uses, including adjustments for various kinds of financial risks. In practice, market-based rates of return put disproportionate weight on returns in the first few years of an activity, thus the assumption that producers are not systematically biased in their expectations of future returns is not as difficult to swallow as it might first seem.

The standard theory of depletable energy supply can be extended well beyond a simple description of a single competitive firm. In addition to uncertainty, already noted, the theory can be extended to incorporate a number of market distortions, including property rights problems, environmental spillovers, taxes, and market power. However, efforts to

describe the exercise of market power by energy producers such as the Organization of Petroleum Exporting Countries (OPEC) and its members have been especially unsuccessful. A number of political and other factors must be incorporated to treat market power properly.

3. THE SIMPLE "CAKE-EATING" MODEL OF RESOURCE EXTRACTION

In the simplest case, it is assumed that a known, finite stock of the energy resource is being allocated over some number of time periods to maximize the present value of net returns. Producers calculate returns to extraction in different periods based on price expectations (in the simple model, expectations are assumed always to be realized), and knowledge of costs based on technological and geological information. Returns across periods are linked in this model by the simple fact that any energy resource produced in some period is by definition not available for production in future periods (energy resources obviously cannot be recycled). Only a finite amount of energy resource is available in this framework, and all of it will eventually be extracted. But the finite availability of fossil fuels is not the only key feature of energy supply, even in the simplest framework. In this framework, the present value of net returns is maximized when the "equimarginal principle" is satisfied. This principle requires that the marginal net return from the extraction and sale of the energy resource be the same in every time period with positive extraction. This, in turn, requires the current value of marginal net profit to be increasing at the rate of discount applied to future returns.

This principle can be stated in simple mathematical terms. Let P_t denote the price of extracted energy resource at time t, and q_t is the quantity extracted at time t, $C(q_t)$ is the cost of extracting P_t, and δ is the discount rate. Then, under the equimarginal principle, it must be that

$$P_0 - C'(q_0) = \frac{P_1 - C'(q_1)}{(1+\partial)^1} = \frac{P_2 - C'(q_2)}{(1+\partial)^2} = \frac{P_t - C'(q_t)}{(1+\partial)^t} = \lambda \quad (1)$$

where λ denotes the common present value of marginal net profit. This number can be interpreted as the present-value shadow price or *in situ* value of the resource stock, because it reflects the incremental increase in present value that would be enjoyed if a resource owner could experience an augmentation of resource stock. It also is referred to in the literature as the "user cost" or "scarcity rent" associated with depletion of the resource stock.

At any point in time, then,

$$P_t = C'(q_t) + (1+\partial)^t \lambda. \quad (2)$$

In any successive time periods,

$$\frac{p_{t-1} - C'(q_{t-1})}{(1+\delta)^{t-1}} = \frac{P_t - C'(q_t)}{(1+\partial)^t} \quad \text{or}$$
$$P_t - C'(q_t) = (1+\delta)[P_{t-1} - C'(q_{t-1})]. \quad (3)$$

These conditions are known as the Hotelling rule (see below) in honor of Hotelling's contribution to the literature. The first efficiency condition requires that at any point in time, the marginal gain from additional extractions equals the full opportunity cost of extraction, including the present value of future losses from a diminished future resource stock as well as conventionally defined incremental production costs. The second efficiency condition requires that the rate of return to holding the asset be equal to the rate of discount. This condition can be thought of in terms of asset market equilibrium, because presumably the discount rate is the rate of return that could be earned by investing in other assets. The markets for assets will not be in equilibrium if the rate of return to holding one asset is greater than the rate of return to holding some other asset. If that were the case, investment in the higher (lower) return asset would increase (decrease). Thus, asset market equilibrium requires that the rate of return to holding a nonrenewable resource asset be the same as the rate of return to other assets in the economy as represented by the discount rate.

The user cost, or shadow price of the remaining stock, depends on future extraction costs and the future price path. These depend, in turn, on developments in resource production technology, the size of the remaining stock, and future availability of substitutes. The future price of the resource can depend on the general level of economic activity, so expectations about population and economic growth are important determinants of the scarcity rent or user cost. Technological progress can affect extraction cost, the availability of substitutes, and the remaining resource stock. For example, the development of directional drilling techniques has lowered the cost of extraction and increased the amount of recoverable oil from some deposits. Increased computing capability has enhanced the ability to use information from exploration activities

and lowered the cost of discovering and developing new oil reserves.

The model just described can be extended in several directions. Switching from considering a single competitive producer to a price-setting monopolist, it is possible to infer that the monopolist will reallocate output from earlier to later in the life of the resource base, because this generates higher prices early on, and near-term returns are worth more than discounted future returns. But because the stock of resource is fixed and is necessarily exhausted under either market structure, resources that are not produced earlier will be produced later. If, to take another scenario, the stock of the resource is fixed but uncertain, then, again, extraction early on would be less than in a situation with certainty about the resource stock, because producers would put weight on the possibility of more scarce and therefore more valuable carry-over stocks. If, on the other hand, there is a renewable backstop energy form that can be supplied if the price of depletable energy climbs high enough, the Hotelling rule will still hold, but the net price path will rise at the rate of discount until it meets the unit cost of the backstop just at the point of full depletion.

Despite its seeming intuitive appeal, however, the basic Hotelling model is built on very shaky assumptions. It assumes a known stock of a resource of homogeneous quality and that the extraction technology does not change over time. In fact, nonrenewable resource stocks are not a given: exploration for new deposits as well as the further development of existing deposits are important features of fossil fuel supply. For many nonrenewable resources, including fossil fuels, the discovery of additional deposits has exceeded consumption, so that known, or proved, reserves has actually increased over many time periods. For example, U.S. oil reserves increased from 13 billion barrels in 1930 to 33.8 billion barrels at the end of 1990, and production in that period was 124 billion barrels. More than 30 billion barrels were produced from 1991 to 2000, but reserves at the end of 2000 were 29.7 billion barrels. The increase in world oil reserves is even more dramatic—proved reserves increased from 660 billion barrels at the end of 1980 to 1009 billion barrels at the end of 1990. This increased slightly to 1046 billion barrels at the end of 2000, even though 250 billion barrels were produced from 1991 to 2000.

Nonrenewable resources, including energy resources, also vary in quality and in their cost of extraction. Moreover, cost conditions for extraction in a specific petroleum reservoir change over the

economic life of the reservoir: as natural drive is depleted, cost rises and yield per unit extraction effort falls, unless costly secondary and other recovery enhancement measures (e.g., injection of water or carbon dioxide) are undertaken to stimulate reservoir pressure. In short, resource stocks are neither fixed nor homogeneous, contrary to the assumptions underlying the simple Hotelling rule. It is not surprising, therefore, that the simple rule has done poorly in describing actual supply behavior (see later). We must look to a richer theory if we want to better understand observed behavior.

Empirically, the resource price should reflect both the marginal extraction cost and the scarcity rent, therefore generally it would be expected from Eq. (3) that the price of a nonrenewable resource would be increasing over time. However, there has not been a persistent increase in prices of fossil fuels (or other nonrenewable resources), but rather fluctuations over various time periods. Fossil fuel prices fell over much of the 20th century, peaked dramatically in the 1970s and early 1980s, and have generally fallen since then (see Figs. 1–3). This further illustrates the need for a richer theory to capture observed behavior.

4. A MORE GENERAL THEORY OF ECONOMICALLY EFFICIENT DEPLETABLE RESOURCE SUPPLY

A more useful general theory must take into account the stylized facts already noted—that resources are heterogeneous, with extraction costs that vary systematically over time with depletion of resource deposits—and that resources can be augmented through exploration and development. Moreover, a complete theory must account for the high degree of capital intensity of the extractive sector and the implications of this in terms of potential constraints on productive capacity.

4.1 Resource Extraction

Let us first address generalization of the Hotelling extraction model to deal with resource heterogeneity. Among the many good papers to deal with this case, those of Pindyck (in 1978) and Heal (in 1976) are particularly noteworthy. To examine this part of the problem, continue to treat reserves as fixed for the moment, and ignore capacity constraints.

The cost of extraction is assumed to be given by some function, $C(q_t, R_t)$, where R_t is the stock of resource that has not yet been depleted. Incorporating this "stock effect" into extraction cost is a simple if somewhat imprecise way to introduce resource heterogeneity into the extraction cost relationship. The relationship is relatively straightforward if we focus on a single energy resource development: as the resource in this development declines, cost is assumed to rise (deeper pits to be dug, more waste material to be removed, weaker reservoir pressure). It is less straightforward if we are attempting to describe heterogeneity among resource deposits (as is discussed later). With cost rising as the resource is depleted, the assumption of complete physical exhaustion from extraction—which is not empirically realistic anyway—no longer makes sense in the theoretical model either. Instead, what drives extraction behavior is economic exhaustion of the resource—at some point, cost becomes so high relative to the price what buyers are willing to pay that a particular mine or field is abandoned.

With resource heterogeneity and incomplete physical exhaustion, the simple Hotelling model summarized by the efficiency conditions [Eqs. (1)–(3)] no longer applies. Instead, the equimarginal principle must be modified as in the following equation:

$$\begin{aligned} P_t &= C_{qt} + (1+\partial)^t \lambda_t \\ &= C_{qt} + \sum_{s=t+1}^{T} (-C_{Rs})(1+\partial)^{t-s}. \end{aligned} \tag{4}$$

In Eq. (4), subscripts q and R on cost C signify rates of change of cost with respect to the extraction rate and the depletion of reserves, respectively. The term λ_t is a generalized measure of user cost that reflects the rate at which future extraction cost is increased as a consequence of future depletion. This stock effect is part of the full opportunity cost of current extraction. Manipulating Eq. (4) a bit algebraically yields

$$P_t - C_{qt} = (1+\partial)\left[P_{t-1} - C_{q,t-1}\right] + C_{Rt}. \tag{5}$$

Equation (5) shows how with increased stock providing a kind of "dividend" in terms of holding down extraction cost over time ($C_{Rt} < 0$), the net return from depletion no longer has to rise at the rate of the discount rate to induce resource owners to retain their holdings. Application of this framework to describe the depletion over time of different energy deposits is frequently done, but is somewhat more problematic. In the simplest case, where resource quality varies across deposits but is homogeneous within a deposit, the optimal extraction pattern generally requires exploiting those deposits in a

sequence from low cost to high cost. The user cost for a lower cost deposit is greater than the user cost for a higher cost deposit. At the time of transition from one deposit to the next most costly deposit, the marginal extraction cost plus user cost is the same at each deposit. This implies that the resource price rises at a rate slower than the rate of interest during the transition. Simultaneous extraction from different deposits can be optimal when marginal extraction cost at a deposit increases with the extraction rate, or if extractive capacity is fixed.

The current pattern of petroleum extraction obviously violates the rule of exploiting lower cost deposits before higher cost deposits. The cost of extraction from petroleum reserves in the Middle East is much lower than the cost of extraction from reserves in the United States. This suggests that the simple modeling device of incorporating resource inventory in the extraction cost relationship probably aggregates over and therefore blurs some important distinctions. The case of petroleum is further complicated by the actions of large oil producers in OPEC using market power to restrict their output to levels below what would occur under perfect competition. The higher-than-competitive price that results provides the incentive for higher cost producers to extract from their reserves. The higher noncompetitive price also distorts the capital investment decision, because the marginal cost of investment in capacity varies widely, from $343 in Saudi Arabia to over $10,000 in the United States. Efficient allocation would result in the equalization of marginal investment cost across geographical regions.

4.2 Exploration and New Resource Development

Exploration is an economic activity and, like other economic activities, marginal benefit and marginal cost play a key role in determining how much exploration occurs. Again, Pindyck published a key paper in the development of this analysis. Expenditures on exploration and development reduce current profit with an expected return of adding valuable reserves for future exploitation. The efficient level of exploration activity balances the expected marginal cost of exploration with the expected benefit of exploration.

The expected marginal benefit of exploration is not just the discovery and development of new reserves per se; in a model of incomplete resource exhaustion, the quantity of the resource stock is not determinative. The marginal benefit of exploration comes from the discovery of reserves for which the cost of development and extraction is less than or equal to the cost of the reserves currently being depleted. In other words, the marginal value of new reserves equals the user cost of current resource depletion along an efficient time path of extraction and new reserve development.

One feature of the full opportunity cost of exploration activity is that it reduces the stock of exploration opportunities, so that future additions to reserves tend to become more costly. In other words, there is a user cost similar to that in Eq. (4) associated with depleting the stock of exploration opportunities, in addition to direct exploration costs. If the conditions for efficient exploration, development, and extraction are then combined, we get

$$\begin{aligned}\text{Price} &= (\text{marginal extraction cost}) \\ &\quad + (\text{extraction user cost}) \\ &= (\text{marginal extraction cost}) \\ &\quad + (\text{marginal direct cost of finding new reserves}) \\ &\quad + (\text{user cost of reduced long-term development prospects}). \end{aligned} \tag{6}$$

The heuristic equality in Eq. (6) can be related to intuition about opportunity cost in economics more generally. The extraction user cost is the cost of depleting an existing inventory, which can be replenished, but only (in the model) at an ever-rising cost. The sum of the marginal extraction cost and the marginal direct cost of finding new reserves gives a measure of the cost of using and replacing the inventory, but it ignores the ultimate cost of natural capital depreciation reflected in the user cost of reduced long-term development prospects.

Once we allow reserves to vary endogenously with economic (and technological) conditions, the inexorable upward movement of prices implied by Eq. (3) or even Eq. (5) no longer need hold. Depending on the degree to which current extraction costs are rising as a consequence of depletion and the cost of new reserve additions, including their user cost, it is possible in the model for new discoveries to outstrip depletion, at least for awhile, causing a U-shaped energy price path. This is a reassuring finding, because such behavior has been observed in energy and other resource markets, and a model incapable of replicating such behavior would have little use. The ability to de facto enlarge reserves through technological breakthroughs that increase recoverability and lower the costs of extraction from existing deposits, or make new deposits easier to find and access (lowering reserve

replacement costs), likewise could exert downward pressure on prices, possibly for a long period of time. The simple model of endogenous exploration and reserves makes the simplifying assumptions that reserves are found on average in order of increasing cost and can be found in infinitely divisible amounts. Given the uncertainties surrounding the exploration process, the former assumption obviously is an oversimplification. When the discovery of deposits is more random, the aggregate extraction cost function cannot be described by a reserve stock indicator alone.

If the discovery of deposits is "lumpy," exploration and discovery can occur in "episodes," with intervals of no exploration between those episodes. Exploration does not generally occur in strictly discrete episodes, but it does vary with the resource price, and large discoveries do put significant but temporary downward pressures on price. The theory would then predict that the *in situ* value of the resource increases between major discoveries and jumps up or down when exploration occurs, depending on whether the exploration outcome is less or more favorable than expected. The resource price path can follow a "sawtooth" pattern while still having a downward trend over some time periods, depending on the actual exploration outcomes. The likelihood that the resource price will be increasing over time increases as unexplored prospects become scarcer.

Exploration also provides new information about future exploration prospects that can lead to revised expectations about the future value of the resource stock and generate new expected time paths for the resource price and quantity extracted. For example, a firm may revise its expectations about the probability of successful exploration either upward or downward in response to information obtained from its current exploration. In this case, a variety of patterns are possible for the realized price path, including a generally downward trend. The arrival of previously unanticipated information can alter the resource price, extraction, and exploration paths so that the observed price path deviates systematically from a deterministic calculation. The observed time paths for the resource price and *in situ* resource value may represent a combination of the initial portion of many different expected price paths rather than outcomes along one fully anticipated price path. Moreover, because individual energy producers can learn something about the information possessed by others via observing their behavior (e.g., by another producer not drilling in a certain area), information has certain public good aspects. To ensure that enough information about energy resources is collected and disseminated to society at large, it may be necessary for the government to undertake or underwrite investments in resource delineation.

4.3 Capacity Investment and Capacity Constraints

The basic nonrenewable resource model does not capture the capital intensity of extractive industries. The development and extraction of fossil fuels are capital intensive, and the timing and size of investment in extractive capacity are functions of the cost of capital and the expected price path. Once the existence of capacity constraints is incorporated, the behavior of the energy resource price along an efficient path generally will depart from the kind of behavior implied by Eq. (5) (or its extension to incorporate new reserve additions). This problem, too, has been studied by a number of authors (Lasserre, Powell and Oren, and Cairns and Lasserre).

If extraction is expected to decrease over time, either because the present value price of the resource is declining or the extraction cost increases with depletion, the extractor would seek to reduce its capital input over time if it were able to do so. However, this is not possible if capital is nonmalleable (i.e., once invested in oil fields, it cannot easily be converted into rail car investments). The energy-producing firm takes this into account when the initial investment is made, and the initial capital investment is lower than it would have been if capital were malleable. Once in place, this lower initial extractive capacity is likely to constrain the rate of extraction from the deposit, at least early in the extraction horizon. In addition, it may be relatively costly to increase extractive capacity, at least quickly. Firms may invest in advance of the need for some capacity in order to smooth out their investment costs over time, but they will also invest slowly in response to previously unanticipated price increases. Consequently, the short-run supply curve for an energy resource may be very inelastic and so variations in market demand (especially increases) may be mediated more by price changes than by quantity changes. The result is that short-term energy prices can be relatively volatile.

In the standard nonrenewable resource model, an increase (decrease) in the interest rate decreases (increases) the relative value of extraction in the future relative to current extraction, and so tilts the depletion path toward the present and away from the future. However, if a large capital investment is necessary before extraction begins, an increase in the

interest rate increases the cost of the capital investment. Thus, a higher interest rate reduces the incentive to use capital, and can lead to lower rather than greater initial extraction whether or not capital is malleable. The effect of the higher interest rate on the capital investment outweighs the effect of the higher interest rate on user cost if the initial resource stock is relatively large. A lower interest rate increases conservation if the interest rate is low (when user cost is high and capital cost is low), but decreases conservation when the interest rate is high (user cost is low and capital cost is high). A higher (lower) interest rate also can increase the capital cost of a backstop technology, increasing the maximum, or choke, price for the depletable energy resource and resulting in less (more) rapid extraction.

5. EFFECTS OF UNCERTAINTY

There is uncertainty regarding the future values of many important influences on the intertemporal supply of depletable energy resources: future price, future extraction cost, the costs and outcome of exploration and development activities, and the cost and timing of the availability of a backstop technology. The intertemporal extraction and resource development patterns and price path are affected by uncertainty in a variety of ways, depending on the source and nature of the uncertainty. From a financial perspective, the risk associated with holding reserves of a depletable energy resource can be mitigated by also owning other assets. The necessary return to holding the energy resource asset—including the rate of *in situ* appreciation plus the benefits of increased reserves in moderating costs—can be less if the return is negatively correlated with the return to other assets in a portfolio, thereby reducing overall risk.

Even with modern developments in financial markets, such as energy commodities futures that more tightly link energy and financial markets and provide added options for risk management, in practice it is not possible for energy producers to completely "insure" away fluctuations in net income. Moreover, firms will not be indifferent to risks even if their basic management posture is what economists call "risk neutral." Work by Pindyck and others shows that these impacts depend on the curvature of incremental cost relationships, among other factors. For example, uncertainty about the growth of demand would shift extraction from the future to the present; if the degree of uncertainty increases with time, a limiting case would be the risk of expropriation, meaning no return from future production. Uncertainty about reserves could increase or decrease the marginal value of new discoveries compared to a situation of the same average conditions with no uncertainty.

6. MARKET FAILURES AND DISTORTIONS

Assessing the effects of various market failures and distortions on depletable energy supply is complicated by the inherently intertemporal nature of these resources. Whether a market imperfection results in depletion that is more or less rapid or extensive than the socially efficient depletion rate or volume depends on how the distortions change over time and interact with dynamic changes in resource scarcity signaled by the extraction and exploration user costs. For example, a monopolist would want to restrict output to raise price and increase returns. This would mean a lower cost of extraction in the future compared to a competitive industry facing the same demand conditions and extracting more quickly. (In actuality, demand conditions would change in response to the higher monopoly prices, as energy users adapted to more energy-efficient and alternative-energy technologies.) This, in turn, would encourage more output. Nevertheless, the monopolist could restrict output over time in such a way that the cumulative depletion of the resource (and cumulative development of new resources over time) was less than under competition. This is a different prediction than the one obtained from a simple model with fixed homogeneous reserves.

Government interventions also can tilt the market's depletion path toward the present or the future. Energy resource industries are subject to a variety of taxes in addition to the taxes paid by firms generally. One motivation for depletable resource taxation is that depletable natural resources such as fossil energy are part of the national heritage, and resource rents should accrue to the general welfare. Depletable energy resources can be subject to severance taxes per unit extracted or royalty payments as a percentage of the resource price. In general, the effect of such a tax on the intertemporal extraction pattern depends on how the present value of the tax changes over time as well as on the magnitudes of depletion effects in the cost structure. For example, the present value of a constant severance tax decreases over time and so shifts extraction from the present to the

future. However, the tax still reduces net returns in any period compared to a no-tax alternative, thereby reducing the contemporaneous incentive to extract. Although less extraction would moderate the depletion effect on cost, it is still likely that total recovery of the energy resource will fall over time as a result of the tax. In particular, reserves that were formerly marginally economic to extract become subeconomic. Moreover, the tax would reduce the return to investment in new reserves.

The extraction and consumption of energy resources are associated with a wide variety of environmental externalities. The effect of externalities on the market's depletion path can depend on the exact nature of the externality. There are two broad categories of externalities: flow externalities and stock externalities. Flow externalities represent a situation in which the environmental damage is a function of the current rate of energy production or consumption. An example relevant to energy supply would be the air pollution by-products of energy use in the process of mining. More persistent stock externalities arise when the environmental damage is a function of cumulative emissions. Examples of more persistent externalities would include atmospheric accumulation of carbon dioxide and its effect on the global climate, contamination of ground water from oil or coal extraction that is only slowly reversed by natural processes, and unremediated damage to natural landscapes through strip mining.

Flow externalities can result in a depletion rate that is too rapid or too slow relative to the socially efficient supply rate, depending on how the present value of the marginal external damage changes over time. The effect of stock externalities is similar to the impact of resource depletion on the cost of extraction: these stock effects imply a slower rate of depletion and less total depletion than the market would choose on its own.

7. EMPIRICAL ANALYSIS OF DEPLETABLE ENERGY SUPPLY

Efforts to test empirically the theoretical implications of resource depletion models as descriptions of observed energy supply behavior are hampered by a lack of data. Data for *in situ* reserve values are not readily available. Market data on the value of firms are generally available, but exclude depletable resource values, and data on extraction and development costs are usually proprietary information. Consequently, the empirical economic analysis of resource supply and scarcity has taken a variety of less direct paths. Analysts have attempted in a number of ways to use available data to construct dynamic empirical models based on the basic theoretical tenets sketched in the preceding sections.

7.1 The Hotelling Valuation Principle for Assessing Resource Scarcity

An illustration of the methods for testing the resource scarcity implications of the depletable energy supply model involves the relationship between average reserve value and current net price using cross-section data. Miller and Upton argued that this relationship can be written as follows:

$$\frac{V_0}{S_0} = \alpha + (P_0 - C_0). \tag{7}$$

Here V_0 denotes reserve value, S_0 is the resource endowment, and $P_0 - C_0$ is the price net of extraction cost; the term α, which can be positive or negative, reflects influences such as changing cost and price trends. The model was found to be consistent with pooled, cross-section data from December 1979 to August 1981 for 39 oil- and gas-producing firms in the United States. A subsequent test of the Hotelling valuation principle using data from August 1981 to December 1983 produced a quite different result: in that analysis, an increase in the net price translated into an increase in average reserve value less than half as large.

An explanation for why the Hotelling Valuation Principle might overvalue reserves, at least in the case of oil and natural gas production, is that it affords producers greater flexibility for choosing output than they actually have. The extraction of petroleum over time is restricted by declining well pressure as the reservoir is depleted. If the rate of extraction declines at the rate a because of declining well pressure, the average reserve value is

$$\frac{V_0}{S_0} = \frac{a}{a + r - g}(P_0 - C_0), \tag{8}$$

where g is the expected rate of change in net price. This example and others in the literature provide strong empirical evidence that a simple model of finite resource depletion does not adequately explain the observed behavior of depletable energy resource prices and in situ reserve values. This is not terribly surprising, given the many other features of depletable resource supply already discussed—such as exploration for and discovery of new deposits, technological

change, and capital investment—that alter the implications of finite availability. It seems clear that these other factors have overshadowed finite availability of the resource as determinants of the observed dynamic behavior of nonrenewable resource prices and *in situ* values.

7.2 Data on Reserves

In the theoretical models of depletable energy supply we have discussed, measures of reserves or resources play a significant role as indicators of cost drivers, not just in terms of physical availability. Before looking at efforts to model empirically depletable energy supply, therefore, it is worth making some brief comments on the nature of available data for reserves.

The classification scheme of the United States Geological Survey defines total resources, including energy resources, as materials that have been discovered or might be discovered and used. Reserves are that portion of total resources that can be economically extracted. Undiscovered resources are classified as hypothetical, if in a known mining district, or speculative. Identified but currently noneconomic resources are categorized as paramarginal or submarginal. The physical measures of reserves often are compared to measures of the rate of use in order to determine the remaining life of the reserves.

Because reserves are defined in terms of economic recovery, whether a deposit is classified as a reserve changes with the resource price and extraction cost. In addition, because costly investment is required to "prove" reserves, there is a limited incentive to prove reserves beyond a certain point. The ratio of reserve to consumption for petroleum increased from 35 in 1972 to 45 in 1990, even though commercial energy consumption increased by more than 50% between 1971 and 1991. Physical measures of reserves thus probably have more meaning as an indicator of inventory on hand than as a more fundamental indicator of resource cost.

7.3 Models of Depletable Energy Supply Behavior

Behavioral models of depletable energy or other resource supply seek to develop empirical counterparts to theoretical efficiency conditions [such as Eqs. (4)–(6)] in order to describe how supply decisions (reserve development and extraction) respond to economic incentives (prices and cost drivers). Much of this work has focused on oil and gas supply, though some applications to mineral resources (e.g., nickel) also can be found in the literature. Relatively little of this kind of modeling work has been done for coal, because the depletion effects central to the development of the dynamic efficiency conditions (discussed previously) seem to be of very limited relevance to coal supply (with large reserves and continued technical progress in resource exploitation).

The problem of developing empirical behavioral models based on the theory of efficient depletable energy supply is quite difficult for several reasons. One problem, noted previously, is the poor data on reserves and costs. But even with better data, it is inherently complicated to develop reliable empirical models for complex dynamic process, and resource depletion is inherently dynamic. Moreover, because behavior depends so much on expectations of unknown future influences in this dynamic framework, the empirical analyst must formulate a hypothesis about the nature of the expectations driving behavior.

Finally, the theory discussed previously applies most directly to an individual decision-making unit and perhaps even to decisions within a specific resource-bearing location. Once the analysis is extended to cover multiple extraction and investment decisions from heterogeneous deposits, some difficult aggregation problems arise. Care is needed not to omit or mix together key influences. For example, the yield from exploratory drilling likely depends on both how much the best resource prospects have been depleted by past activity and what advances in drilling technique can do to raise discoveries per unit of effort.

Basically, two types of modeling approaches are found in the literature: process optimization simulation models and econometrically estimated models. Process optimization simulation models specify and numerically solve sets of equations based on first-order efficiency conditions such as Eqs. (4)–(6). For example, the model could incorporate a specification in which the reserves discovered per foot of new drilling depend on cumulative past drilling in that province. This specification could be used along with other information to determine the efficient level of reserve development as a function of the direct cost and user cost of drilling, plus the marginal (shadow) value of additional reserves. One prominent example of such a model in the United States is the oil and gas supply component of the National Energy Modeling System (NEMS) operated by the Energy Information Administration (EIA); Deacon has provided a smaller-scale example.

Numerical parameters in such models come from a variety of sources: statistical curve fitting, engineering experience, and informed judgment, among others. Because these models are not derived from statistically fitting equations to data, it is not possible to construct classical confidence intervals and statistics for assessing the reliability of the model outputs. They are useful principally for "what if" exercises—by supplying different sets of input variables (e.g., oil prices and technical recovery parameters for drilling), the consequences of changes in these assumptions can be seen. Whether the model structure is properly specified empirically cannot be independently assessed. The simulation models also do not incorporate uncertainty and expectations formation. Implicitly in dynamic optimization models, individuals are assumed to judge the future accurately.

Econometrically estimated models also are rooted in the theoretical efficiency conditions. However, these models are parameterized using statistical methods that seek to define supply decisions as functions of causal variables. The most sophisticated of these frameworks explicitly model expectations formation using the rational expectations time series approaches pioneered in macroeconomics by Epple, Hendricks and Novales, and Walls. In brief, these methods explicitly include representations of expectations formation based on past observations of price and cost influences; assuming that producers are not systematically biased in their expectations and fairly rapidly learn about a systemic change in market or technological conditions, statistical techniques can be used to estimate the parameters of the expectations process and the underlying parameters linking supply choices to the relevant economic influences. The point is to provide consistent estimates of the basic technological and geological parameters undergirding the supply process, so that the effects of policy intervention or shifts in market conditions can be separated out and understood. However, success with this class of models has been limited, notwithstanding their conceptual appeal. The models are difficult and data intensive to construct and estimate; they are not well suited to geographical or other finer grained breakdowns of activity into constituent parts; and the results have not always been very powerful. In particular, some approaches have not coped well with what appear to be basic nonlinearities in the relationship between unit supply cost and reserves. A prospect for future work is a better blending of the engineering expertise found in energy systems modelers with the dynamic economic models discussed here.

8. CONCLUDING REMARKS

Finite availability is one defining characteristic of a depletable energy resource and generates the "Hotelling rule" that the marginal value of a nonrenewable resource stock increases at the rate of interest. However, many other factors, including exploration, capital investment, and heterogeneous reserve quality, also are important to the economics of energy depletion and development. The investigation of how these other factors affect the empirical implications of the Hotelling model has been spurred by the frequent failure of the basic Hotelling model to explain the observed dynamic behavior of nonrenewable resource prices and *in situ* values.

These other factors can affect price and depletion paths in a number of ways, particularly when considered in combination with each other. The variety of possible outcomes makes it difficult, if not impossible, to make any general predictions about the overall impact on price and extraction paths. These other factors, particularly the discovery of new deposits and technological progress that lowers the cost of extracting and processing nonrenewable resources, appear to play a relatively greater role than does finite availability in determining observed empirical outcomes. Although models that include these other factors have enriched the Hotelling model, they have not completely reconciled the economic theory of nonrenewable resources with the observed data. The distinction between the responses of supply to anticipated versus unanticipated changes in extraction cost, interest rate, reserve discoveries, availability of backstop substitutes, and other factors figures prominently as a topic for future empirical research. The empirical evidence also indicates that the discovery of new deposits and technological progress in resource extraction and discovery have significantly mitigated the impacts of finite geological availability on the relative cost and supply of depletable energy resources. Although the future holds promise with respect to the development of new substitutes for fossil energy and greater energy efficiency, improvements in extraction and exploration technologies that reduce costs and allow the economical use of lower grade reserves also are likely to continue.

Glossary

direct energy The energy used in the specific process of production of a good or service.

embodied energy The energy associated, directly or indirectly, with the production of a good or service.

energy analysis A family of tools that follow economic production and consumption processes through their (physical) energy consequences.

energy carrier (also energy vector) A portable substance that can release energy when desired (e.g., liquid petroleum fuel).

indirect energy The energy used in preparation of intermediate inputs to a process.

net energy The amount of energy available from an energy transformation system after deduction of the energy expended in creating the capital equipment for mining and refining and the energy used in operating the system.

Human society is a complex system, in turn embedded in another—the natural environment. Since humans are totally dependent on the natural environment for the necessities of life, and since human economic activities strongly influence both human and ecosystem health, we need to be well informed about key aspects of the state of the human system and the natural "supersystem" within which humans exist. One such key aspect is associated with the flows of energy, both natural and human influenced, throughout the biosphere.

Economic systems depend on the availability and use of energy resources for their every function. In this context, the ability of a form of energy to "do work" in a thermodynamic sense (e.g., run a machine) is often referred to as its availability (or exergy). Highly "available" forms of energy such as electricity are better able to perform a range of important functions in the economy than, for example, fuelwood, which has a significantly lower availability. The energy in seawater is much less available, and although the overall quantity is huge, its ability to do economically useful tasks is small. The term quality is often used to describe a fuel's economic usefulness (e.g., as gross domestic product produced per heat unit of fuel used), and although this is related to its ability to do work in a strict thermodynamic sense, it is not the same thing.

From the mainstream economic standpoint, the economy is seen as a system of production, organized according to a system of signals in the form of prices paid by consumers to producers in order to obtain a good or service. These prices are determined in a marketplace, where willing buyers and willing sellers reach an understanding of the price to be paid for the product. Anything that is scarce has a price, provided ownership can be established.

On the other hand, from the biophysical systems standpoint, an economy is seen as a social system characterized by the physical activities that take place in it. That social processes are involved in the myriad of decisions made in that society is to some extent secondary to the physical processes that are occurring. From this perspective, physics, particularly thermodynamics, provides the tools for understanding both what is happening now and what is either possible or impossible, in physical terms, in the future. Clearly, the two perspectives are very different; part of the purpose of this article is to show

 © 2004 Elsevier Inc. All rights reserved.

how at least a partial integration of perspectives is possible.

1. PHYSICAL FOUNDATIONS OF ECONOMIC ACTIVITY

The term energy not only applies to wood, coal, oil, gas, and electricity but also has a fuller scientific meaning. This is because the laws of thermodynamics apply, without exception, to all physical processes on Earth. They are true whether applied to the actions of people and machines in an economy, all forms of life, circulation in the atmosphere and the oceans, or movements of the planets. Inputs of available energy are essential to the functioning of any economy, not only directly as fuels but also indirectly through the natural solar cycles that provide the "ecosystem services" (air, water, soil, etc.) essential for all forms of life, including the economic.

The associated transformation of available into unavailable energy resources (in accordance with the second law of thermodynamics) is an unavoidable part of the functioning of all economies. There is no process known that did not begin by using some form of high-quality raw material (available energy) and that will not end up somewhere as waste (unavailable energy). Directly or indirectly, most source energy comes from or came from the sun, and all sink energy is eventually dissipated to outer space. Heat from the earth's interior is also an important source of energy for some economies, and it is obviously relevant in many geological processes important to human life.

Early human societies evolved in a context in which they obtained the essentials of life from their surroundings via natural mechanisms by which most of the products they used were obtained, directly or indirectly, from the sun. Needs for food, clothing, shelter, and so on were met from plants and animals by hunting and gathering, and humans traveled or migrated as necessary to ensure continued supply. Early industrial societies also used solar-derived energy resources, especially wood as fuel, often converted to charcoal for more specialized purposes (e.g., high-temperature metal smelting). By the 18th century, large-scale mining of coal, together with associated technologies for the production of iron and steel, was fueling the industrial revolution and the rapid economic and population growth that eventuated. Later technologies, similarly based on prior use of high-quality energy resources, enabled exploitation of oil and gas, in turn powering further economic growth. The ability of these fuels, together with their associated technologies, to do "work" in economic production processes vastly increased the ability of humans to control and transform their physical environment.

Each stage of industrialization was built on a foundation of previous industrialization. Without exception, all required prior consumption of available energy from the environment and, implicitly, the "investment" of that energy in the creation of the artifacts (machines, processes, and buildings) needed for physical production of goods and services.

From the physics standpoint, it is also important to note that what the marketplace calls energy is actually consumer fuels (coal, oil, gas, and electricity) since they are the form in which energy is traded commercially. In the generalized scientific sense, however, energy has no substitutes. Only fuels, which can be seen as "energy carriers," can often be substituted, one for the other (e.g., oil for coal). An energy carrier is a portable substance that can release energy when desired (e.g., petroleum fuel such as gasoline).

The interaction between energy and matter is the basis of life; therefore, it is also the basis for human life and culture. However, this is not to suggest that life is only energy. Far from it. It is nevertheless vital to recognize the key role of energy in the physical world because otherwise it is fatally easy to fall into the trap of thinking that all processes of importance in human decision making are internal to the economy. Unfortunately, this view is typical of all major economic theories. This does not leave much room in the political spectrum for other views, but it is essential to do so and thereby add important information to both.

Probably the most notable exponents of the physical basis of economics are Nicholas Georgescu-Roegen, Kenneth Boulding, and Herman Daly, economists who have made extensive contributions to the literature on physical limits to the use of resources in economic production.

The inclusion of energy in a worldview highlights the help that the biophysical systems perspective can provide in clarifying questions about the relationship between a social system and its physical environment. It also helps us see where the biophysical viewpoint contrasts with the political–economic and thus indicates areas where conventional assumptions may need deeper examination.

2. ENERGY IN THE ECONOMIC SYSTEM

Starting with primary resources such as coal, oil, and gas in the ground, raw energy is processed into "consumer" form, suitable for use in society, via power stations, cables, oil refineries, gas pipelines, and so on. The resultant fuels, such as gasoline, piped natural gas, and electricity, are then used to produce energy services—transport, warmth, cooking, lighting, and so on.

Like energy, matter also enters an economic system as raw resources from the environment. Even if temporarily accumulated within the economy (e.g., embodied in capital goods) or recycled for awhile within the economic process, it must be disposed of. This gives rise to pollution, acknowledged by the concept of externalities in economic terminology. These are also seen as feedbacks in systems terminology.

The flow of matter into and through an economic system can be characterized in terms of the high-quality available energy required to carry out the transformation processes in which the matter is involved. Thus, energy consumption can be used as a "numeraire" enabling a wide variety of goods and services to be accounted for in terms of the quantity of one important characteristic, the energy expended in the processes of transforming them into marketable products. From this viewpoint, capital accumulation and stocks of durables are seen as a temporary store for energy resources. In time, these depreciate and wear out, and they eventually end up as waste.

In physical terms, as in economic terms, energy is only of value by virtue of its ability to cause physical or chemical change or to do "work." From the biophysical systems perspective, what is important is the amount (i.e., the physical cost) of energy used in a process and thereby embodied in a product, not its price in the marketplace. In contrast to the political–economic perception, however, energy analysis follows only the physical processes of production and not the social valuation of the product in the marketplace.

Energy is a means of following the way in which an economy works, usually via techniques of energy analysis. Embodied energy is the energy associated, directly or indirectly, with the production of a good or service. In this context, direct energy is the energy used in the specific process of production; indirect energy is used in the preparation of intermediate inputs to that process. Although the term embodied energy is widely used, it has many different interpretations, depending on the context.

The use of energy as a complementary means of describing the workings of a social system can also be seen as an attempt to address the apparent inability of standard economics to take full account of the central position of physics in economic production.

3. THE ECONOMICS AND PHYSICS OF PRODUCTION

From a conventional economic perspective, the marketplace is where decisions are made about the uses of energy. Energy is simply a tradable commodity, like all scarce resources, the demand for which is affected by its price. Everything the economy needs to know about energy is incorporated in its price, and the freer and more competitive the market, the more accurate is the price evaluated by it.

Goods are said to be substitutes if (other things being equal) an increase in the price of one leads to a shift toward consumption of another, whose price is lower. Thus, if an increase in the price of coal causes some consumers to switch to natural gas as a heating fuel, these are substitutes. Note, however, that in the generalized scientific sense, energy has no substitutes. Only fuels, which are energy carriers, can often be substituted, one for the other.

Energy consumption has been used for decades as an indicator of the level of wealth of an economy. As a broad generalization, it appears that there has often been a strong relationship between energy consumption and gross domestic product (GDP), with the ratio E:GDP commonly known as the energy intensity of GDP. There are problems with this criterion, however, because some very different countries have approximately similar energy demands, whereas other similar countries have different demands. Nevertheless, greater energy consumption was long viewed as a necessary prerequisite for economic growth.

The relationship between energy consumption and economic activity is significantly less direct than was the case in the past for a number of reasons, including substantial improvements in the technical efficiency of use of energy, especially in technologically advanced countries that previously consumed large quantities of fuel. In some cases, this increase in efficiency was the result of switching to other, higher quality fuels, which enabled a greater amount of GDP to be produced per unit of fuel used.

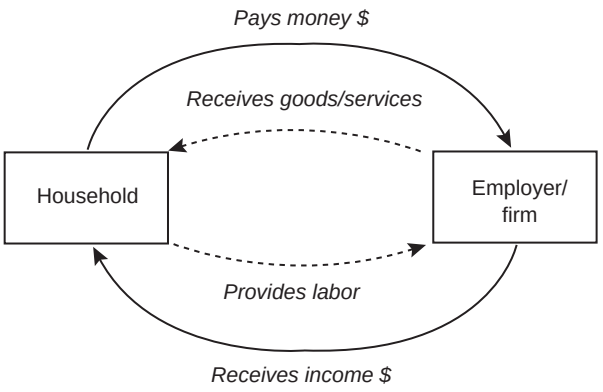

FIGURE 1 The basic macroeconomic model.

3.1 Economic Models of Production

The circular flow diagram of Fig. 1 characterizes the conventional model of the economic process. In this model, goods and services made by employers/firms (producers) are sold to households (consumers), who in turn obtain money either by selling their labor to or investing their savings in the producing firms (often via financial institutions).

The model is developed further in Fig. 2, which shows the distinction between different types of households and introduces government and financial institutions. The model is nevertheless conceptually the same as that in Fig. 1. In this model, money flows, which represent the tokens that are exchanged for goods and services, labor, and capital, are one representation of reality. It is easy to forget that the underlying reality is of goods and services and people, which is apparently forgotten in some economics textbooks and is implicit in Fig. 2. The whole economy then becomes something that is described and quantified in monetary terms, with the total of "net income" transactions being equal to GDP.

The model of Fig. 2 is actually a map of the flows of exchange value in an economy—no more and no less. Exchange relationships between capital (employers/firms) and labor (households) are the primary determinants of behavior of the system.

This model of production and consumption linked in a circle of flows of exchange value can be modified by acknowledging the essential role played by the flows of raw resources from the environment through the economy and out as pollution, as shown in Fig. 3. Although the monetary exchange system is circular on one level (money being exchanged for goods), the physical products start at one place and end up somewhere else. In the process, much energy is consumed, and major disposal problems are generated. This model therefore illustrates the "metabolic" aspect of economic activity, in which the economy is "fed" by raw resources from the environment and "excretes" wastes back to that environment.

The model of Fig. 3 is also the basis for the application of conventional welfare economic concepts via resource and environmental economics. In both, the key issue is that of clarifying property rights as an essential step toward the evaluation of

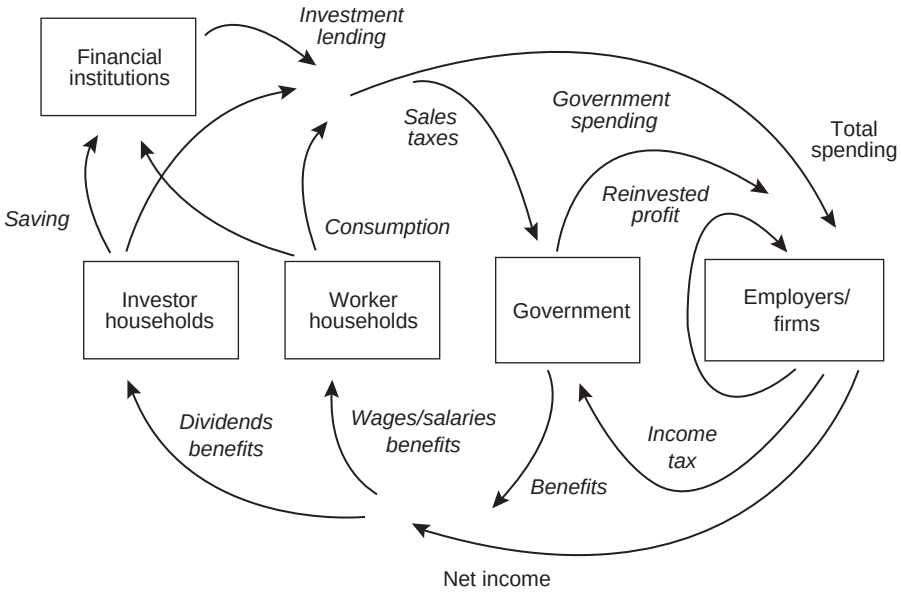

FIGURE 2 The extended macroeconomic model.

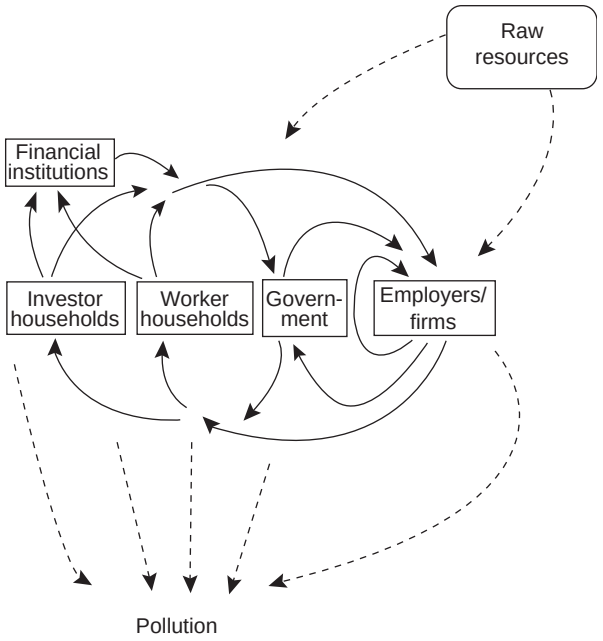

FIGURE 3 Resource requirements of economic activity.

"externalities." In environmental economics, the solution to environmental problems becomes one of creation of markets in pollution rights and ecosystem services on the principle that damage must be paid for, which acts as a disincentive to pollute. Related tools in resource economics involve application of discounting of the value of future events such as resource depletion in order to determine the most economically efficient use of resources over time.

Therefore, there is a sense in which the mainstream economic model regards the environment as simply a subsystem of the economy—a source of resources and sink for wastes, with the primary purpose being to enable the economy to grow without limit. Figure 4 illustrates Daly's critique of this perception. The special place of energy in the biophysical worldview is completely absent from this model, other than as just another resource.

All these attempts to incorporate the reality of environmental pollution into social policy development have involved biophysical issues interpreted via economic theories. From a scientific viewpoint, one may observe that in this approach the needs of the total system are interpreted in terms of those of one of its (dependent) subsystems (the economy) for reasons that appear to owe little to science. Nevertheless, there is little doubt that if properly applied, tools such as environmental and resource economics could give rise to more environmentally and socially benign outcomes than current outcomes via the use

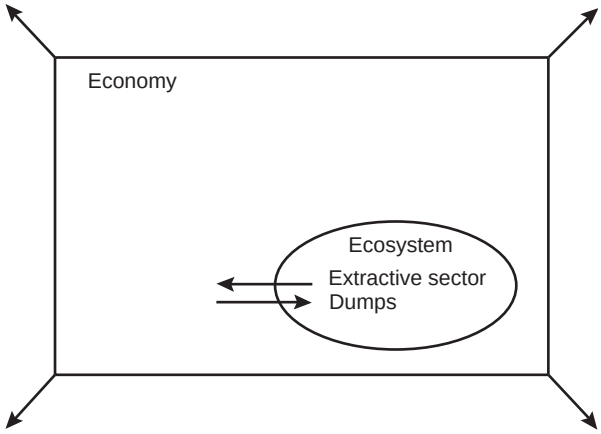

FIGURE 4 Ecosystem as subsystem of the economy. From Daly (1999), with permission.

of improved technologies for converting resources into end-use human services.

3.2 Physically Modified Economic Models of Production

The model in Fig. 3 has limitations due to the particular place energy has in the processes of production and consumption. If we separate out raw energy resources from other material resources, we obtain a different picture, despite the fact that some raw energy resources, such as coal, oil, and gas, may also be raw resources in their own right (e.g., when used for petrochemicals production). This is not a problem as long as we remember the distinction between the two functions.

Figure 5 indicates the special function of the energy sector as an energy transformation system. A flow G of raw energy resources (coal, oil or gas in the ground, water in mountain lakes, geothermal heat, solar input, and so on—often referred to as primary energy) is transformed into a flow E of consumer energy (often referred to as secondary energy)—such as delivered, refined fuels, electricity, process heat, etc.—transformed in coal mines, oil/gas wells, refineries, thermal power stations, hydro dams, boilers, and so on.

These processes always involve loss of some of the input of raw energy resources, as a direct reflection of the processes involved, such as oil drilling, pumping and refining, thermal or other electricity generation, and so on. Some of the consumer energy output of these plants is often needed to run the plants (e.g., electricity to run auxiliary machinery in a thermal power station). Note that flows of waste energy and material pollution are not included in this simplified model but are also important.

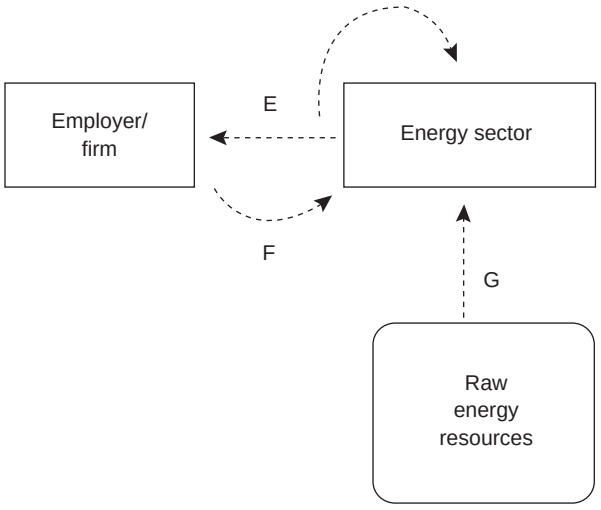

FIGURE 5 Energy transformation system.

The energy transformation system comprises large capital works constructed from steel, concrete, and other materials, in turn created using energy and material resources in the past. Figure 5 includes a feedback arrow showing the energy flow *F* embodied in the goods and services (as manufactured capital, etc.) needed from the production sector to build and maintain the energy sector.

Even consumer, or secondary, energy is not the real end product. What economic production or consumption processes actually need from energy is the services that energy provides, such as heat, light, motive power, chemical conversion, and operation of electronic equipment. This is illustrated in Nørgård's model in Fig. 6, which shows the chain of conversion of raw, primary energy through secondary energy to energy services and to the ultimate end, the energy services and other inputs to lifestyle and satisfaction of needs. In this model, the fact that energy is a means to an end is very clear. Also very clear is the importance of efficiency of conversion at each stage and the fact that each increment of satisfaction of needs requires a substantial infrastructure of capital equipment and a steady consumption of raw resources. Sooner or later, there is an associated and inevitable conversion of all the resources into waste.

Gilliland's model (Fig. 7) integrates the perspective of Fig. 5 into the economic model of Fig. 2 and shows how a significantly richer picture of economic activity is obtained if resources are separated into their material and energy components. This thermophysical model shows the economy as a pathway by which energy resources are used to run the processes

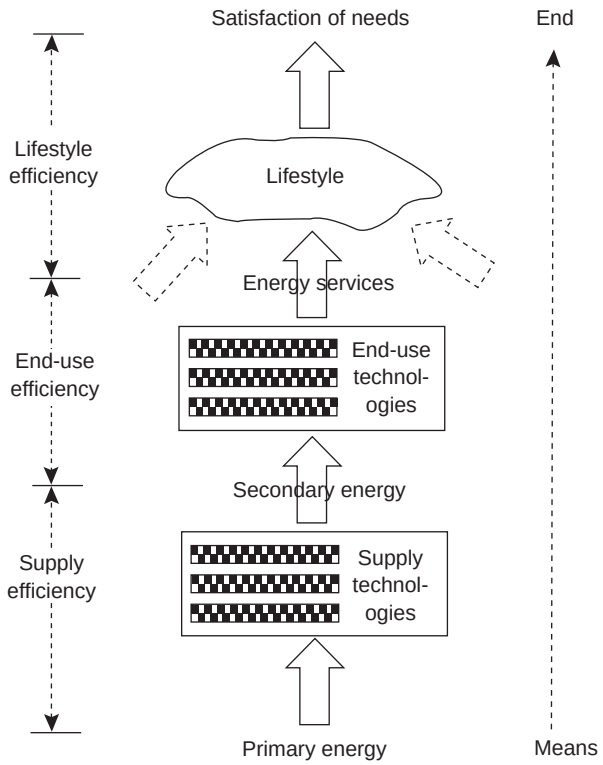

FIGURE 6 Conversion of primary energy to energy services. Courtesy of Nørgård, J. S.

that convert raw materials into the goods and services needed for everyday functioning of the economic system.

In Fig. 7, it is clear that money flows in the opposite direction as energy. In addition, although money flows are circular, energy flows are essentially linear (in one end and out the other), as is typical of all metabolic processes.

In the thermophysical context, energy use—or, more correctly, the degradation of available input energy into unavailable output energy—can be seen as representing physical "cost." However, this is a different concept from money flow in the economic perspective, which normally represents market price. Therefore, it is not suggested that energy consumption is an adequate measure of social value in an economic context, although undoubtedly it can have significant long-term implications for prices.

Again, however, to make our approach operational, it is desirable to view the place of important component subsystems in our conceptual model of the system of society within the supersystem environment. Figure 8 shows the thermophysical economy of Fig. 7 within its total ecological environment of planet Earth. The energy concept is central to this description of the thermobiophysical "engine" that enables

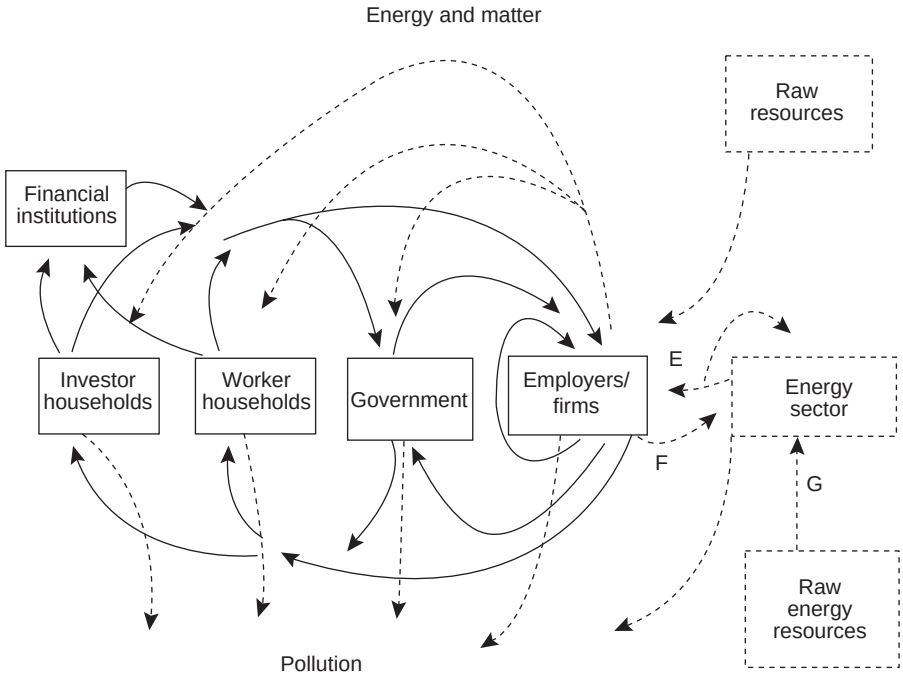

FIGURE 7 The thermophysical macroeconomic model of Gilliland.

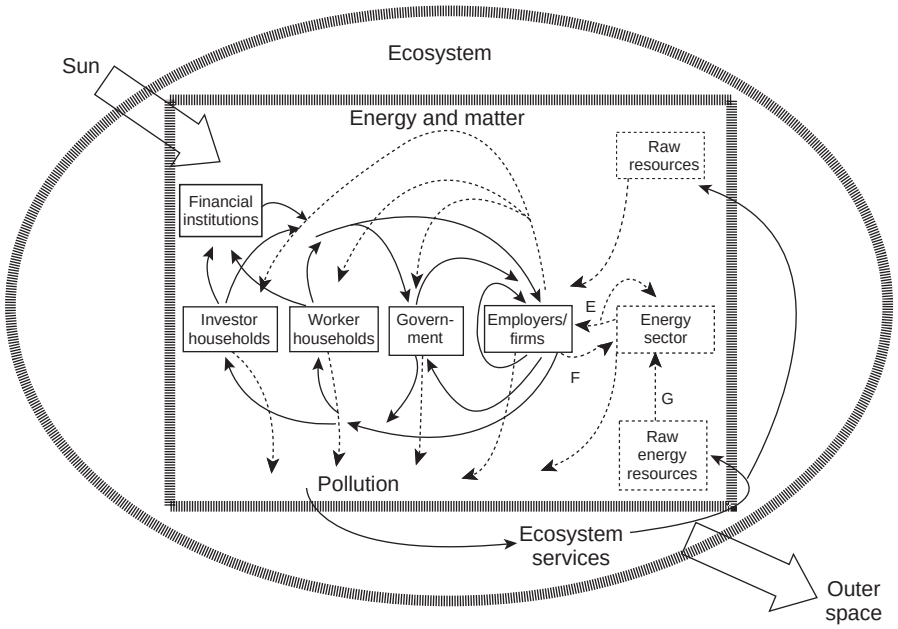

FIGURE 8 Biophysical economic model as part of planet Earth.

the global ecosystem to function, with high-quality incident solar energy driving all the natural processes on which the activities of living things depend, before eventually being rejected as waste heat into the vast sink of outer space. Within the earth's system, that energy is stored for a short time in processes such as circulation of the atmosphere, for longer times in plants that absorb energy for photosynthesis, and for even longer times in geological deposits.

The energy in fossil fuels was originally derived from solar energy many millions of years ago, captured mainly through photosynthesis in plants

and then via the plants (and the animals that fed on the plants) whose remains were transformed over very long periods of time by geological processes into the hydrocarbon fuels coal, oil, and gas. The fact that humans currently have access to these resources (for a period that will be very short in the context of geological or even human time) does not affect the validity of Fig. 8 as a general model.

4. ENERGY ANALYSIS OF ECONOMIC PROCESSES

An important characteristic of an energy transformation sector is that it functions by absorbing capital, operating, maintenance, and other inputs from the economy, represented in Fig. 5–7 by the feedback flows F of energy embodied in those goods and services. It is only when the flow of useful, consumer energy E is greater than the sum of embodied feedback flows that there is a supply of net energy to the economy. This concept is analogous to one common in economics in that revenue or turnover alone are not enough to indicate financial success of a project; net cash flows or profit are important.

Energy analysis comprises a family of tools that follow economic production and consumption processes through their energy consequences, usually expressed in terms of the first law of thermodynamics (i.e., the heating abilities of energy). More advanced forms of energy analysis, such as exergy analysis, address the ability of energy to do work in terms of the second law of thermodynamics.

In its basic form, energy analysis involves the determination of the energy embodied in the process of delivering consumer energy or end-use energy or in making a good or service. As Fig. 7 indicates, both the losses of raw energy and the energy required to run the energy sector may be substantial. In the case of coal-fired thermal electricity generation, approximately two-thirds of the raw (primary) energy is dissipated in producing the consumer (secondary) electricity output, even before the efficiency of conversion into end-use forms is taken into account.

There are two common techniques for evaluating the embodied energy of goods and services—process analysis and input–output analysis. Process analysis involves the systematic study of the inputs to and outputs from a process, with determination of energy requirements for each input. These are then summed to give the total energy requirement of the product.

For example, a process energy analysis of running a home would first concentrate on electricity and heating fuel consumption since these are the most obvious large energy inputs. Less important direct inputs would then be assessed. Energy for agriculture, harvesting, processing, transport, merchandising, and cooking of food also needs to be evaluated, together with the energy involved in the manufacture of clothing, furniture, cleaning materials, paint, carpet, and so on from their raw materials and the energy to transport and deliver them to shops and the home. If one goes back further, one could consider the energy required to make or process the house construction materials (steel and concrete for foundations, lumber and other materials for the structure, and the energy needed to build the machines and factories where these parts were made) and, before that, the energy required to build and run the mines, forests, and so on from whence came the raw materials, and so on.

Clearly, the task is daunting, and few process analyses have been carried out beyond the first or second stage. This technique is good at giving an accurate estimate of direct energy inputs but not for evaluating the indirect inputs, such as the energy required to process the timber for the building, the lumber mill, or the steel mill or the mines from which the iron ore came to make the steel. These indirect inputs can often be very large, especially in the service-sector industries, which on the surface often appear to have relatively small energy demands but whose indirect demands may be many times higher.

The second common technique is input–output energy analysis, a modification of a standard economic tool. This employs a detailed survey of transactions in an economy. In effect, it addresses the production part of the economy, with explicit accounting for the energy inputs required to keep the economy going. By a straightforward computer-based method, all the energy inputs to the processes that preceded the output of a given good or service in the economy are summed, back to the coal mine, oil well, power station, or gas field.

In general, process analysis is appropriate for study of specific production technologies and is a technique widely used in engineering. Input–output analysis is more appropriate for examining the effects of changes in technology, resource use, etc. for a whole economy. The difference in quality, or availability to do work, of the various forms of energy is not specifically determined by either approach, although it is possible to evaluate it.

Both techniques are involved, as appropriate, in applications such as life-cycle analysis.

Incorporation of the extra information gained from a material/energy analysis inevitably raises problems of commensurability of units because activities within the economy are conventionally represented in monetary units, whereas those in ecological and industrial systems are better represented by measures of material and energy/entropy flows. The emerging field of ecological economics addresses these and related issues.

5. PHYSICAL ACCESSIBILITY AND THE CONCEPT OF NET ENERGY

There are significant differences in the ways different researchers measure the net energy performances of energy transformation systems that deliver a flow of consumer (secondary) energy E to an economy (Fig. 5) from a raw (primary) energy resource flow G using a feedback flow F. However, the net energy criterion (in whatever form) is the means of indicating the physical accessibility of a resource. It is the amount of effort (measured in energy terms) required to extract the resource, process it as required, and deliver it to the consumer. The greater the effort, the lower the accessibility of the resource. As indicated previously, production of electricity from coal via conventional thermal power stations results (in heat equivalent terms) in only approximately one-third of the energy in the mined coal being delivered to consumers in the form of electricity. However, the ability of the electricity to do work, especially running machines and electronics, makes it a more valuable energy source to an economy than the raw coal.

During the past three centuries, economies in industrialized countries have changed from an almost complete dependence on biomass-based fuels (mainly wood) to coal and then to oil and natural gas. Each transition was characterized by change to a more accessible energy source, but that change was not possible until technology developed to the point at which the improved accessibility was achievable. Thus, coal could not be supplied in large quantities until underground mining technology was developed, and open-cut coal required heavy earth-moving machines to be developed. Oil and gas were not accessible until drilling, transportation, and refining technologies were applied. All of these depended heavily on the development of systems for long-distance transportation of both raw materials and products.
